Abstract

In interactive machine translation (MT), human translators correct errors in automatic translations in collaboration with the MT systems, which is seen as an effective way to improve the productivity gain in translation. In this study, we model source-language syntactic constituency parse and target-language syntactic descriptions in the form of supertags as conditional context for interactive prediction in neural MT (NMT). We found that the supertags significantly improve productivity gain in translation in interactive-predictive NMT (INMT), while syntactic parsing somewhat found to be effective in reducing human efforts in translation. Furthermore, when we model this source- and target-language syntactic information together as the conditional context, both types complement each other and our fully syntax-informed INMT model shows statistically significant reduction in human efforts for a French–to–English translation task in a reference-simulated setting, achieving 4.30 points absolute (corresponding to 9.18% relative) improvement in terms of word prediction accuracy (WPA) and 4.84 points absolute (corresponding to 9.01% relative) reduction in terms of word stroke ratio (WSR) over the baseline.

1 Introduction

Interactive MT (IMT) is viewed as an effective mean to increase productivity in the translation industry. In principle, IMT aims to reduce human effort in automatic translation workflows by employing an iterative collaborative strategy with its two most important components, the human agent and the MT engine. Figure 1 represents the interactive protocol.

As of today, NMT (Bahdanau et al., 2015; Vaswani et al., 2017) represents the state-of-the-art in MT research. This has led researchers to test interactive-predictive protocol on NMT too, and papers (Knowles and Koehn, 2016; Peris et al., 2017) that pursued this line of research suggest that NMT is superior than phrase-based statistical MT (Koehn et al., 2003) as far as interactive-predictive translation is concerned.

In a different MT research context, Nádejde et al. (2017) have successfully integrated CCG (combinatory categorical grammar) syntactic categories (Steedman, 2000) into the target-side of the then state-of-the-art recurrent neural network (RNN) MT models (Bahdanau et al., 2015). In this work, we investigate the possibility of modelling the target-language syntax in the form of supertags (Bangalore and Joshi, 1999; Steedman, 2000) as a conditional context in an interactive-predictive protocol on Transformer (Vaswani et al., 2017).
2017), the current state-of-the-art NMT model. In a reference-simulated setting, we found that our target-language syntax-informed interactive setup can significantly reduce human effort in a French-to-English translation task.

We also extract syntactic features from constituency-based parse trees of the source French sentences following Akoury et al. (2019), and use them as the conditional context in the interactive-predictive Transformer framework. Experiments show that this contextual information can reduce human efforts in translation to some extent.

In addition, we apply the above strategies together, and model supertags and constituency parse tree-based features collectively as the conditional context for interactive prediction in NMT. Our experimental results indicate that these syntactic feature types are complementary. As a result, this collaborative strategy turns out to be the best-performing in the French-to-English task while significantly outperforming those setups that include either feature type on WPA and WSR. To the best of our knowledge, this is the very first study that investigates the possibility of integrating syntactic knowledge into an interactive MT model.

2 Related Work

Foster et al. (1997) were the first to introduce the idea of interactive-predictive MT as an alternative to pure post-editing MT. There have been a number of papers that explored this strategy in order to minimise human effort in translation and cover many use-cases involving SMT: e.g. applying on classical MT (Hassan et al., 2007; Haque et al., 2011), and is continually being applied to improve the current state-of-the-art NMT models, e.g. (Luong et al., 2016; Nádeje et al., 2017).

3 Fully Syntactified Interactive NMT

This section presents our fully syntactified interactive NMT model. In NMT, at time step \( i \), the conditional probability of predicting output token \( y_i \) given a source sentence \( x_i^J \) and the previously generated output token \( y_{1:1}, y_{1:1-1} \) is modelled as \( p(y_i|\{y_{1:1}, ..., y_{1:1-1}\}, x_i^J) \).

In the interactive protocol, the user corrects the wrongly translated word (by the MT system) which appears at the left-most side. The feedback is returned back to the MT system in the form of \( \hat{y}^{i-1}_1 \) which is the validated prefix together with the corrected word \( \hat{y}_{i-1} \). Thus, in interactive NMT, the conditional context becomes \( \hat{y}^{i-1}_1 \), and the conditional probability of predicting output token \( y_i \) is modelled as \( p(y_i|\{\hat{y}_{1:1}, ..., \hat{y}_{1:1-1}\}, x_i^J) \). This model serves as our baseline in this work.

In our supertag-based interactive-predictive scenario, we first predict the CCG supertag \( \hat{s}_i \) of the word \( (y_i) \) to be predicted next. As a result, the length of the conditional context becomes twice the number of words in context plus one. As far as the target-syntactified interactive NMT is concerned, the conditional probability of predicting the output token \( y_i \) is modelled as \( p(y_i|\{\hat{s}_1, \hat{y}_{1:1}, ..., \hat{s}_{i-1}, \hat{y}_{1:1-1}, \hat{s}_i\}, x_i^J) \), where \( \hat{s}^{i-1}_1 \) is the CCG sequence of the validated prefix \( \hat{y}^{i-1}_1 \) and \( \hat{s}_i \) is the supertag of the word \( (y_i) \) to be predicted next.

As for the modelling of source-side syntax, we extract a chunk sequence from the constituency parse tree of a source sentence by setting random a maximum chunk size (\( \{1..6\} \)) for every sentence (cf. Section 4.2).

Let us define a chunk sequence \( c_i^M \) extracted from the input source sentence \( x_i^J \), where \( M \) is the number of chunk identifiers (a concatenation of the constituent type and subtree size) of the chunk sequence. This results in an input sequence \( l_i^{1+M} \), where \( J \) is the total number of words arbitrarily separated by \( M \) number of chunk identifiers. In this model, at time step \( i \), the conditional probability of predicting output token \( y_i \) given a source sequence (words and chunk identifiers) \( l_i^{1+M} \), and the validated prefix together with the corrected token \( \hat{y}_{1:1}, ..., \hat{y}_{1:1-1} \) is modelled
as \( p(y_i | \{ \hat{y}_1, ..., \hat{y}_{i-1} \}, l_1^{J+M} ) \).

In our fully syntactified interactive NMT model, the conditional probability of predicting the output token \( y_i \) is modelled as \( p(y_i | \{ s_1, \hat{y}_1, ..., \hat{y}_{i-1}, \hat{s}_i, s_i \}, l_1^{J+M} ) \), where \( s_1^{i-1} \) is the CCG sequence of the validated prefix \( \hat{y}_i^{i-1} \), \( \hat{s}_i \) is the supertag of the word \( (y_i) \) to be predicted next, and \( l_1^{J+M} \) is the input sequence constituting \( J \) and \( M \) numbers of words and chunk identifiers, respectively.

4 Syntactic Context Features

4.1 Modelling CCG Supertags as Target Language Context

This section explains why we consider a rich and complex syntactic feature, supertags, as context in our experiments. Supertags (Bangalore and Joshi, 1999; Steedman, 2000) are known to be context-sensitive tags that preserve the global syntactic information at local lexical level. Having this property, supertags resolve ambiguity in short- and long-distance dependencies by capturing the preceding and succeeding syntactic dependencies of a lexical term. For example, they signify whether a particular lexical term is expecting a preposition as a part of the conditional context for the prediction of the remaining hypothesis. It implies that the setup follows the interleaving technique of Nádejde et al. (2017) in which the CCG tag of a modified word is provided to the MT model for the prediction of the remaining hypothesis. Nonetheless, the source-side context including our syntactic parse features remains unchanged over the course of generation of the target translation.

We model target-side syntactic contexts (CCG supertags) as conditional context in two different ways as follows. In our first setup, we directly use the supertags that are predicted by Transformer as a part of the conditional context for the prediction of the remaining hypothesis. It implies that the setup follows the interleaving technique of Nádejde et al. (2017) in which the CCG tag of a token is kept before its token as shown in Table 1. For example, word \( d_i \) is produced by the decoder in a hypothesis having \( ceg \) as its CCG supertag that was predicted in the previous time step. If the

Table 2: An example showing applying On the fly CCG supertagger on hypothesis.

user sees that word_{i} is not appropriate in the context (i.e. it is incorrectly predicted by the system), the user edits/removes word_{i} and replaces it with a new token word_{new}. Now, when the modified context (i.e. validated prefix) is fed back to the NMT model, word_{new} will have the tag of word_{i}, i.e. ccg_{i}. In other words, the final two tokens of the conditional context would be ccg_{i} word_{new}. We carried out an analysis to see how closely these supertags are related to the new words added by the user (cf. Section 6.4). In this regard, we applied BPE segmentation on the training sentences. The sub-word units of a word inherit the CCG category of the word. As an example, we show an English sentence with supertags in Table 1. We see from row E of Table 1 that CCG ‘N’ of a word ‘Oberthür’ is distributed over its sub-words (i.e. Ober@@ th@@ @ @ and r). Our first experimental setup is referred to as PredCCG.

Akoury et al. (2019) showed that integrating target-side ground-truth syntactic information into Transformer at decoding time significantly improved translation quality, and their syntax-based model outperformed the baseline Transformer model by a large margin in terms of BLEU (Papineni et al., 2002). In reality, there is no way of obtaining the target-side ground-truth syntactic information at decoding time. However, in interactive-predictive mode, we found a way to obtain a slightly better CCG sequence for the partial translation (i.e. validated prefix) and inject them into the model at run-time, which we believe can positively impact the model’s subsequent predictions. In other words, in our second setup, we integrate a CCG supertagger into our INMT framework, and apply that on the validated prefix and unchecked suffix on the fly. The tagger is invoked when the user makes a correction. As an example, when the user inserts a new token word_{new} in place of an incorrectly predicted token (word_{i}), the CCG supertagger is invoked and applied to the validated prefix and unchecked suffix on the fly. In Table 2, we show how On the fly CCG supertagger is applied in our interactive interface. We see from rows 6 and 7 of Table 2 that the user replaces the wrongly predicted token just with a correct token just. The CCG supertag (((S\NP)/(S\NP))\((S\NP)/(S\NP))) of the incorrect token ‘just’ is assigned to the new token just, which is incorrect in this context. When the user commits this change, On the fly CCG supertagger is invoked and applied to the corrected hypothesis.
(a combination of validated prefix and unchecked suffix). As can be seen from row 8 of Table 2, a new CCG tag sequence is generated for the hypothesis, and we see that CCG (N) of the newly added token ',' is correct. Finally, INMT predicts another suggestion (row 9 of Table 2) where we see the remaining predictions are correct in the context. We call this experimental setup OnflyCCG. Note that the model is trained at sub-word level and generates sub-words at output; however, word level tokens are presented to the user. Naturally, On the fly CCG supertagger is applied to a hypothesis of word level.

5.2 MT systems

We carry out experiments with French-to-English with the UN corpus2 (Ziemski et al., 2016). The training and development sets contain 12,238,995 and 1,500 sentences, respectively. We use 1,500 sentences from the WMT15 news test set newstest2015 as our test set. In order to build our MT systems, we use the Sockeye3 (Hieber et al., 2018) toolkit. Our training setups are as follows. The tokens of the training, evaluation and validation sets are segmented into sub-word units using BPE. We performed 30,000 join operations. We use 6 layers in the encoder and decoder sides, an 8-head attention, hidden layer of size 512, embedding vector of size 512, learning rate 0.0002, and minimum batch size of 1,800 tokens. EasyCCG4 (Lewis and Steedman, 2014), a CCG supertagger, is used for generating the CCG sequence for the English sentences.

Table 3: The BLEU scores of baseline and syntactified NMT systems.

</tbody>
</table>

Table 3 shows the performance of our baseline and syntax-sensitive NMT systems in terms of BLEU. The second and third rows represent the NMT models that incorporate source- and target-language syntactic contexts, respectively, which we call source- (SS) and target-syntactified (TS) NMT systems, respectively. We see from Table 3 that the BLEU scores of these two MT systems and Transformer are very similar. Additionally, we performed statistical significance test using bootstrap resampling methods (Koehn, 2004).

5.2 MT systems

We carry out experiments with French-to-English with the UN corpus2 (Ziemski et al., 2016). The training and development sets contain 12,238,995 and 1,500 sentences, respectively. We use 1,500 sentences from the WMT15 news test set newstest2015 as our test set. In order to build our MT systems, we use the Sockeye3 (Hieber et al., 2018) toolkit. Our training setups are as follows. The tokens of the training, evaluation and validation sets are segmented into sub-word units using BPE. We performed 30,000 join operations. We use 6 layers in the encoder and decoder sides, an 8-head attention, hidden layer of size 512, embedding vector of size 512, learning rate 0.0002, and minimum batch size of 1,800 tokens. EasyCCG4 (Lewis and Steedman, 2014), a CCG supertagger, is used for generating the CCG sequence for the English sentences.

We found that the differences of the BLEU scores of these MT systems are not statistically significant.

The fourth row shows the BLEU score of the NMT system that integrates both the source- and target-language syntactic contexts (i.e. supertags and syntactic parse, respectively) together. We call this model our fully syntactified (FS) NMT system. The FS NMT system produces a 0.46 BLEU point (corresponding to 1.7% relative) gain on the test set over the baseline. The differences of the BLEU scores of the FS and baseline Transformer models are not statistically significant either. When we integrate the source- and target-language syntactic contexts individually into Transformer, they do not positively impact the system’s performance. However, when we integrate them collectively into the model, we see that they bring a moderate gain in terms of BLEU over the baseline, and the gain is very close to the significance level (p-value: 0.059) too. It seems that both contextual features complement each other and bring about an (moderate) improvement. Although the primary objective of this work is to observe the prediction of Transformer in an interactive-predictive platform while modelling different syntactic constraints as conditional context, this can also be seen as an important finding to MT research.

6 Results and Discussion

In this section, first we explain the strategy that we adopted for evaluating the interactive-predictive MT systems. Then, we present our evaluation results along with some discussions and analysis.

6.1 Evaluation Plan for INMT

We evaluate the performance of the INMT systems using two evaluation metrics, WSR and WPA. WSR denotes the total number of token replacements required to obtain the desired hypothesis (Peris et al., 2017). WPA is the percentage of words that the INMT system predicts correctly, given a prefix of all the previous translator-produced words (Knowles and Koehn, 2016). WSR and WPA are calculated on word level. The process of evaluating translations in interactive scenarios is expensive as it requires human evaluators. As an alternative, we adopted a reference-simulated evaluation strategy as in Peris et al. (2017), where instead of taking feedback from the real user, the reference sentence is used as the feedback. In other words, each time an interactive MT model generates a hypothesis it is com-
pared with the reference sentence from left to right.

6.2 Evaluation Results

6.2.1 The SS INMT System

In this section, we present the evaluation results that we obtain using the source-language syntactic constituency parse as conditional context in the interactive-predictive Transformer model. The WSR and WPA scores of the baseline and SS Transformer models are shown in Table 4. Note that WSR is an error metric, which means that lower scores are better. We see from the table that integrating this context into the model brought about a 0.56 point absolute (corresponding to 1.04% relative) reduction and a 0.31 point absolute (corresponding to 0.66% relative) gain in terms of WSR and WPA, respectively, over the baseline. We use approximate randomization (Yeh, 2000) to test the statistical significance of the difference between the two systems. We found that these differences are not statistically significant. These results indicate that using the syntactic constituency parse as context in interactive neural MT models has only a minor impact on reducing human effort in translation.

Table 4: Performance of the SS INMT System.

6.2.2 The TS INMT System

In this section, we obtain experimental results to evaluate the interactive-predictive Transformer model that uses target-language supertags as conditional context on the test set. We report the results in Table 5. The third and fourth columns of Table 5 represent two setups (PredCCG and OnflyCCG) that we describe in Section 5.1. The first column of the table represents the baseline Transformer system. The gains in WSR and WPA over the baseline are found to be the highest when On the fly CCG supertagger is applied on the user modified hypothesis (cf. Section 5.1). With this, we achieve a 3.16 point absolute (corresponding to 5.87% relative) reduction and a 2.65 point absolute (corresponding to 5.65% relative) improvement in terms of WSR and WPA, respectively, on the test set over the baseline. These differences are statistically significant. When we compare PredCCG and OnflyCCG setups, we see that OnflyCCG brings a 1.09 WSR point absolute (corresponding to 2.10% relative) reduction and a 1.18 WPA point absolute (corresponding to 2.44% relative) improvement over the PredCCG setup, which
are statistically significant too. This indicates that especially with the OnflyCCG setup supertags as target-language context can have significant impact on reducing human effort in translation.

For comparison we also report the WPA and WSR scores of our TS INMT system on an ideal setup, i.e. when we feed Transformer with ground-truth CCG supertags instead of those predicted by the Transformer or generated by On the fly CCG supertagger. As expected, this setup surpasses the baseline and context-based setups by a large margins in terms of WSR and WPA.

### 6.2.3 The FS INMT System

As discussed above, we use both source and target syntax as the conditional context in interactive prediction in NMT. The first two rows of Table 6 represent the evaluation results obtained by integrating both as a collective feature into the INMT model. This feature brings about a statistically significant improvements in terms of WPA and WSR, respectively, over the baseline across two setups: PredCCG and OnflyCCG. We see from Table 6 that OnflyCCG is the best-performing setup that produces a 4.84 point absolute (corresponding to 9.01% relative) reduction and a 4.30 point absolute (corresponding to 9.18% relative) improvement in terms of WSR and WPA, respectively over the baseline.

### 6.3 Impact on Sentence Lengths

For further analysis, we place the sentences of our test set into four sets (c.f. Figure 2) as per the sentence length measures, i.e. number of words $nw < 15$, $15 < nw \leq 25$, $25 < nw \leq 35$ and $35 < nw$. This division was made based on the lengths of reference sentences. In Figure 2, we plot the distributions of WPA and WSR scores over the sentence length-based sets. As can be seen from the figure, both the TS and FS INMT systems produce increasingly better WSR and WPA scores as the length of the reference sentences increases. As discussed above, supertags encode wider context of a sentence, which could help the decoder to capture long-range word-to-word dependencies at generation time. In other words, as the length of the validated prefix increases, the corresponding CCG supertag sequences help better predict the subsequent tokens correctly.

### 6.4 CCG supertags of the Words of User Choice

As for PredCCG and OnflyCCG, the FS INMT model with OnflyCCG statistically significantly surpassed the one with PredCCG as far as reduction of human effort is concerned. As above, we see that the ideal setup (GT) again surpasses the baseline and context-based setups by large margins. We make a comparison of Table 5 and 6 for the three setups (PredCCG, OnflyCCG, and GT), and differences in WSR and WPA scores are presented in the last rows of Table 6. We see consistent reductions in WSR and improvements in WPA across the three setups with the combined contextual features, which are statistically significant.

CCG as target context and, to a certain extent, syntactic parse as source context were found to be effective in reducing human effort when applied individually. Nevertheless, CCG (target) and syntactic parse (source) together as a context turn out to be the best-performing setup with statistically significant gains over either feature type. In this sense, we can say that source and target-side syntactic contextual features complement each other as far as neural interactive prediction is concerned. We conjecture that since the conditional context includes source-language syntactic constituency parse and target-language syntactic constructs in the form of CCG supertags together, it provides the NMT model with better syntactic agreement between the source and target sentences, which, in turn, helps the model generate better predictions.

### Table 7: % of CCG supertags that becomes incorrect when the user replace the incorrectly predicted token in hypothesis with the token of his choice.

As mentioned in Section 5.1, we came up with two different ways to use the target-language su-
pertags as conditional context for the predictions in INMT. First, in the PredCCG setup, if the user makes a correction, the user’s choice of word inherits the CCG supertag of the word that the user has just corrected, which, in fact, is predicted by the INMT system. The new word and the incorrect word that the user has just corrected could be syntactically or semantically different. As a result, the supertag that the new word inherits could be incorrect. We calculate the percentage of CCG supertags that are incorrect for the new words when the predicted words were wrong and edited by the user. We also produce such statistics for the second experimental setup, OnflyCCG. In Table 7, we show the percentage of CCG supertags those were incorrectly assigned to new words on both the experimental setups. We clearly see from the table that the second setup (OnflyCCG) is far better than the first setup (PredCCG) in terms of assigning correct CCG tags to the new words that the user has just corrected, i.e. better by 17.06% to 17.12%. This is seen consistently across the sentence length-based sets too. When we compare this across the TS and FS INMT systems, we see that the percentage of correctly assigned CCG tags to the words of the user’s choice in the FS INMT system is higher (by 1.43%) than the TS INMT system on the test set.

6.5 Latency for the CCG supertagger

We calculate the average delay for a correction (i.e. processing time) by the user for baseline, PredCCG, OnflyCCG and GT (ground-truth) setups using the TS INMT system, which are shown in Table 8. We see from the table that the delays are comparable across the systems. As for Onfly-CCG, we exclusively calculate the average latency for applying the CCG supertagger, which is found to be 0.12 seconds only. Hence, the supertagger does not bring much computational overhead and impact latency as far as translation time in the interactive-predictive platform is concerned.

6.6 Average Number of Partial Hypothesis Processed

In the interactive protocol, when the user makes a correction, the MT system re-translates the source sentence given the validated partial hypothesis. Finally, the new translation is shown to the user. In Table 9, we show the average number of partial hypotheses processed (i.e. how many the MT system has to re-translate) for each sentence in the test set. For this analysis, we consider all the experimental setups (PredCCG, OnflyCCG and GT) and MT system types (SS, TS and FS INMT). We see from Table 9 that the OnflyCCG on FS INMT setup wins out if we omit the ideal setup (GT). In other words, source- and target-language syntactic contexts in combination have more impact in INMT than either type individually.

7 Conclusion

In this paper, we have integrated a rich and complex syntactic knowledge in the form of supertags and/or syntactic constituency parse into the current state-of-the-art neural MT model, Transformer. Furthermore, we tested whether integration of such knowledge sources into Transformer could indeed reduce human efforts in translation in an interactive-predictive scenario. We carried out our experiments on French-to-English, a high resource widely-used translation-pair in industry. We compared our syntax-informed and baseline Transformer models on an interactive-predictive platform. The use of syntactic constituency parse as conditional context has minor impact on reducing human effort in translation. We modelled target-language supertags as conditional context in interactive NMT in two different ways, and both of these significantly positively impact productivity in translation.

Interestingly, supertags (target) and constituency parse (source) together as a context turns out to be the best-performing setup with significant gains over either feature type. In this sense, we can say that source and target-side syntactic contextual features complement as far as neural interactive prediction is concerned. In fact, the conditional context in this setup includes both source-language constituency parse and target-language CCG, which essentially provides the INMT model with better syntactic agreement between the source and target sentences.

Table 9: Average number of partial hypothesis processed.
We conjecture that this could be the reason why this collaborative strategy turned out to be best-performing.

Our analysis shows that the OnflyCCG setup (where CCG assigned by On the fly CCG supertagger) significantly outperformed PredCCG (where CCG predicted by Transformer) in terms of assigning correct CCG to the words of user’s choice by large margins (17.06% to 17.12%). In fact, our proposed setup (OnflyCCG), to a certain extent, provides a way to inject correct context into the interactive model. This could be the reason why OnflyCCG turned out to be best-performing.

Our analysis unraveled many sides of our syntax-aware models in an interactive-predictive environment. For an example, we particularly found that our syntax-informed interactive-predictive models have positively impacted more for the translation of longer sentences. Given the importance of interactive MT in translation industry, the findings of this work can be crucial for their production as our methods can positively impact their productivity gain in translation.

Given the fact that linguistic tools such as supertaggers and constituency parsers are only readily available for a handful of languages, in future, we will continue to pursue this line of investigation with exploring integration of language-independent contextual knowledge in interactive-predictive NMT. In future, we plan to evaluate our interactive MT systems with human agents.

8 Acknowledgement

Authors gratefully acknowledge the generous grant of TDIL, MeITY, Govt. of India for the project "Hindi to English Machine Translation for Judicial Domain [11(3)/2015-HCC(TDIL)]" to carry out this research. Asif Ekbal acknowledges Young Faculty Research Fellowship (YFRF), supported by Visvesvaraya PhD scheme for Electronics and IT, Ministry of Electronics and Information Technology (MeitY), Government of India, being implemented by Digital India Corporation (formerly MediaLab Asia). Rejwanul Haque and Andy Way acknowledge the ADAPT Centre for Digital Content Technology, funded under the Science Foundation Ireland (SFI) Research Centres Programme (Grant No. 13/RC/2106) and is co-funded under the European Regional Development Fund.
