The analysis of students' activity on the first four configurations showed that the interactions between the students and the task didn't seem sufficient to cause an evolution in their activity towards complete conceptualization of the flipping over property. However, an evolution has occurred in their ability to construct and validate, towards a better consideration of this property: their first idea was to translate the figure without flipping it over for the first four configurations, but they flipped it over directly for configurations 5 and 6. How can we understand what drove this evolution?

What we chose to observe leads us especially to pay attention to oral interactions during task completing. Consistently with our theoretical frame, this leads us to identify that, in this example, the evolution of pupils' activity is caused by a double process, adaptationist (students interacting with a task) and social, (essentially here through interactions between students and teacher). How do both interactions between the students and the task and interactions between students and teacher articulate to contribute to the evolution of the ability of students to acknowledge the flipping over property?

We distinguish two types of interactions: the interactions between the pair and the teacher, when she comes to talk to them during their validation; the interactions between the students and the teacher during collective discussions. Each of these types is a place where teacher and students' activities articulate, completing interactions between students' and the task, in order to make their understanding of the task and of the 'milieu' change. During the interactions between the students and the teacher, we identify three objectives of the teacher: helping them to identify mistakes (about the alignment of segments, in configuration 4), asking them to use tracing paper to control their answer to make them go back to material actions (configuration 3), and helping them using tracing paper correctly to flip it over and replace it so that the two lines match: what is at stake here is the link between the flipping over of the figure and the switch in the orientation of 1D elements. The teacher accompanies them in what interactions with the task was not sufficient to ensure. We suggest that, among these interventions, some have a productive function (Robert, 2008) (help students to complete the task) and some have a more constructive function (Ibid.) (help students transform activity into knowledge).

During collective discussions, the teacher based the debate on students' productions and mistakes. She made students explicit the flipping over property, then put it into words, and decontextualized it. However, she didn't emphasize the link between this property and the material action of folding or flipping tracing paper as much as she does when interacting with the two students (except for configuration 6).

RESULTS AND CONCLUSION

Our analysis of the evolution of productions of a pair of students on a task about symmetry allowed us to identify factors of this evolution: the feedbacks provided by the task but also interactions between students and between students and teacher. It points out how an adaptationist and a social process intertwine to ensure this evolution.

Finally, we claim that, in the observed sessions, students' progression towards a better consideration of the flipping over property results from articulation of four types of interactions between students and milieu:

- interactions between the students and the task, their use of instruments and the way they adapt to pragmatic feedback coming from the control with tracing paper;
- the verbal interactions between the two students in the pair;
- the interactions between the pair and the teacher, when she comes to talk to them during their validation;
- the interactions between the students and the teacher during collective discussions.

This study also informs on the way the teacher's activity may articulate with students' one: choice of the task, interactions with them during research, use of productions during collective discussions. Finally, it points out that linking various dimensions of activity (material, verbal and conceptual) is a condition to ensure learning.

Teaching geometry to students (from five to eight years old)

Jacques Douaire[1] and Fabien Emprin[2]

1 LDAR, Ermel Team-IFé, Paris, France, jacques.douaire@wanadoo.fr

2 University of Reims Champagne-Ardenne, CEREP, Reims, France, fabien.emprin@univ-reims.fr

For students from 5 to 8 years old, the spatial and geometrical learning concern mainly the control of its relations to real space (tracking, travelling), the recognition of objects and shapes, and their representation by drawings using straight lines. The ERMEL team, in France, is experimenting teaching situations on space and geometric learning in the 2nd cycle of primary education (5–8 years old student) and is building complete engineering to teach math in elementary school. Our methodology involves an analysis of the student's way to solve problems and thus their abilities. Experiments conducted in a great number of classrooms allow us to better understand the components of this learning in terms of knowledge and abilities. Thanks to these results, our hypothesis and choices have evolved.

Keywords: Geometry, teaching, learning, primary education, spatial problems solving.

RESEARCH'S PRESENTATION

Issue of this paper

Our research takes place in the French context of geometry teaching in primary school. Our goal is to build proven, complete and reliable teaching engineering and thus to improve geometry teaching.

By submitting our results and remaining questions we want to contribute to the working group's thought. In a European context we also want to compare our approach to others and seek our results significance.

Why working on geometry teaching?

For a long time, Berthelot and Salin (1992, 1993), highlighted the difficulties of geometry teaching in France:

> No one disputes, for example the usefulness of knowing how to do a multiplication, so learning it in school, has been normal for a century or so. [...] For the geometrical knowledge, beliefs are less assertive, [...]. So they feel "authorized" to take leeway with the school curricula, that is to say, to ignore this part (as well as high school teachers ignore 3D geometry) (translated from (Berthelot & Salin, 1993, p. 39))

An analysis of teachers' representation about geometry teaching (in process) confirms that in 2014, things have not really changed. This work, based on interviews, also shows that both geometrical and didactics knowledge of teachers (even experienced) is weak.

As far as geometry is concerned, textbooks mainly focus on students' work, on drawings and being able to write the proper name on the proper drawing.

Geometry learning is not seen as a social necessity by the families and sometimes by teachers. Moreover, its contribution to subsequent learning is often reduced in the classrooms at an early learning, even ineffective, of geometrical vocabulary.

This research is also based on the idea that students' abilities are insufficiently taken into account in geometry teaching in primary school. Thus we have to identify the knowledge at stake in this learning and take former students' knowledge into account.

By starting our research from the analysis of students' abilities and geometric concepts we develop an uncommon methodology (described below).

About us

ERMEL is a research team on mathematics education in primary school (in French "Équipe de Recherche en Mathématiques à l'École Élémentaire"), which belongs to the French institute of education (IFé). This team is made up of primary school teachers, teachers' trainers and researchers working in different cities of France (Châlons-en-Champagne, Grenoble, Lyon, Paris...).

The ERMEL team conducted studies on teaching and learning of number system and arithmetic's form 1985 to 1998 and since 1998 on geometry teaching and learning. Results of theses researches lead to comprehensive book publications on teaching engineering (Équipe de Recherche en Mathématiques à l'École Élémentaire [ERMEL], 1998, 1999 & 2006).

The aim of the current research is to analyse spatial and geometric skills that 5 to 8 years old students can build.

Methodology

Our research has been and is sometimes called "action research" in the French tradition. We do not deny that term in its meaning and use Hugon and Seibel's (1988): "Research in which there is a deliberate transformation of reality; research that has a dual purpose: to transform reality and produce knowledge about these changes." Our research actually intended to produce resources that are analysing issues of education in relation with school curricula and their changes.

On the other hand, our methodology is quite different form the English tradition of "action research in education" as defined by Sagor (2000, p. 3):

> It is a disciplined process of inquiry conducted by and for those taking the action. The primary reason for engaging in action research is to assist the "actor" in improving and/or refining his or her actions. Practitioners who engage in action research inevitably find it to be an empowering experience.

Even if teachers and teachers training have an important place in our research, we define our methodology as a didactic engineering. Our approach has in common with the didactic engineering concept the general questions it allows to address. In fact, the term "didactic engineering" appears in the mathematics teaching in France in the early 80s as a way to answer two fundamental questions translated from Chevallard (1982 as cited in Artigue, 2002, p.59):

> How to take into account the complexity of the classroom in research methodology?
>
> How to think about the relationship between research and action on the education system? [...] As a research methodology, didactic engineering is different from the usual experimental methods by its validation mode. This internal validation method is based on the confrontation between an a priori analysis in which are engaged a number of assumptions and a post hoc analysis that relies on data from the actual implementation.

The ERMEL research team develops an analysis of students' knowledge, issues of teaching, and offers a didactic engineering based on an experiment conducted in many classrooms for several years.

This research is derived from the analysis of the challenges of teaching mathematics in the field. Once the needs are identified, such research involves several steps:

1) An analysis of the mathematical knowledge (problems, properties...) at stake, as well as students' knowledge and abilities;

2) An explanation of educational issues and the organisation of the study of the different notions throughout the years;

3) Development of teaching situations and tests in several classrooms.

These last three components interact: the identification of students' abilities is the outcome of experiments conducted.

4) Writing a book for teachers and trainers with an explanation of the issues of learning and teaching, a description of the identified learning situations, a reasoned choice of learning roadmap and syllabus planning. These books are often references in training in France.

The diagram below (Diagram 1) illustrates our methodology.

Analysing teaching and learning process require theoretical frameworks.

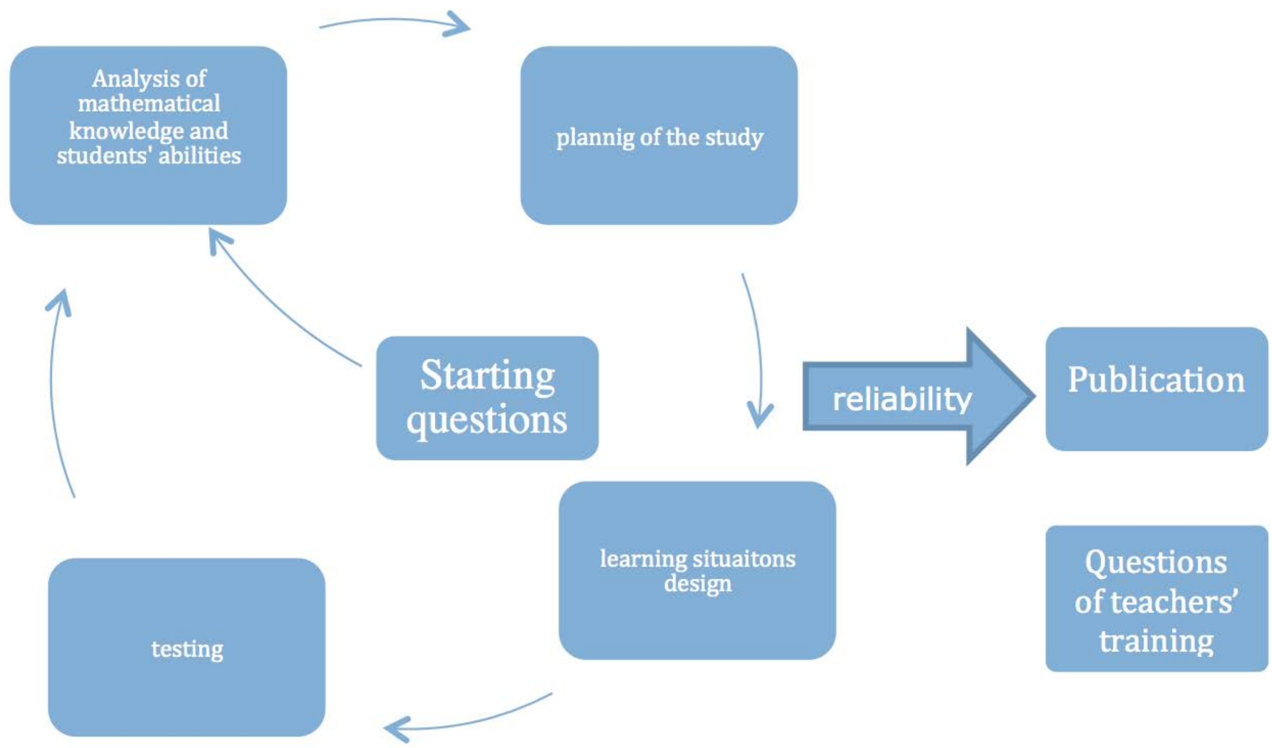

Diagram 1: Steps of ERMEL's methodology

Theoretical frameworks

We mainly focus on a framework that is preeminent in the French context, the Theory of Didactical Situations based on the ideas below:

> Mathematicians don't communicate their results in the form in which they discover them; they re-organize them, they give them as general a form as possible. Mathematicians perform a "didactical practice" which consists of putting knowledge into a communicable, decontextualized, depersonalized, detemporalized form.
>
> The teacher first undertakes the opposite action; a recontextualization and a repersonalization of knowledge. She looks for situations which can give meaning to the knowledge to be taught. But when the student has answered to the proposed situation (...) she will have to redepersonalize and redecontextualize, with the assistance of the teacher, the knowledge she has produced so that she can see that it has a universal character, and that it is re-usable cultural knowledge. (Brousseau, 1997, p. 227)

For teachers, building learning-situations is building a problem where the knowledge is recontextualized. By solving this problem, the student will acquire the knowledge at stake. There are different kinds of problems corresponding to different ways to reach the knowledge (more or less efficiently).

As far as geometry is concerned, we also use concepts highlighted by former researches. We distinguish between spatial knowledge and geometrical knowledge:

> In general we can distinguish between two kinds of problems:
>
> — spatial problems thus characterized: their purpose concerns the sensitive world; they can focus on implementing actions: making, shifting, moving, drawing, etc. communication about actions or findings [...] The success or failure is determined by the subject itself by comparing the expected result and the result;
>
> — geometric problems, like that word is used in mathematics: Solving a geometrical problem is an activity involving the necessary and non-adversarial nature of certain properties of the geometrical objects" (translated from Berthelot & Salin, 1993, p. 41).

We also use the work of these authors, which defines different kinds of space in which spatial problems can be placed: micro space (very close to the subject, object can be moved, touched, turned) meso-space (surrounding space, between the arms of the subject, he can have a comprehensive view, he can move in the space) and macro space (far space, the view is more local, subject has to conceptualize). The space defined by the sheet of paper can be called graphical space and has also special features. Computer screen also form a new type of space depending on software uses (for example dynamical geometry software). Theses spaces are so many choices and so many parameters of the learning situation.

We focus on the alignment and straightness concept to make our approach explicit.

ALIGNMENT AND STRAIGHTNESS IN THE 2ND CYCLE OF EDUCATION

(2nd cycle of French school is 1st and 2nd grade in the USA)

This research was attributable mainly to the fact that the teaching of geometry in the primary grades does not adequately take into account the knowledge children can develop when solving problems. This research therefore requires identifying the skills involved in these learnings and take into account the initial knowledge in these fields.

As often with geometric concepts introduced in elementary school, the concept of straight line has a double aspect:

- it allows to represent real-world objects or actions

- it is a component of a geometric knowledge constitution that has properties that students gradually discover: in this case it is the properties of the straight line and the constraints of its drawing.

This learning raises several questions: in the 2nd cycle, what are the possible links between these two aspects (alignment of points and straightness of lines)? In particular can the procedures developed in the meso-space be reused on the paper? Is it better to start with experiences in the meso-space to show a straight line as a solution of an alignment problem?

Meanings of the straight line

The notion of straight line can be understood by the 2nd cycle's student through different meanings induced by perception or experience, which can be used in problems for:

1) The graphic representation of physical objects soliciting properties of the straight line, including:

— a material object: a stretched wire, a straight edge object, a light ray, the fold of a paper ...

— a border between material objects :

  — two planar regions of space, as the edges of a polyhedron;

  — two regions of the map, as the sides of a polygon, of half-planes ;

— a subject of the graphics world : a straight line (which may be extended beyond the ends);

— a trace :

  — a print trace produced by a path with the ruler ;

  — a print screen trace caused by the "straight" tool in a dynamic geometry software (like Cabri Geometry)...;

— the path of a rectilinear object (ball ...).

For all these problems in connection with these first meanings, the points do not play an important role.

2) a set of aligned points : the locus of points aligned with two points, for instance for sight problems in the meso-space.

Properties

Our previous work research (ERMEL, 2006) on geometric learning has confirmed that the properties attributed to the straight line by the students aged 8 to 9 (CE2), are limited to those related to the perception of lines drawn. From a theoretical point of view, if a straight line can be characterized in various ways, as the effect (invariance) of a transformation, as the intersection of planes, for the student of six or seven years old the concept of the direction (extension) is the first they meet. In fact for students of this age a straight line is simply the straight line drawn on a sheet. Several properties of the line, as a mathematical object (in particular the fact that the line is formed by an infinite set of points) are not accessible to the primary school.

Questions

One of the challenges of our research on 2nd cycle was for us to determine:

— What is the initial knowledge of the students? What perceptions, what experience do they have of straight lines?

— Among the meanings of straight line which must be preferred?

Initial hypothesis

We therefore sought to clarify the meanings of straight lines that may be encountered or that are accessible to 2nd cycle students and to create problems, allowing a passage to geometric knowledge.

We thought that the fact that a line can be extended for solving an alignment problem should be learned.

At the beginning of this research, we considered teaching a grasp of the concept of alignment through the experiment centred on the idea of hiding an object (using the sight) in the meso-space, then again on paper in order to highlight the utility of using the straight line.

We proposed a problem ("Plots") that takes place in the schoolyard (Figure 1): students have to find locations (using the sight) where an object hides another one (I see the red plot hiding the green one and the yellow plot hiding the orange one). The problem was after proposed on the paper sheet (representing a top view of the yard). In solving the problem on paper the students were not using straight lines to find the locations; broken lines have been uses to depict alignments.

These experiments revealed activity transition-related difficulties conducted in the meso-space activities on paper.

First experimental results for CP (1st grade US – Year 2 GB) and CE1 (2nd grade US – Year 3 GB)

Students had developed spatial resolution procedures based on the sight and other gestures in the meso-space. But the modelling by a straight line was not effective in solving a similar situation on paper. In addition there were difficulties for drawing straight lines with a ruler, many productions included broken lines and not straight lines to represent the target.

Analysis of the difficulties in the transition from meso-space to micro-space

They seem related to:

1) An understanding of modelling on a sheet of a situation experienced in the schoolyard:

— Meso 3D / micro 2D (top view ...) and the disappearance of the subject (student) in the micro-space device.

— A representation of physical objects by schematizations (circles, dots).

2) What the straight line was supposed to represent.

3) For the drawing of plots straight lines.

The use of dynamic geometry software (DGS) seemed to enable this switch in CE1 (7-years-old): students using the straight lines to produce with DGS a solution to the alignment problem. However, we have not been

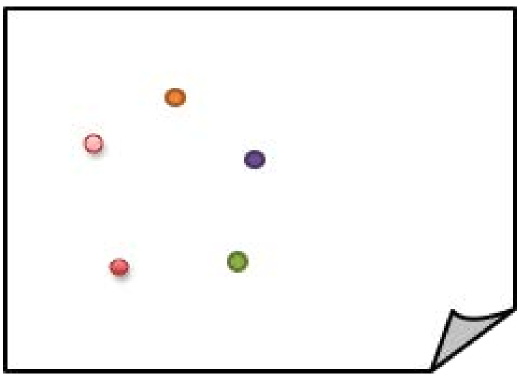

Figure 1: "Plot" situation in the schoolyard (left) and in sheet of paper (right)

able to check the reinvestment in the longer term on the sheet of paper.

The analysis of these problems (items 2 and 3 above) also highlighted the need for a specific work to allow the apprehension of the meanings and some properties right from the 2nd cycle (the term « straightness ») relatively independent of the alignment point problems. This corresponds to the first set of meanings of the straight line as shown on page 5.

Rolet (2003, p. 7) who also analysed 8-year-old students' work in different spaces noticed difficulties: "[students] they took the piece of rope not like a part of a line but like a segment. [...] Cabri-geometry was also a good instrumented space to give a real status to concepts like points: 'visible' vs defined, 'draggable' (or independent) vs fixed (or dependent). But understanding of these concepts still presents many difficulties for all students."

SPECIFIC LEARNING OF STRAIGHTNESS

Meanings of the concept of straight line

The meanings of the straight line can be associated with problems concerning either: the production of straight lines, the identification of straight lines (judgment), the choice and use of instruments that could be used to identify or produce an alignment or a straight line.

Among the meanings of a straight line, we chose to emphasize, for 6-year-old students, those of edge parallel strips, contour of a geometric figure. Validation criteria are either simply perceptual (regularity of the trace or resemblance to a model) or related to a more or less explicit reference to parallelism (direction ...) or consist of a practical validation (coincidence ends, overlay actions objects ...).

Presentation of a situation and common Goals

Students are working on "superpositioned form". They have to do a stack of shapes (rectangles, triangles) and draw their superposition.

These meanings can be associated to problems concerning either:

— the production of straight lines;

— the identification of straight lines (judgment);

— the recognition and use of instruments that could be used to identify where to produce an alignment or a straight line.

This work on the notion of " straightness", although it can be started in kindergarten (Year 1 in GB, called "grande section" in France) with the production of regular lines made in drawing activities, really takes its geometric dimension at 1st grade (6-years-old, CP in France) where the properties of straight line can therefore be apprehended. These properties are not yet objects of study for themselves, but are first experiences:

— a line can represent something that does not leave a physical form (e.g. sight);

— a drawn line may be associated with instruments;

— a line may be extended, for example to represent a hidden object.

Different levels of understanding control may be associated with these meanings:

— understand the need to draw a straight line to solve the problem; this is the role of formulations (validation through language, rather consensual), role of gestures (hands);

— learn how to place the ruler to draw a longer line; it is the knowledge of the method and the technological aspect: name tools, describe the action...

— mastery of drawing (validation by production).

ASSESSMENT FINDINGS AND QUESTIONS

Robustness/reliability of situations

— Devices (progressions, situations) that we have developed favour a knowledge construction based on problem solving. They have a certain "robustness" due in particular to the fact that the results and procedures that will be produced by students in a class are described in the description of situations, allowing the teacher, in general non-specialist in mathematics, to anticipate their decisions based on its own class productions. This reliability seems partly due to the coherence between the concepts of learning and the proposed situations and, secondly, to their experimentation in many classes for many years.

One of the challenges of our methodology is to allow ownership by teachers of educational created devices.

The conditions that we consider necessary for the appropriation of our devices by those teachers are:

— a better perception of the relationship between spatial knowledge and geometrical knowledge that students can develop;

— an awareness of all the meanings of a concept and situations associated;

— the identification of the essential characteristics of teaching situations;

For this we highlight these elements in our publications.

The level of understanding geometric measurement

Eszter Herendiné-Kónya

University of Debrecen, Institute of Mathematics, Debrecen, Hungary, eszter.konya@science.unideb.hu

The perimeter and area are two important geometric concepts, which are taught through many years in schools. Although the curriculum and the textbooks in Hungary consist of both qualitative and quantitative approaches by teaching area and perimeter, the students' performance is low. The main goal of this research is to investigate students' ideas of the concepts area and perimeter from 5th to 8th grade. We identify typical solving strategies in order to understand students' imagination connected to these mathematical objects.

Keywords: Perimeter, area, geometric measurement, concept formation.

INTRODUCTION

The perimeter and area are two important geometric concepts, which are taught through many years in schools. We know from the works of many researchers and from our experience too that the teaching-learning process on this topic poses many problems. Although the curriculum and the textbooks in Hungary consist of both qualitative and quantitative approaches by teaching area and perimeter, the students' performance is low. In Hungary quite the same misconceptions and troubles are observed as in other countries.

The main goal of this research is to investigate students' ideas of the concepts area and perimeter from 5th to 8th Grade. We find the students' long term memory interesting, because it forms a correct view about the level of understanding concepts examined in the study. It happens in schools usually that teachers examine students' new knowledge in a few days after teaching a certain topic and they find that the students acquired the new concepts and procedures. The good result of such kind of tests can be misleading: some month later students don't even remember the basic ideas.

THEORETICAL BACKGROUND

One of the goals of education is to help students store information in long-term memory and to use it in order to solve problems. There are three different parts of long-term memory. Episodic memory refers to our ability to recall personal experiences from our past. Semantic memory stores concepts, rules, principles, and problem-solving skills. Information is more easily stored in semantic memory when it is easily related to existing, well-established schemata. Procedural memory refers to the ability to remember the steps of performing a task or employing a strategy (Baddeley, Eysenck, & Anderson, 2010; Skemp, 1975).

The topic of measurement is very useful to develop students' skills in problem solving, spatial sense, estimation and concept of numbers (Korenova, 2014).

In primary school by teaching measurement, general measurement principles are used: quantity conservation; direct comparison of quantities without measuring; the need for repeated (standard or non-standard) units; estimation before measuring; exploration of the inverse relationship between the size of the unit and the number required to measure; choosing an appropriate standard unit for a concrete quantity (Curry, Mitchelmore, & Outhred, 2006; Herendiné-Kónya, 2013). In Hungary in the teaching of length, mass or capacity these principles are accepted, but they are not followed in the teaching of area and perimeter. The steps listed are mainly left out; the emphasis is usually placed on the measurement of length and mode of calculation.

The perimeter and area are at the same time geometric concepts and measurable quantities too. This is the reason we use two approaches in the teaching of this topic, a qualitative and a quantitative one.

> In the teaching of area two approaches are generally used. One that can be considered as formal which refers to the calculation of areas with formulae and another, informal, that emphasizes the conservation of area in figures of a different shape. (Acuna & Santos, 2012, p. 1)

We agree with Acuna and Santos, that there is a gap between these aspects of the area, furthermore there is also a gap between the qualitative and quantitative aspects of the perimeter. We know very well, that students used to have deficiency of area and perimeter measurement. Researchers describe that these problems arise among others from the early teaching of formulas (Baturo & Nason, 1996; Vighi & Marchini, 2011; Zacharos, 2006).

Usiskin (2012) speaks about a multidimensional approach of understanding, which helps to clarify the meaning of a certain concept and elaborate teaching materials to develop it. The dimensions of understanding of area and perimeter according to Usiskin are the following:

1) Skill-algorithm understanding: Knowing how to get an answer, i.e. choosing an appropriate algorithm to calculate the area and the perimeter of a given figure.

2) Property-proof understanding: Knowing why the way of obtaining the answer worked, i.e. knowing the derivation of the basic formulas and the relation between area and perimeter of the same figure.

3) Use-application understanding (modelling): Knowing when doing something, i.e. recognizing area and perimeter measurement in everyday life problems.

4) Representation-metaphor understanding: Knowing represent the concept in some way, i.e. area with congruent tiles, perimeter with the length of a fence.

According to Usiskin, the dimensions are relatively independent, and there is no precedence among them in terms of difficulty. In the present study the focus is on the 1st and 4th dimension. We compare the level of the skill-algorithm and the representation-metaphorical understanding in different grades.

RESEARCH QUESTION

The present research is looking for the answer to the following questions:

What do the concepts of area and perimeter mean for students at different ages? What are the students' typical strategies and misconceptions by solving area and perimeter tasks?

Our hypothesis is that the older students perform better with respect to the two investigated dimension of understanding (skill-algorithm and representation-metaphor), due to the expanding knowledge. We assume furthermore that the most frequent mistakes arise from identifying the formulae with the concept itself.

METHODOLGY

The research sample comprises 84 students from the same school in Hungary, from the following classes: 26 students from the class 5/A, 29 from the class 6/A, 19 from the class 7/A, 21 students from the class 8/A. The age of the students was from 11 to 14. The four classes are special language classes, they have more language lessons per week as usual and only the minimum mathematics lessons; 3 lessons per week. Students involved in this study didn't show particular talent and interest in mathematics.

We made interviews with the mathematics class-teachers in order to know the exact teaching-learning situation connected to our topic. By studying the curriculum and relevant textbook we can outline the teaching-learning process in the previous school years.

4th class, 8–10 lessons per year: Recognizing area and perimeter as an attribute of plane figures. Measuring perimeter of polygons by adding the side lengths. Measuring area by counting congruent tiles. Finding the perimeter of a rectangle, applying the formulae $(a+b)\cdot 2$, or $a\cdot 2+b\cdot 2$. Measuring areas by counting unit squares, finding the area of a rectangle with whole-number side lengths by multiplying the side lengths and applying the formulae $a\cdot b$.

5th class, 10–12 lessons per year: Finding areas of rectilinear figures by decomposing them into rectangles and adding the areas of the parts. Finding the area and perimeter of rectangles/rectilinear figures in the context of solving real world and mathematical problems. Recognising rectangles with the same perimeter and different areas or with the same area and different perimeters.

6th class, 4–6 lessons per year: Finding the area of right triangles, other triangles, and parallelograms by cutting and rearranging into rectangles.

7th class, 10–12 lessons per year: Knowing the formulas for the area and perimeter of triangles, special quadrilaterals, circles and use them to solve problems.

To investigate and compare the actual level of the understanding of area and perimeter, we designed a 30-minute written test. In one part of the tasks, the area and the perimeter of concrete shapes had to be calculated with the use of known formulae, where we either gave the required lengths or they had to be measured. In case of solving other part of tasks the development or representation of qualitative images were required. The first three tasks were the same in every class. As these tasks are considered very easy routine tasks for those in the 7–8 grades, we assumed they would need shorter time to solve them, so we assigned two further tasks for them. Students were familiar with the type of the tasks, because they solved such kind of problems earlier. It was considered to be also important to have a real-size picture to every task.

While we are interested in students' long term memory, we did the test on the first week of the new school year, on the 3rd of September 2014. This date provides that the students haven't dealt with mathematics especially with area and perimeter for at least 3 months, so we can consider our test as a delayed test.

TASK ANALYSIS AND RESEARCH FINDINGS

The structure of the test

Task 1: Students had to calculate the perimeter and area of three rectangles with the sides 3 cm x 7 cm, 5 cm x 5 cm, and 2 cm x 8 cm. The rectangle's position on the worksheet was usual; the sides were parallel or perpendicular to the paper edges. We wanted to know if students use the adequate calculating method correctly. The perimeter of the rectangles was the same, the area was not. We asked the following question: "What do you observe?" We wondered whether students notice that the same perimeter not necessary results the same area.

Task 2: *Calculate the perimeter and area of the plane figure.* (Figure 1)

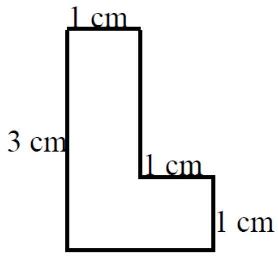

Figure 1

In this case there are no concrete formulae for perimeter and area. Students have to know that the perimeter of a polygon means the sum of the lengths of every side.

They also learned about the additivity of the area and finding area of rectilinear figures by decomposing it. Following Vighi and Marchini (2011), only the necessary numbers are given. We were looking for the level of understanding of these two concepts and typical solving strategies.

Task 3: "*Find the area of the triangle if the distance between two adjacent grid points is 1 cm. Draw two other plane figures with the same area as the triangle has.*"(-Figure 2)

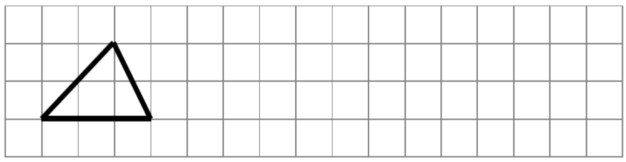

Figure 2

The area of a plane figure means the number of unit squares which cover the figure without gaps and overlapping. Determining the area often requires appropriate cutting and rearranging. There is also a possibility to apply the area formulae for triangles: $b \cdot h/2$. Drawing figure with a given area means more than formal understanding of the procedure for calculating the area.

Task 4 (for Grade 7–8): "*Calculate the area of the triangle.*" (Figure 3)

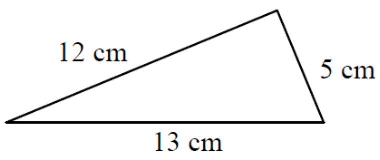

Figure 3

We wonder whether students know the concept of altitude, and apply the formulae learned last school year. The question was the following: is there any student who recognizes that the triangle has a right angle?

Task 5 (for Grade 7–8): "*Calculate the area of the parallelograms. Measure the necessary data by ruler.*" (Figure 4)

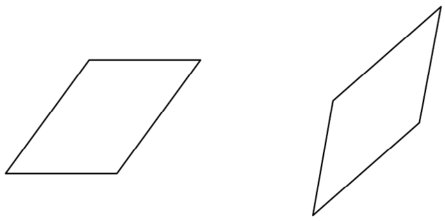

Figure 4

The parallelograms have the same sides but different angles. The first was in "usual" position and the second was rotated. We assume that the unusual position causes problems by determining the altitude of the parallelogram. While the parallelograms have the same perimeter, it's easy to recognize that the areas are different.

The understanding of the idea of perimeter

Every student from the Classes 5 and 8 determined the perimeter of the rectangles in Task 1; except 3 students from Class 6 and 2 from Class 7 gave correct answers too, which means that they are familiar with the calculating method of rectangle perimeter.

The solution of the Task 2 indicates whether the student understands the perimeter concept well or not. In this case there isn't any formula; students have to add all the sides of the rectilinear figure. The diagram below (Figure 5) shows the result of students in different classes. We found that the percentage of the correct answer (10 cm) is not more than 40% in the classes, and what is more, the 5th Graders performed the best. We detected four mistakes as typical. (1) Students often left out one or maximum two sides from the sum. This side is obviously the horizontal side of 2 cm. (2) They added only the given numbers, which indicates the lack of the perimeter meaning. (3) Relatively lots of students applied wrong formulae blindly which is analogue to the rectangular formula. For example: (3 cm + 1 cm + 1 cm +1 cm) · 2. (4) The "additivity of perimeter" also appears in a following way: some students divide the figure in two parts, calculate the perimeters of these parts than add them. It means that the procedure used when calculating the area doesn't work when calculating the perimeter. Vighi and Marchini (2011) call this symptom as "area-perimeter conflict", i.e.: "the use of a procedure for area to compute perimeter". The only distinction is that we experienced this problem not in the Grade 4, but Grade 8.

Reviewing the results of the classes we can establish that the level of understanding perimeter doesn't increase and from the detected solving strategies the wrong rectangle analogy disappeared in Class 8, but we came up with another: using perimeter as an additive quantity.

We noticed that there are 4; 1; 2 and 1 student in Classes 5; 6; 7 and 8, who mixed the words "perimeter" and "area" consequently through all the tasks. The present test was not able to say whether they interchanged only the words, i.e. the label of the concepts or the

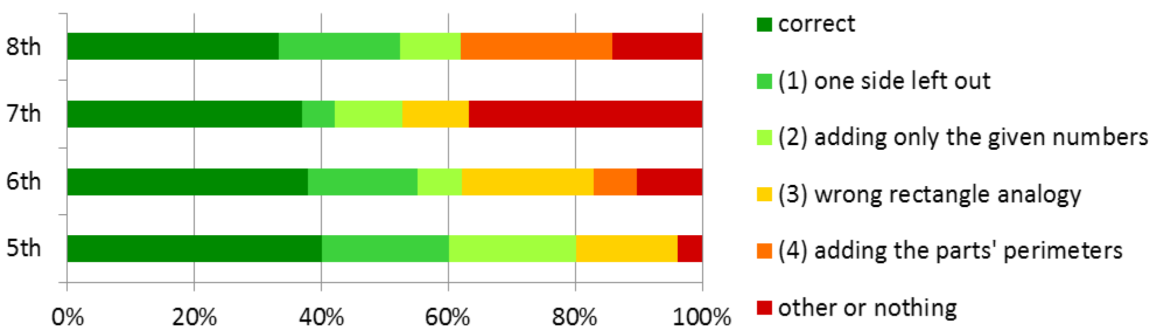

Figure 5: Calculating the perimeter of a rectilinear figure

concepts itself. This finding requires further research on real life word problems.

The understanding of the idea of area

The solution of the Task 3 gives information about the representation-metaphorical understanding (Usiskin, 2012) of the concept of area. The grid suggests the unit squares (*1 cm*^{2}) for determining the area of the triangle. If a student is able to draw another figure with the same area it means that he/she has a correct mental image of the concept even if he/or she can't make the connection between this image and the calculation (Figure 6). Studying the result on the Figure 7 we can see, that the percentage of the correct answer is significantly lower than in case of perimeter. Furthermore students from the Class 8 achieved the best result (close to 50%), it's more than they achieved in the perimeter task.

The most frequent misconception was measuring the sides of the triangle. Most of the students who measured the length of the sides multiplied the three lengths in order to achieve the area. Some of them added the sides or completed the triangle to a minimal rectangle which includes it. The percentage of incorrect answers in Class 6 and 7 are remarkable. 6th Graders forgot about the square grid which is a tool for area measurement, so their solutions were unsuccessful. 7th Graders learnt about decomposing figures and about the formulae of the triangle last year, but the grid-context was "new" for them, so they tried to apply something similar to the well-known rectangular formulae.

Task 2 is based on the knowledge that the area is an additive quantity (area conservation). The diagram on Figure 8 shows that the rate of correct answers in Classes 5; 6 and 7 are very low. Two typically wrong solving strategies can be detected: multiplying sides (some or all) and applying wrong rectangle analogy. In this last case we recognised not only using a procedure for rectangle to compute the area of the rec-

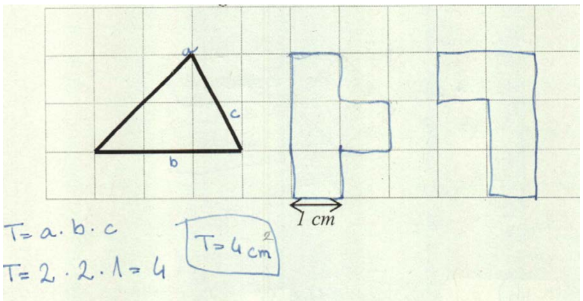

Figure 6: The solution of ***Dorina*** from Class 7

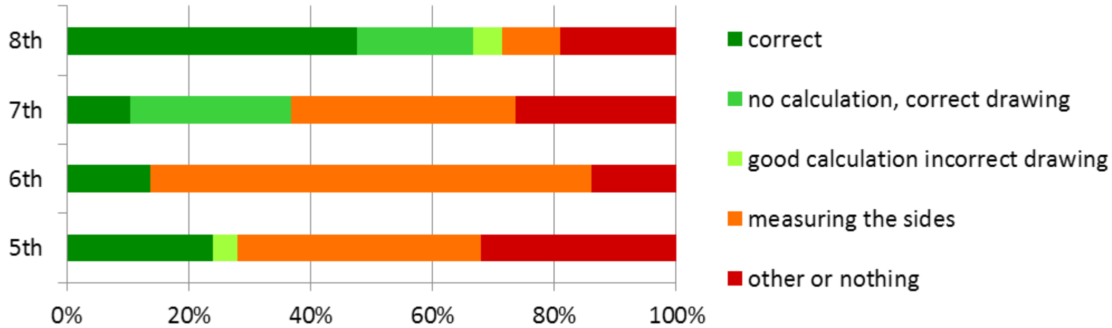

Figure 7: Calculating the area of a triangle drawn on a grid

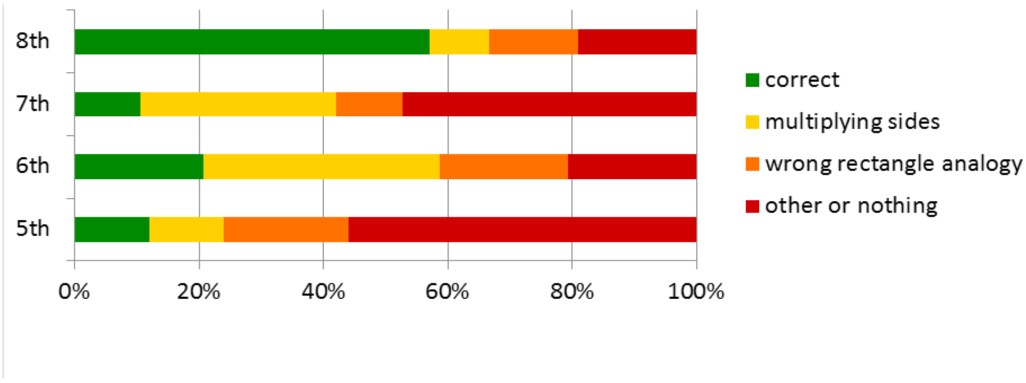

Figure 8: Calculating the area of a rectilinear figure

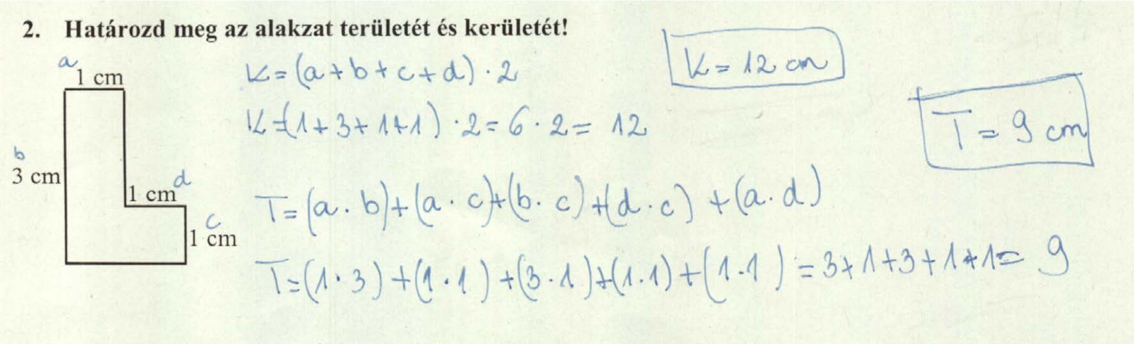

Figure 9: Dorina's (Class 7) solution

tilinear figure, but using a procedure similar to the surface area of a rectangular solid.

For example in the work of *Dorina* (Class 7) (Figure 9), we can notice the use of a procedure for computing the perimeter (K) of the rectilinear figure, analogue to the perimeter of a rectangle. She determines the area (T) with special formulae: she produces each different product of two factors from given sides then ads these factors.

Students who gave the correct solution for Task 2 or 3 were able to solve Task 1 too.

Relation between the area and the perimeter of rectangles

In Task 1, after determining the perimeters and areas of the three rectangles we asked "What do you observe?" There were only a few students (3; 3; 2 and 4 in Classes 5; 6; 7 and 8) who described explicitly that the same perimeter doesn't imply the same area in case of rectangles: "The perimeter of all of the rectangles are the same while the areas are not." One student in Class 8 gave some more explanation:

Lili: The perimeters of the three rectangles are the same, but the areas are different. It depends on the ratio between the sides of the figures.

Determining the area of triangles and parallelograms

While students learnt about the area of triangles and parallelograms in Grade 6, we wonder whether students in Class 7–8 are able to solve such kind of simple tasks.

We constructed the Task 4 and 5 to observe the use of appropriate formulae, the understanding of the concept of altitude and the influence of the position of the figures. In Class 7 there was only one student who calculated the area of the triangle correctly ($12 \cdot 5/2$) and nobody was able to calculate the area of the parallelograms. In Class 8 the result was better: 11 students had success with the triangle and 2 students with the parallelograms. 10 students (Class 7) and 2 students (Class 8) calculated the area of the triangle as the product of the sides. Nearly the same was the situation in Task 5: 10 (Class 7) and 5 (Class 8) students thought that the area of the parallelogram is the product of the two different sides. So the area of the two parallelograms became the same and the students didn't use visual control: it was easy to see that the areas are different. A new example confirmed our earlier opinion that the formulae without any meaning substitute the understanding of the concept itself. 5 students from Class 8 who tried to use the diagonals of the parallelograms ($e \cdot f/2$), did not take into consideration that this parallelogram isn't a rhombus, and the diagonals aren't perpendicular. Of course the position of the figures leaded to misconception too.

CONCLUSION

The findings of our study show the lack of understanding the two geometric concepts we investigated. We thought that the older students perform better due to the expanding knowledge. In contrast we can see for example from the analysis of Task 3, that the mental image of the area concept didn't necessarily develop, students even forgot the ideas established earlier. The formulas cover the meaning of the concepts and cause many misconceptions. One of the main findings of our research is that students think of the concept of area as the product of the sides. The new knowledge also brings mistakes if this knowledge hasn't a strong basis. The additive feature of the area implies the additive property of the perimeter. The introduction of a new formula (e.g. $e \cdot f/2$ for the area of the rhombus) causes trouble in finding the adequate calculating method. We observed and confirmed many misconceptions which were mentioned in the literature before.

Our experiences related to this research highlight the fact that students can easily forget concepts and procedures if they do not have the possibility to establish and practice it. The efficiency requires meaningful and continuous practice. The present study is the part of a wide research which aims at developing a complex teaching experiment in classes 3–8, on the topic of geometrical measurement.

Using the geometric working spaces to plan a coherent teaching of geometry

Alain Kuzniak and Assia Nechache

University Paris Diderot, Laboratoire de Didactique André Revuz, Paris, France,
kuzniak@math.univ-paris-diderot.fr, assia.nechache@hotmail.fr

A frequently-asked question by in-service teachers during training sessions relates to the overall organisation of the geometric work at primary school level. Indeed, teachers have difficulties to integrate the various resources and activities discovered during their training in a general progression for their teaching of geometry. This issue is difficult even for teacher trainers who have to meet students' expectations. In this paper, we consider some elements that could help teacher trainers devise an overall coherent teaching of geometry. We address this issue from the analysis of a teaching sequence in geometry proposed for Grade 4 - 6 students. This analysis is mainly based on the Geometric Working Spaces model used as a tool to clarify and structure a coherent teaching of geometry.

Keywords: Geometry, geometric working space, pedagogical progression.

INTRODUCTION AND OBJECTIVES

As a teacher trainer, one of the authors (Assia Nechache) is in charge of several training sessions, especially in geometry, for in-service primary school teachers. Various activities are used during these training sessions and are selected from available resources written in French and dedicated to teacher training, such as the book *Concertum* (2002) edited by the French Commission for primary school teachers' training or journals like *Grand N*. The trainees expressed their interest and pleasure in discovering and doing these activities, but at the same time they were very anxious about devising and organising an overall progression of the teaching of geometry using these new, specific activities in their classrooms.

Indeed, it is usually possible to find ideas and examples of activities to implement in a classroom situation: resources such as those we mentioned above are relatively numerous. By contrast, very few are concerned with providing tools to help teachers reflect on and develop their own overall progression in geometry.

In these conditions, we may wonder how a teacher trainer can help teachers integrate new and interesting tasks in their classroom progression. This is by no means an easy question to answer, even for teacher trainers. We therefore focused our study on possible tools to help teacher trainers deal with this specific issue.

In another context, that of the research in geometry, the model of the Geometric Working Spaces (GWS) is used to understand and structure the various ways of thinking about the teaching of geometry throughout compulsory schooling. We wondered whether this model originally designed for education research could also be a tool for the training of primary school teachers, as it could help them conceive and implement a progression in geometry. Thus, as a first step, we decided to explore the use of the GWS model with teacher trainers to highlight the main elements that organise a long teaching sequence on a specific topic and see how it can help structure an overall progression.

In this paper, we first present the model of the Geometric Working Spaces and then report an analysis of a complex and long sequence of activities on the concept of circle. The analysis was conducted with a group of 27 teacher trainers during a working group devoted to the teaching of geometry. The analysis is mainly based on the GWS model and it allows us to highlight some key points to think about the teaching of geometry in elementary school. The reported experiment is not a product of pure mathematics education research according to the standards of didactic engineering, but can be considered as an action research process, and thus as an initial attempt to adapt and transpose a theoretical tool from research to teacher training education.

THE MODEL OF THE GEOMETRIC WORKING SPACES

The Geometric Working Spaces (GWS) and geometrical paradigms have already been presented, including during former CERME sessions. For a general presentation of paradigms, we refer to Houdement and Kuzniak (2003) where the three paradigms GI, GII and GIII are identified. An introduction to GWS was presented in a plenary lecture during the last CERME session in Turkey (Kuzniak, 2013). The GWS are now part of the more general framework of the Mathematical Working Spaces (MWS) described by Kuzniak and Richard (2014)[1]. We will summarise here some key points which we think are useful to understand the analysis that we will report in the paper.

The Geometric Working Spaces

The description of the geometric work done by students in school is the main purpose of the Geometric Working Spaces (GWS). As its name suggests, the geometric work is at the centre of the model and motivates the reflection on the teaching and learning of geometry (Kuzniak, 2014). In this approach, the crucial function of educational institutions and teachers is to develop a rich environment which will enable students to solve geometric problems in an appropriate way.

To describe the specific activity of students solving problems in geometry, the GWS is organised into two planes or levels. The first, "epistemological" plane defines *a priori* expectations about the activity according to the requirements of the mathematical domain, in this instance geometry. As regards geometry, three interacting components are characteristic of geometric activity in its purely mathematical dimension:

- A real and local space as material support, with one set of concrete and tangible objects such as figures or drawings;
- A set of artefacts such as drawing instruments or software;
- A theoretical reference system based on definitions and properties.

The geometry that is taught and learnt at school is not a disembodied set of properties and objects reduced to signifiers which can be manipulated by formal systems – it is first and foremost a human activity. Therefore, it is essential to understand how communities of individuals, but also specific individuals, use and internalise their knowledge of geometry in their practice of the discipline. This implies a second, "cog-

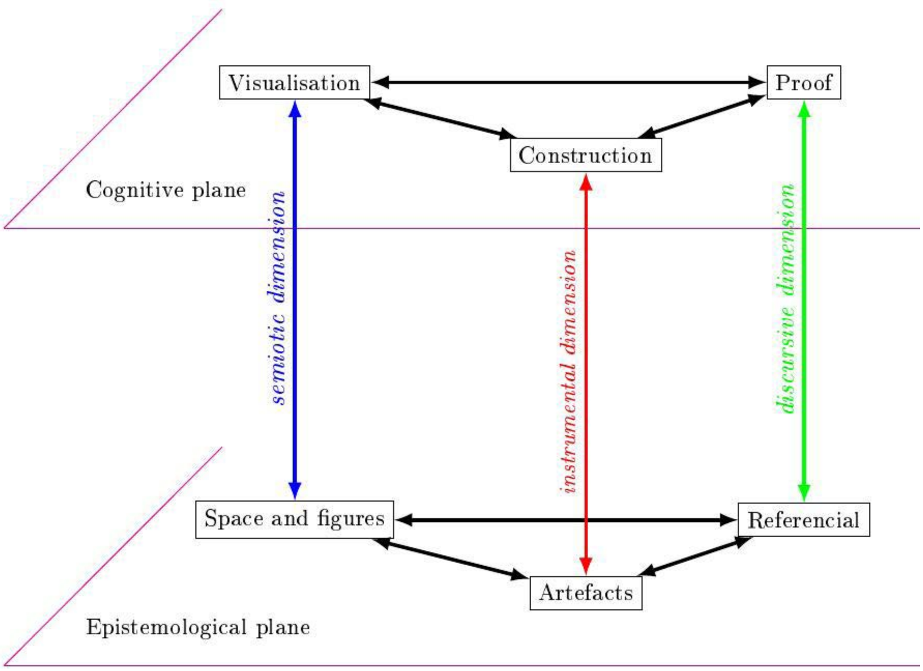

Figure 1: General diagram of the Geometric Working Spaces

nitive" level centred on the subject viewed as a cognitive subject solving problems. Considering geometric activity, these processes are as follows:

— A process of visualisation related to the representation of both space and the material support;

— A process of construction and function of the used instruments (e.g. rulers, compass) and the respective geometrical configurations;

— A discursive process producing arguments and proofs.

This set of relationships could be described proceeding from the elements of the following diagram which, in addition, shows the relationships between the two levels with three different dimensions or geneses: semiotic, instrumental, and discursive.

Various types of input in the geometric work
The above diagram shows three specific work dimensions between epistemological and cognitive planes which will require three specific genetic developments named geneses.

1) A figural and semiotic genesis that gives the tangible objects their status of operating mathematical objects;

2) An instrumental genesis that transforms artefacts into tools within the construction process, which is crucial in the case of geometry;

3) A discursive genesis of proof that gives a meaning to the properties used within mathematical reasoning.

The diagram in Figure 1 shows three vertical planes that match the connections between these dimensions and that will help us later to specify the precise geometric work existing in the GWS when students solve tasks given by their teachers. The three levels can be identified by the genesis they implement [Sem-Ins] (blue), [Ins-Dis] (red) and [Sem-Dis] (green). The objective of the analysis we present in this present was to understand precisely the nature and dynamics of these planes during the resolution of a series of geometric problems.

DIDACTIC ANALYSIS OF A TEACHING SEQUENCE THROUGH THE GWS VIEWPOINT

According to the theoretical framework, we assume that a geometric work can be considered "complete" when a geometric entity is built throughout the three semiotic, instrumental, and discursive dimensions of GWS. For this reason, a geometric entity, here the "circle", will be considered a triplet [sign, artefact (material or symbolic), property]. As a result, building a progression in geometry first requires the identification of key geometric entities in the curriculum and then the analysis of the work associated with these entities in terms of GWS dimensions. We focus here only on the second point related to a long teaching sequence on the circle entity.

The selected sequence "Le cercle sans tourner en rond" was conceived and implemented by two well-known and experienced French scholars in the domain, Fénichel & Taveau (2009). It has been tested in various classrooms under different conditions and is relatively known by teacher trainers. Dedicated to Grade 4 – 6 students, the whole program is very ambitious and includes eight sessions – from half an hour to one hour – which can be administered over three months according to a spiral program. The main objectives of the sequence are to introduce the global notion of circle as the set of all points equidistant from a given point, the centre; to use this property to solve distance problems; to relate it to construction with compass used also to transfer distances. According to our analysis, the "circle" entity targeted by the sequence can be described with the triplet [circle as drawing, compass, equal distance].

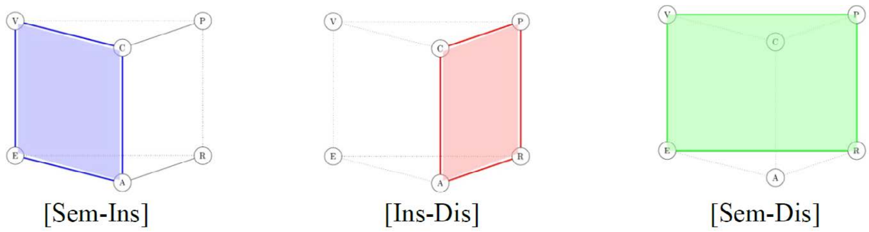

Figure 2: GWS vertical planes

Some activities of the sequence have been chosen for a common analysis with the 27 teacher educators in a working group setting. We here only report on the activities corresponding to classroom sessions 1, 2, 3, 4 and 7.[2] Each of the five selected sessions has been analysed using the GWS model. In particular, participants in the working group were asked to identify, if possible, the different input dimensions (semiotic, instrumental, discursive) in the geometric work and the favoured planes (plane [Sem-Ins], plane [Sem-Dis] and/or plane [Ins-Dis]). This identification highlights the dynamics of the geometric work during the different studied sessions and allows for the characterization of the overall implemented GWS.

We first detail the analysis of session 1.

The objective of the session is to highlight the fact that the circle is the set of all points equidistant from a given point, the centre. A varied amount of material and artefacts is made available: blank and tracing paper, twine, square set, compass…

Students are asked to draw 15 points at a given distance from a point A. During this phase of action, they need to place a point A on the white sheet and then a point B. After that, they need to place 15 points "situated at a distance from A which is the same as the distance of B from A". The geometric work starts in the plane [Sem-Ins].

Then, during a phase of formulation, some students' productions are displayed on the blackboard and discussed. The strategies they used to carry out the task are clarified and formulated. The objective is first to validate the notion of circle as discussed by the pupils based on the pupils' constructions. The notion of equidistance to a given point is expected to emerge. Some geometric terms are institutionalized and the characteristic property of the circle is given by the teacher and enriches the theoretical referential in the GWS.

The analysis made by the teacher educators is summarised in the following table (Table 1).

We have carried out the same work with other sessions. The different forms of the geometric work identified in the five sessions are presented in the following table and linked to a GWS diagram (Table 2).

To summarise, the geometric work is centred on the development of the notion of "circle" viewed as the set of all points equidistant from a given point and it is closely linked to the use of the compass. The epistemological plane can be defined by the triplet [circle as drawing, compass, and equal distance].

The geometric work conceived by the designers of the sequence is based, firstly, on the material artefact to bring out a property and enrich the set of theoretical tools. Then, the material artefact is set aside to promote a discursive reasoning using the theoretical notion of circle associated with the notion of equal distance.

At the end of the sequence, a return to the material artefact is operated to introduce a new use of the compass, which triggers a new circulation of the geometric work trough the different vertical planes. All the aspects of the work pertain to Geometry I but the sequence clearly paves the way for a prospective work in Geometry II at secondary school.

Teacher trainer viewpoints

As mentioned above, the global analysis of the sequence has first been conducted by the two authors and then some of the activities have been chosen for a common work with teacher trainers during a working group: that ensures a stronger relevance to the final

Sessions	Input in geometric work	GWS Diagrams
Session 1 The circle defined as the set of all points equidistant from a given point, the centre	The geometric work starts in the plane [Sem-Ins] and is concluded by the enunciation of the characteristic property of the circle which enriches the theoretical referential in the GWS. Properties and definitions of various figures used in this Grade are included in the referential. At this level, figures are generally introduced by "ostension"; it is worth noticing that such is not the case here: the proposed session clearly contrasts with traditional classroom sessions.	 [Sem-Ins] → Dis

Table 1: The analysis of session 1

Sessions	Input in geometric work	GWS Diagrams
Session 2 Geometric problem solving with use of the stated property during session 1	The new theoretical property needs to be used to solve a problem. The input into the work is first rather semiotic but the use of a discursive proof is required to validate the solution. The use of drawing instruments strongly depends on the previous identification of the characteristic property of the circle. Artefacts are proposed, in option, as verification tools after the task is solved in the plane [Sem-Dis].	 [Sem-Dis] (→ Ins)
Session 3 Giving sense to Session 1 property by using it on freehand drawings.	The geometric work is this time in the plane [Sem-Dis] but with a clear discursive input because freehand drawings are used and can be considered as symbolic signs. Drawing instruments are set aside. As a consequence, the discursive dimension is now essential to the validation of the solution. The idea is to show that the “circle” is a theoretical object grounded in a characteristic property and not only an empirical object perceptively and instrumentally linked to a drawing. Validation is based on a discursive proof within Geometry I and appropriate to the primary school level, but it is paving the way for Geometry II, which is the challenge of geometry teaching in French secondary education. As was the case previously, the authors still give students the opportunity to return to the experimental validation if it is necessary for their understanding.	 [Sem-Dis]
Session 4 Discovering circle and disk uses to solve equal distances problems.	This time, the activity supposes a construction after modelling the problem. Once the task is interpreted, the geometric work is mainly located in the plane [Dis-Ins] using the theoretical referential: the characteristic property of the circle appears as a theoretical tool to build the solution. The data are provided in the semiotic register and the circle property ensures the validity of the solution.	 [Sem-Dis]→[Dis-Ins]
Session 7 Triangle construction using the circle property and introduction of the compass as length-transferring tool	The compass will acquire a new function. Initially considered as a tool dedicated to the construction of circles, the compass is used to transfer lengths and construct other geometric figures such as triangles. An enlargement of the use of the artefact is intended and it is related to the theoretical referential and the “circle” figure. The geometric work starts in the plane [Sem-Dis] and then enriches the instrumental dimension.	 [Sem-Dis] → Ins

Table 2: The analysis of the other sessions

analysis which is based on the convergence of the different contributions made by participants.

In relation to in-service training and our initial question, the identification of the types of input in geometry seems successful in helping teacher trainers consider an overall progression in the teaching of geometry based on the organisation of a set of geometric tasks to promote a complete geometric work along the three GWS dimensions. Teacher trainers agree with this idea and underline that it is possible to have a global vision of geometry thanks to the GWS model. Moreover, teacher trainers have been aware of the importance of linking the different dimensions (semiotic, instrumental and discursive) within the geometric work.

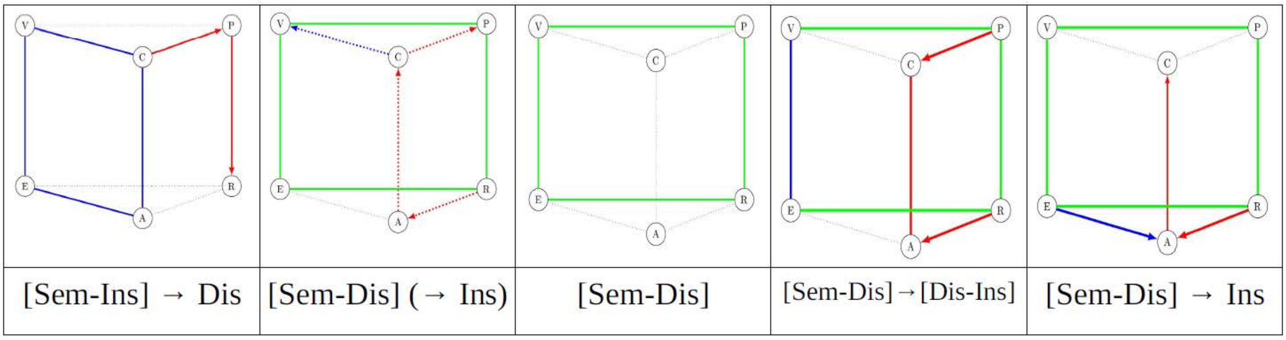

Figure 3: The dynamic evolution of the mathematical work during the different session

Teacher trainers insist on the fact that an analysis using the GWS model is relevant to highlight the dynamic evolution of the mathematical work during the different sessions. The evolution of the work is illustrated in the following global diagram (Figure 3).

CONCLUSION

Our initial question was how to devise an overall progression in the teaching of geometry at primary school. As the issue is very complex even for teacher trainers, we started our study by working with them during a workshop. To deal with this issue, we introduced a twofold approach: first, the foremost mathematical entities targeted by the curriculum need to be identified; then, activities and tasks related to a specific entity can be analysed according GWS model to ensure a global consistency. In the paper, we focused on the analysis of a sequence of activities on the "circle" entity to identify the different favoured GWS dimensions. The GWS which appear in the selected sequence are structured around a set of tasks related to the triplet [circle-drawing, compass, equal distance]. This set of tasks mobilises different articulations[3] between the three vertical planes of the GWS diagram and gives birth to a real and complete dynamic cycle in the geometric work.

According to the teacher trainers involved in the study, this approach gives a global vision of the geometric work and highlights the choices of the designers. It allows teachers to assess the consistency of a sequence and permits them to discuss the choices made. For instance, some teacher trainers did not agree with the idea of focusing on the characteristic property of the circle at this level of schooling. We may then wonder what are the consequences of other inputs giving priority to the use of software or spatial activity on the geometric work. With the GWS tool, it seems possible to discuss the « best dynamics » to favour the geometric work among teachers and pupils.

The question remains of the use of the model in teacher training and teachers' practice. We hypothesize that it is more adapted to teacher trainers than to teachers. Indeed, the priority in teacher education is to explain the mathematical content involved in teaching sequences but our reflection on the didactic transposition of the GWS theoretical model should be furthered and is one of our prospective research topics. What is clear from our experience is that it is not necessarily required to present the GWS model in depth to teacher trainers: a short introduction based on the GWS diagram has enabled us to conduct our analysis with convincing results.

This study aims to understand the contributions of collective moments of whole-group discussions for the construction of didactical pathways, based on geometric tasks experimented with children in the 2nd and 3rd years of primary school (6–10 years old). The experiment contributes to the understanding of Battista's model in its two dimensions of spatial and geometric structuring as well as the relationship between them (Battista, 2008). The data we gathered, although its analysis is still in progress, help us to build a framework from which it seems possible to identify a connection between the individual forms of mathematical knowledge for each student, the taken-as-shared mathematical practices of the classroom community and the taken-as-shared mathematical practices of wider society (Cobb, Yackel, & Wood, 1992).

Keywords: Spatial structuring, geometric structuring, whole-group discussions.

INTRODUCTION

In the Portuguese educational context the teaching of elementary geometry is still very poor and has adverse consequences for future teachers (Tempera, 2010). As pre-service and in-service teacher educators we recognize the need to enhance this area, seeking to produce useful materials for teacher education. These requirements are consistent with research interests in this area (Battista, 2007).

This communication is part of a PhD research project of the first author whose purpose is to study the teaching and learning of geometry in the early years. Its main objective was to design, test and evaluate teaching didactical pathways in Geometry and Geometric Measure for the first cycle of basic education (6 to 10 years old children). Our investigation, a design research (Van den Akker, Gravemeijer, McKenney, & Nieveen, 2006), was guided by a framework in three phases (Jackson, Garrison, Wilson, Gibbons, & Shahan, 2013). This framework, which arises from Stein, Smith, Henningsen and Silver (2000), includes the installation of a task, *phase 1*, and its implementation, split in two distinct components, *phase 2*, the moment when students work on the task, and *phase 3*, the moment of whole group discussion. Progressively, implementing tasks in different classes *phase 3* has gained greater importance increasing the role of the researcher as a teacher, but always acting together with the class teachers.

The objective of this study is to identify and understand the contributions of collective moments of whole-group discussions for the construction of didactical pathways, based on tasks focused on the spatial and geometric structuring (Battista, 2008). We try to highlight the importance of these moments and some critical aspects that help to decide the orientation of the pathways and to establish the links between the tasks that integrate them.

THEORETICAL CONSIDERATIONS

The research is based on three fundamental axes: the structuring of geometric reasoning (Battista, 2008; Freudenthal, 1991); didactical pathways based on hypothetical learning trajectories (Confrey & Kazak, 2006; Gravemeijer, 1998; Simon, 1995); implementation of mathematical tasks (Jackson et al., 2013; Stein et al., 2000; Yackel & Cobb, 1996).

We adopt the structuring perspective of Battista (2008) involving three items: (a) Spatial structuring; (b) Geometric structuring; and (c) Logical/Axiomatic structuring. At this level of instruction we only face the first two, although we have in mind that the development of good formal logical structuring depends on a good geometrical structuring, as the development of the later depends on the quality of spatial structuring. According to Battista:

> Spatial structuring determines a person's perception/conception of an object's natures or shape by identifying its spatial components, combining components into spatial composites, and establishing interrelationships between and among components and composites. (p. 138)

For instance, a geoboard is an instrument of spatial structuring through an orthogonal normal structure. We use it to spatially structure rectangles. If the sides of the rectangle coincide with the lines, structuring is immediate. If not, it is necessary some kind of visualization feature to spatial structuring the rectangle. On the other hand, analyzing a number of different rectangles and identifying the existence of four right angles as invariant we are geometric structuring rectangles. This way we are constructing a rectangle model. This conceptual scheme allows the square to be recognized as a rectangle. This example illustrates, as Battista says, how "for a geometric structuring to make sense to a person, it must evoke an appropriate spatial structuring for the person" (p. 138).

In our investigation, we follow the visualization perspective of Presmeg (1997):

> Visualization is taken to include processes of constructing and transforming both visual mental imagery and all of the inscriptions of a spatial nature that may be implicated in doing mathematics. (p. 304)

In the context of geometry, the need for research on the nature of tasks that develop spatial visualization skills and visualization is recognized for the development of spatial and geometric structuring. We connect this with learning trajectories. We use the name of didactical pathways to identify a set of tasks suitably structured, based on hypothetical learning trajectories, after experimental use in a classroom which allows its refinement from experimentation. In a way, a didactical pathway can be considered as a photograph of a journey of learning and teaching, already performed, including their reflective analysis.

We attend to students different roles and responsibilities, distinguishing thinking responsibility and participation responsibility (Wood, 1999; Wood & Turner-Vorbek, 1999), the sense of orchestrating to promote productive classroom discussions (Smith & Stein, 2011; Stein & Smith, 1998; Stein et al., 2008), the role and kind of questions (clarification, argumentation, confirmation) and their importance to obtain productive exchanges (Boaler & Brodie, 2004; Wood & Turner-Vorbek, 1999).

METHOD

Concerning the method, this research is an *educational design research* according to Van den Akker and colleagues (2006). At the end of the fieldwork conducted by the first author, we managed to get four didactical pathways. Many of the tasks have been tried more than once, in different classes and years of schooling, with particular focus in the 2nd and 3rd years. The goal was to keep improving their implementation, as well as sequencing. Each path operates as a learning cycle (Simon, 1995) and the development of research constitutes itself as a cumulative cyclic process where interpretation of a trajectory provides added value for the planning, experience, reflection and interpretation of the following cycles. So intervention dimensions, iteration and orientation processes were valued. The introduction of new tasks was one of the important aspects in the iteration of cycles of experiences.

The tasks are of an open nature and provide collective discussions based on students' productions. They provide an easy adhesion because their understanding is very simple and students can reason and act in a personally meaningful manner (Gravemeijer & Cobb, 2006). Students worked first individually and the tasks were performed with geoboard or dotted paper as a visual thinking support.

The fieldwork was divided into two periods. The 2nd one is marked by a dual role of the researcher who assumed the leadership of phase 3. This change occurred because during the 1st period collective discussions were very poor or nonexistent. This change was possible due to the established relationship with the four teachers involved as well as with their students. In the second period, which occurred in two consecutive school years, all tasks have been tried with the same students from one of the classes in their

2nd (episode 1) and 3rd years (episode 2) of schooling. These lessons were recorded on video. Subsequently, we identified several relevant episodes of collective discussion as the unit of analysis.

EXAMPLES, COUNTEREXAMPLES, SPATIAL AND GEOMETRIC STRUCTURING

The following two episodes pretend to illustrate the role of examples constructed by students, as well as of counterexamples. They also illustrate various aspects of spatial and geometric structuring present in the tasks and the importance of giving them prominence in geometric figures as the work was going on.

Episode 1 – "Almost equal"

The proposed task consisted of identifying pairs of congruent figures. Two squares raised some controversy. The researcher asked the students if the two last copies were or not congruent (Figure 1). Almost all students said they were equal, although one student said they were not. The researcher asked one student,

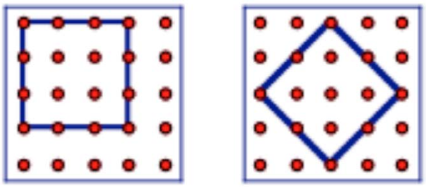

Figure 1: Squares that generated the controversy surrounding the congruence

Beatriz, to show her colleagues why they were equal.

As we expected this could happen, we prepared two acetates with figures and we gave them to Beatriz to experiment, corresponding to the practice of anticipating (Smith & Stein, 2011). She tried to overlap them, at the overhead projector, so they matched. Beatriz said nothing, but went around the acetates to get the match. During this process the other students observed. The researcher asked "who does still think that the two squares are equal?". Several students were saying "they are not equal". However, Beatriz remained stubbornly trying to match them. The researcher asked students to argue:

Ana: One of the squares is larger than the other.

Leonor: We can't put one above the other.

Joel: The number of dots inside the square is different. One square has 4 points and the other 5.

We have three different validations and the last one is more elaborate, denoting a more refined visualization. Leonor and Ana still seem to think based on the figure as a whole, while Joel shows the ability to distinguish the underlying structure to the figure to conclude that the two squares can not be congruent. Should we follow the reasoning of this student and share it? What is the contribution of this reasoning to the geometric structuring? This tension between taking advantage of good individual contributions and deciding the orientation of the collective movement was present in several episodes. It is the basis of significant dilemmas that teachers face during practice classroom (Carter & Richards, 1999; Wood & Turner-Vorbek, 1999) and acting as a filter of students' contributions (Sherin, 2002).

Episode 2 – "The rectangle that is not rectangle"

This second episode occurred later. It takes place in another pathway in which quadrilaterals have been worked as composite figures, highlighting its components and seeking to establish simple relationships between these elements, namely the angles. The pathway consisted of six tasks that allowed four moments of collective discussion. This episode occurred at the end of the second task and the discussion was about the students' work conducted in tasks 1 and 2. The task was to find out as much of squares and rectangles on geoboard. Students' works were exhibited with the solutions they found for squares and rectangles.

In the first part of the discussion the researcher and the teacher tried to interest students on the discussion they intended to create, as the appropriation by the students of social rules of whole-group discussion is a slow process and built over several experiments (Wood & Turner-Vorbeck, 1999). The discussion began with an appeal to respect different opinions, highlighting the value of students' opinions, with attention and care to not repeat what others have said which is very common among small children.

The researcher asked the students if they had any different figure, squares or rectangles. Two students, Inês and Beatriz, raised their fingers. They went to the black board to expose their magnified figures. This preparation of figures occurred during *phase 2*, corresponding to the practice of selecting, according to

Smith and Stein (2011), as we already knew that these figures would be important for the discussion. Those students thought that they had made a rectangle, however, when they showed it to their colleagues these at once identified it as a parallelogram.

Two students in chorus:
It is a parallelogram.

The researcher asked students to remain calm and asked Inês to justify why she thought her figure was a rectangle. The episode evolved with a long dialogue with many voices involving several students trying to show why Inês' parallelogram was not a rectangle.

Hugo: It is so because it has two beaks on one side.

Hugo shows with his fingers and surrounds the parallelogram. He points to two opposite sides and says they were inclined compared to the rectangle he considers not to be inclined. Hugo must reinforce the comparison with another figure, a rectangle in prototypical position "on high", identifying important elements for this decision. Given his difficulty in justifying his reasoning, the researcher decided to ask another student.

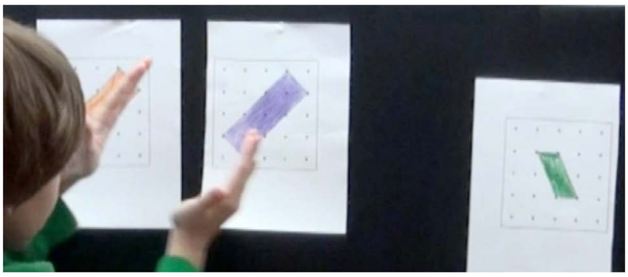

Figure 2: The controversial parallelogram and the rectangle Duarte used to compare

Duarte: It is not a rectangle because it is wry. Instead of being like this, is like this.

Duarte accompanied what he was saying with gestures with his hands (Figure 2). First he made with the hands two parallel segments, ||, then he made two inclined parallel threads, //, and surrounded the parallelogram with his fingers. Moreover, he was able to do with his hands the necessary modification to transform the parallelogram into a rectangle, the angle of two consecutive sides should be a right angle. He compares with another rectangle exposed in a non-prototypical position, that is, "tilted". Although Duarte showed that he had very clear ideas about geometric justifications, he was not able to fully verbalize them.

All this discussion focused on the observation and analysis of quadrilaterals, showed the need to work more aspects of spatial structuring of quadrilaterals and the need to give more attention to spatial structuring, required for geometric structuring of quadrilaterals (Battista, 2008). It also emphasizes the requirement to pay attention to the elements that compose a figure, in this case the angles and sides. It also identified difficulties in verbalizing the reasoning, revealing that in most cases the mental images of students are correct and appropriate to their arguments.

This episode revealed the need to enhance students' language and to provide them with a simple tool of visualization to highlight and compare angles. This object, which we call "right angles' detector", is not more than a corner of an A4 sheet cut so as to be easily manipulated and had already been widely used in previous experiments of these tasks. This episode marked guidance route for the sequence of this didactical pathway, which focused mainly on the spatial structuring. The following tasks were directed to discovering and comparing angles in quadrilaterals. Thus highlights the focus on the right angle as a reference for spatial and geometric structuring, without even resorting to any measurement system to identify acute, obtuse and right angles in plane geometric figures.

Both described episodes, as well as many others experienced, illustrate how students gradually assumed responsibility for discovering examples and counterexamples, incorrect or not complying figures with the established conditions, families of quadrilaterals in hierarchical classification. This was found successful to give students leadership in validation of mathematical knowledge in spatial and geometric structuring tasks.

DISCUSSION

We follow two lines of discussion, the first about geometry and the other on social constructivist aspects of learning.

We consider that the data collected value the potential of the structuring model of Battista (2007, 2008), and help us to better understand spatial and geometric structuring, as well as the relation among them. We emphasize the importance of visualization in spatial structuring of quadrilaterals and the need to find strategies and objects to support visualization, for example, dot papers, colouring the angles, the “right angles detector”. We saw the importance of structuring quadrilaterals as composed by four angles figures, especially the rectangle as a four right angles composite figure, (Battista, 2008), aimed to structure each of the various types of quadrilaterals in hierarchical classification (de Villiers, 1994). We emphasize the need to incorporate several spatial structuring models to obtain personal’s mental models that determines her or his own way of thinking (Battista, 2008).

With regard to the geometrical structure, it seems to give new contributions for the classification of angles embedded in composite figures (quadrilaterals) and for an understanding of the geometric structure of quadrilateral on several levels (isolated figure, as part of a class, class relation). The examples we worked on showed us it is possible to implement meaningful tasks for young children, demanding in terms of geometric structuring (congruence of figures, understanding of a figure as part of a class, the class understanding, organization of quadrilaterals in hierarchical classes) from didactical pathways. Applying these pathways, with special attention to the collective moments of whole-group discussions proved to be a key factor in design tasks and for taking decisions for tasks sequence.

Second part of discussion is about social constructivist aspects of learning. The data collected makes us aware of the challenges associated with a practice focused on student work when you want them to become providers of mathematical knowledge (Wood & Turner-Vorbeck, 1999), and seeks a balance between the mathematical value of the work of each student and ensuring that this work is in the mathematical point of view recognized and accepted (Cobb et al., 1992; Yackel & Cobb, 1996). We are in the process of establishing indicators and frameworks based on videotaped episodes. We are trying to construct a framework on learning environment, roles and responsibilities for learning in whole-group discussions from inquiry tasks (Figure 3).

Comparing columns A and B (Figure 3), we face the relation between teacher and students. Teacher action is more like a double mirror reflecting but also allowing seeing through it. As Wood and Turner-Vorbeck (1999) says this is a matter of ways of structuring social interaction and discourse to create contexts for learners’ personal construction of meaning.

The parallel that may exist between both columns and the approximation of the identified practices, highlight the student’s responsibility in the construction of mathematical knowledge. It seems therefore that this work getting closer forms of mathematical knowledge for each individual student, shared mathematical practices of the community classroom and shared mathematical practices of wider society (Cobb et al., 1992).

The lived episodes help us to understand the requirement of the teacher role at moments of whole group discussions. This requirement is expressed in simultaneous attention needed to give individual student’s contributions and the collective movement that teacher has to provide so the whole class advances, ensuring that the ideas and processes at play are widely accepted as having mathematical value and are necessary for future school mathematics learn-

Figure 3: Framework for whole-group discussions from inquiry tasks (in construction)

ing. It also illustrates the critical importance of collective moments to construct a challenging learning environment for students, giving them autonomy and authority in the validation of ideas and mathematical knowledge, their own and those of colleagues. Regarding the teacher's role the indicators of orchestration practices are relevant (Smith & Stein, 2011), questions with potential (Boaler & Brodie, 2004) and dilemmas (Carter & Richards, 1999; Wood & Turner-Vorbeck, 1999).

As a final idea for this discussion, we return to the initial purpose of this research to recall the importance this experience has taken to help design and evaluate teaching pathways in geometry, showing as one of the critical aspects of these pathways the links that can be established between the tasks that integrate them.

Combining epistemological and cognitive approaches of geometry with cK¢

Joris Mithalal-Le Doze

Université Paris 4, ESPE de Paris, Laboratoire de Didactique André Revuz, Paris, France, joris.mithalal@espe-paris.fr

In this article, we study the issues in making students use deductive geometry, both from epistemological and cognitive points of view. We show that working on geometrical objects needs at the same time working on diagrams in a specific way (instrumental and dimensional deconstruction), and that this can be trained by specific tasks. In this process, instrumental work is a crucial point of the work and, using the cK¢ model, we characterize two instrumental deconstruction that are involved in this evolution of the geometrical work.

Keywords: Dynamic 3D geometry, visualization, geometrical paradigm, dimensional deconstruction, cK¢ model.

INTRODUCTION

The issue of pupils using diagrams in order to solve deductive geometry problems is well known and has been studied a lot in this working group: they can *read* results so that mathematical proof is useless to them. We presented (Mithalal, 2009) preliminary results about didactical situations, based on Cabri 3D (a 3D Dynamic Geometry Environment), that aimed at making students use natural axiomatic geometry (Houdement & Kuzkiak, 2006). We shown (Mithalal, 2009, 2010) that such conditions leaded them to work on geometrical objects, and not only on diagrams. At first sight, making them use deductive reasoning could be considered as the major part of this evolution. In this article we will show that, in fact, instrumental activity should be considered as a pivot point that makes the whole process possible. We use Duval's (2005) framework, and show that instrumental deconstruction is the link between iconic and non-iconic visualization. We use the cK¢ model (Balacheff & Margolinas, 2003) to combine an epistemological and a cognitive understanding of geometrical activity into an operational tool for its precise analysis. We show that two instrumental deconstructions are to be distinguished. On the one hand, there are only small differences between them, but on the other hand moving from the first to the second one is fundamental in this process. At the end, deductive geometry turns to be meaningful because of new conceptions about construction tasks.

USING DIAGRAMS FOR DEDUCTIVE GEOMETRY

Epistemological and cognitive points of view

Using diagrams is very ambiguous for pupils when learning deductive geometry: they are used to reading results on it, but suddenly this turns to be forbidden. Now, they have to use diagrams for heuristic work but not for proving, which is very confusing as they *see* what will take much time to be proved. Nevertheless, many authors, such as Parzysz (1988), Chaachoua (1997) or Jahnke (2007), have shown that that geometry involves a mix of practical activities and axiomatic reasoning, and that "inventing hypothesis and testing their consequences is more productive for the understanding of the epistemological proof than forming elaborate chain of deduction" (Jahnke, 2007, p. 79). Working with diagrams is, then, fundamental.

Laborde and Capponi (1994) made a distinction between drawings and figures: a drawing is a graphical object (hand-drawn shape, diagram, digital representation, manipulative....), while a figure is the matching between an ideal object and a set of drawings that represent it correctly. This emphasizes that a drawing can be considered for itself or as a representation of something, and extends Fischbein's (1993) theory of figural concepts. Considering that our question is now "*how could we make pupils work on figures instead of drawings?*", two kind of issues must be take into account: epistemological and cognitive ones. We already gave a few words about epistemological issues, and we will use the well known framework of geometrical paradigms (Houdement & Kuzniak, 2003, 2006) to express it: pupils have to move from natural geometry (GI) to natural axiomatic geometry (GII) which is about figures.

Cognitive point of view

A cognitive point of view is essential, as it explains why using drawings is unavoidable, and why this is so hard to perform. Chaachoua (1997, pp. 32–42) showed that drawings play fundamental roles in the geometrical activity – which not only includes the resolution process –, both for teachers and learners. In order for the resolution to be correctly performed, drawings must satisfy three conditions: (i) they have to display geometrical properties the text doesn't necessarily mention (ii) they may carry out an illustration function, to illustrate either the problem's statements, the resolution steps or the final solution (iii) they may carry out an experimentation function, so that the "geometer" can work on the drawing, which leads to perceive new sub-figures or relations, to make or evaluate conjectures, etc. Therefore, to be able to work with drawings is fundamental, and teaching geometry without using drawings would be a nonsense.

However, Duval (2005) showed that this operations are very hard to perform, because of visualization issues. He explains that there are two ways in which one sees a drawing: the iconic and the non-iconic visualization. **Iconic Visualization** (I.V.) means that the recognition of an object is due to the similarity of its shape with an already known object: if something looks like a square, it is one of those. A well-known consequence is the obstacle of typical configurations, which leads some pupils to identify a square as a rhombus, but not a square, because its position is the typical position of a rhombus (Figure 1). Another consequence is that you cannot modify or analyse the drawings: adding lines changes the shape, and then the nature of the objects decomposing the object into lines is impossible as nothing but the global shape is perceived. This second consequence, more subtle, is fundamental for deductive geometry which involves experimental work and analytic study of the drawings.

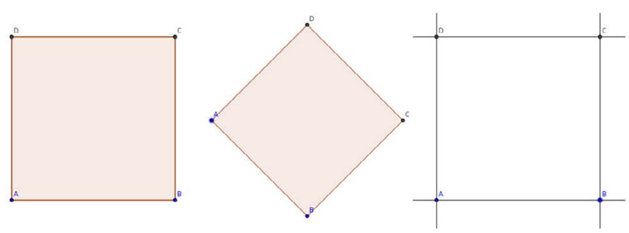

Figure 1: A square, a rhombus and "something from a square" (Iconic visualization)

With **Non-Iconic Visualization** (NI.V.), one considers that a drawing is nothing but one of the representations of a geometrical object, and there is no contradiction between modifying the drawing and considering that it remains a representation of the same object. Moreover, the general shape is no longer a fundamental characteristic of the drawing, which results of assembling lower dimension components, the *figural units* (such as points, lines, segments, circles, etc.) Then, visualization is based on three operations: mereological deconstruction, instrumental deconstruction (one answer to the following question "*How is it possible to construct this drawing with a given set of tools?*") and dimensional deconstruction (a discursive process in which a figure is seen as a set of figural units linked by geometrical properties, which leads to the geometrical object). Mathematical proof becomes meaningful to the pupils when they use non-iconic visualization and dimensional deconstruction. Nevertheless, Duval (2005, pp. 45–48) claimed that going from iconic to non-iconic visualization is neither easy nor natural. We showed (Mithalal, 2009, 2010) with space geometry, iconic visualization is no longer efficient. Construction tasks with 3D DGEs make 10th grade students use dimensional deconstruction. In this article, we assume this evolution is not a *revolution*, and we will study how continuous this process is. More precisely, we will show that instrumental deconstruction can be related both to iconic and non-iconic visualization, depending of tiny differences, and helps the pupils' activity evolution.

GOING FROM ICONIC VISUALIZATION TO DIMENSIONAL DECONSTRUCTION: AN EXPERIMENTAL STUDY

The following case study aims at describing such a continuum and the role of instrumental deconstruction. We will use the results of an experiment more precisely exposed in Mithalal (2010), that consists of a knowledge diagnosis simple construction task.

Let $ABCDEHGF_1F_2F_3$ be a truncated cube (Figure 2), the pupils had to find as many ways as possible to construct the missing vertex, and to verify that the cube was still a cube when dragging point A to modify its size: the construction procedure had to be based,

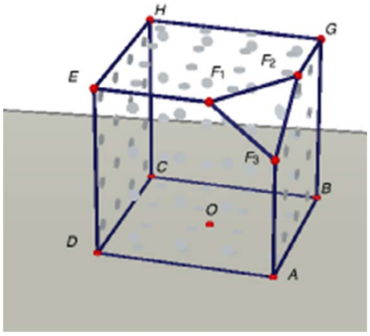

Figure 2: The truncated cube pupils had to complete

explicitly or implicitly, on geometrical properties so that the result was robust (Healy, 1994). They were asked to describe each method in a few words.

Interpreting the question with the various points of view we mentioned led to distinct aims and methods. For instance, with an "iconic" interpretation, the aim was to construct the missing part of the shape without considering geometrical properties, whereas a "non-iconic" interpretation should lead to use the cube properties (such as symmetry) to construct nothing but F. We identified (Mithalal, 2010) four distinct interpretations corresponding to specific resolution strategies: (1) to draw the missing part so that the result looks like a cube (iconic) (2) to draw the missing part so that the result looks like a cube and with the same length as the original (iconic) (3) to draw a point using a construction procedure that fits with a cube (instrumental deconstruction) (4) to construct a point linked to the truncated cube with its geometrical properties (dimensional deconstruction)

Instrumental deconstruction: Connected both to I.V. and to NI.V.

We propose now to illustrate the evolutions of two groups' geometrical work, representative of usual evolutions: on the one hand Pierre and Ludovic, moving from iconic visualization to instrumental deconstruction, on the other hand Paul, Julie and Marie, whose interpretation of the task went from instrumental (3rd strategy) to dimensional deconstruction (4th strategy). Pierre and Ludovic's aim was to construct the shape: "Why do you absolutely want to use 'triangle'?" – "Because it *is* a triangle!" (5'43) They spent about 25 minutes trying to put a point at the right place, but this is almost impossible. They concluded so after multiple trials and viewpoint changes, and decided that they needed new methods:

16'06 Ludovic: Anyway, we can't see anything.

21'57 Pierre: It looked good, but when we move it, it looks like nothing...

26'22 Pierre: We have to find another solution.

Their aim still was that "it looks good", but they realised that the means for it had to be improved. Then, they tried various methods, including intersecting the three truncated edges (two would have been enough), constructing parallels, or trying to use vectors (they failed): they started using instrumental deconstruction. Very often, pupils interpreted robustness properties as mechanical ones, but did not connect it to geometrical properties. This is why Duval (2005) considered there was no link between the two deconstructions. However Cabri 3D's mechanical tools are based on geometry, so even "mechanical" problems make dimensional deconstruction very useful for anticipating the strategies and their validities, and for convincing each other. This happened with Marie, Paul and Julie. They first decided that "reconstructing the cube" was not sufficient and that they had to fill it in: it was a shape problem, and they used similar methods to the former group.

13'19 Paul: Maybe we should try with a point, just a point here, at the right place.

13'24 Marie: But in this case you leave it to chance!

13'27 Paul: No! I mean, yes! Well, you make it...

Their problem was to be sure that the construction was good, and they eventually decided that it was "approximatively good", which was enough for them. This is why they decided to use more sophisticated methods based on dimensional deconstructions of a cube, such as edges intersections or symmetry, but during half an hour the correctness was determined by the shape (iconic) and the robustness (instrumental). But the fact that a new method was *really new* turned to be a dimensional deconstruction problem. They previously constructed F by intersecting 3 edges (Figure 3, left). Then, they tried another solution, constructing the symetrical of the truncated cube, and using it to draw lines (Figure 3, 2nd & 3rd pictures).

25'46 Julie: Look, you construct the same next to it. You'll see, the shape will do schlack, schlack, you see it will be a rhombus. Then, you use from this one to that one. To its symmetrical. Then, you only have to do this... Then you create the line, and you're done.

31'50 Marie: Wait, wait, because I just thought about it: the [second] cube is absolutely useless...

32'14 Paul: Yes, in fact you just did the same!

32'15 Marie: Exactly. That's it, you just added a cube on the two sides.

The result was visually very different, and so was the construction process, but they used the same lines: this statement made them decide this was not a new method, no matter they constructed it differently, because they used *the same dimensional deconstruction of the cube*. This shows how the two deconstructions can be strongly linked: the dimensional one is a good way for designing instrumental deconstruction and for controlling its validity, and reciprocally the instrumental problems make dimensional deconstruction (and deductive geometry) play a greater and greater role.

The fundamental role of Instrumental Deconstruction

The example we mentioned here show the two main reasons for the pupils to move from iconic to non-iconic visualization. First, they needed to act more easily and to make vision more efficient. Then, they needed to better control and anticipate their actions, so that dimensional deconstruction was required to control instrumental processes. This points out that, in fact there are two kinds of instrumental deconstruction. The first one (we call it I.D.$_{iv}$) is linked to iconic visualization problems, and a second one (I.D.$_{niv}$) is a way for dimensional deconstruction to be operative. More than these two processes, moving from I.D.$_{iv}$ to I.D.$_{niv}$ is fundamental because it strongly modifies the way problems are interpreted, becoming more theoretical, which makes deductive geometry meaningful. Our aim is now to confirm this statement. External signs of these two instrumental deconstructions are usually very similar, which make it hard to analyse. Same processes might be used with different purposes, and a similar aim may generate different strategies, depending on the pupil's knowledge, cognitive abilities, and interpretation. To get a more precise description of the deconstructions, we used the cK¢ model that perfectly fits the duality between acting and controlling the actions.

ANALYSING INSTRUMENTAL DECONSTRUCTION WITH CK¢

The cK¢ model

cK¢ is a knowledge model (Balacheff, 2011), linked to the Theory of Conceptual Fields (Vergnaud, 1990) and to the Theory of Didactical Situations (Brousseau, 1997). Mathematical knowledge is characterized by the problem it solves. It is both determined by a subject and the milieu that generates the problem, so this is a [subject<>milieu] system balance, with an action/feedback loop: the subject acts, and the feedback from the milieu has to be good. This is very local, deeply linked to a specific context, and Balacheff (2011) calls it *conception*. Then, *knowledge* is a set of one subject's conceptions, and concept is a more general set of "knowledges". The social, more general, textual construct is called *savoir*.

Conceptions are what pupils work with during problem solving, and the cK¢ model describes it as a collection of 4 sets. **P** is a set of problems (p_i). A problem is basically a disturbance of the system balance, and the conception may solve these problems. **R** is a set of operators (r_i), that turn a problem into another problem belonging to P. It causes action, and this is the most directly visible part of the conception. **L** is a representation system for P and R expression. Σ is a control structure that ensures the conception is coherent and judges whether an operator has to be used

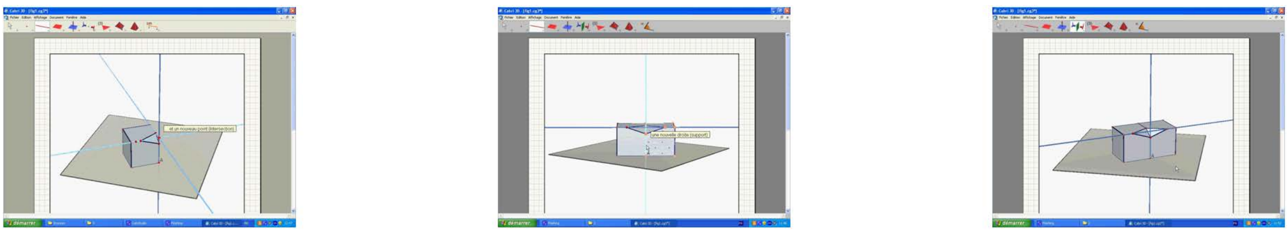

Figure 3: Construction with three lines or with the symmetrical of the cube

or not, whether a problem is solved or not... Σ is a set of controls (σ_i). As we can see, this is a very formal description, and it is essential to be conscious that it does not give any theoretical explanation for what happens, but it methodologically helps describing observations in a way that is supposed to be precise enough. In our case, L is always the same – drawings, oral language – and the possibilities of initial problems of a conception are well identified. The main evolution during the experiment is about R, Σ, and the relation between it.

Some nuances in very similar examples

Let us go back to the former examples. Pierre and Ludovic, Marie, Paul and Julie, used exactly the same construction process: construct the lines from the truncated edges, make the intersection, fill in the cube so that "it looks like a cube". From a mathematical point of view, the third line was useless, so that we consider that all of them tried to draw the original shape. Pierre and Ludovic "[had] to find another solution" (26'22) and reproduced what another group was doing (*We'll do the same as they do!*, 27'25), but the shape was so important that they also constructed the three "missing" triangles. Marie, Paul and Julie tried this strategy at the beginning:

3'11 Paul: (Marie created a line on a truncated edge.) Tell me what you're doing!

3'20 Marie: You perfectly see what I'm doing.

3'22 Paul: Yes, you put a line, but explain us what you want to do.

3'28 Paul: (Marie: created the two other lines.) Ok, and then?

3'30 Marie: And then, you think I'm stupid! Don't you see the cube is done?

Marie knew what she was doing and that the solution was right, because she used the properties of the cube to control, a priori, the construction process. This helps understand why she didn't need visual control to validate the construction, and at the end little differences are very meaningful.

In other words, the two procedures and the results were very similar, but our interpretations of it are different: Marie, Paul & Julie considered that all was about the shape, but they could use geometrical knowledge to control their actions. Pierre & Ludovic failed when geometrical controls were unavoidable. The great difference was about controlling, which leads to the following conclusion: the first group used a I.D._{iv} interpretation, whereas the second one interpreted the task with I.D._{niv}, so that geometrical knowledge and mechanical properties were connected.

Operators and controls

Analysing these examples, we didn't fully describe the students' conceptions. Would it be possible, this paper is too small. We used cK¢ to point out the main aspects of their conceptions, but this is more accurate when studying operators and controls.

An operator is an association between a purpose (I want to do this) and a mean for it ([aim ⇒ action]). For instance, an operator could be "I want to construct a parallel to (d), so I have to use the "parallel tool" of Cabri 3D to select (d) and a point". Nor the aim, neither the action, reflect the kind of geometry used, the interpretation has to be based on their association (⇒). Let us consider another frequently used operator, "I want to construct a parallel to (d), so I have to use the line tool, select two points to create a line (d'), and move one of the points so that (d) and (d') are parallel". The purpose is the same, but the action shows that neither robustness nor geometrical properties are taken into account, and that "are parallel" mean something very perceptual, so that this operator is associated more to iconic than to non-iconic visualization. A control isn't directly linked to an action, it is a judgment on it, and then it is a [Statement1 ⇒ Statement2] system. The first one is a fact, the second one is a conclusion, and here again the association (⇒) mean something about the kind of geometry used.

	Pierre and Ludovic	Marie, Paul and Julie
Interpretation, final control	Shape (iconical)	
Operators	Three lines, 3 triangles	Three lines
Control of actions	Visual-instrumental	geometrical

Table 1: Two interpretations of the problems

One of the greatest issues with defining operators and controls is the not so clear frontier between them. Balacheff (2003) mention that, for instance, "the symmetrical of a segment is another segment" could be either an operator — that indicates how to draw it — or a control — to judge the correctness of a construction. Our formal description helps understanding this: a single property may be linked to an operator or a control, because it mainly justifies the (⇒) link in both cases, but it is a tool in one case — linked to an action — and a fact, an object, in the other one. Operators are easier to catch, and also give information about their visualization. For instance, constructing three lines was useless, so this combination of operators (we call it procedure) indicated an iconic interpretation of the problem.

The two main ways to catch controls are dialog analysis and inferences from the observed procedures: an observation is associated to a procedure, linked to a set of controls and a type of conception. It is all the more important that the differences we shown between the two former instrumental deconstructions were mainly based on some specific controls, and on their role, but not on operators. Indeed, controlling the final validity with some dimensional deconstruction-based control mean something very different than using this deconstruction only as a tool to control the action. This is why we need to take into account the moment when the controls are used.

1. Before acting, controls determine the interpretation of the problems, a set of possibly adequate operators, i.e. a selection function (Vadcard, 2000), and a priori reasons for the validity of a strategy.
2. During the action, controls ensure that operators are adequate and help interpreting the feedback.
3. After acting, controls provide a posteriori judgment about the validity of a solution.

(2) is close to a "tool" role for using operators, and then for the kind of geometry they are based on. (1) and (3) are more about how geometry problems are interpreted and about the pupils' knowledge. Of course, using deductive geometry requires that (1) and (3) mainly involve controls based on dimensional deconstruction, but identifying (2) controls is very important. It gives information about the coherence of the conception, about knowledge that are used only for practical reasons, and most of all about the evolution mechanism of the conception.

Characterization of two instrumental deconstructions

With this description, it is now possible to make the difference more clear. The two instrumental deconstructions both consist in considering the objects as the result of a construction process that involves figural units and some specifications about "how it works". But the kind of objects involved, their properties, the tools pupils use and the controls that are needed, can be different. Of course, these are prototypes.

Pierre and Ludovic gave us a very good example of I.D.$_{iv}$ we already analysed. Leelah and Catherine's deconstruction was very different. At the very beginning they tried approximate shape constructions, but they gave up immediately and repeated many times that the shape didn't matter (6'06, Catherine:

	Instrumental deconstruction.$_{iv}$	Instrumental deconstruction.$_{ni.v}$
Properties	Shape, mechanical	Geometrical
control (time 1 and 3)	about shape or mechanical properties	about mechanical or geometrical properties
control (time 2)	visual; knowledge about the tools of Cabri 3D; prototypes of procedures	geometrical properties, knowledge about the tools of Cabri 3D
operators	geometrical properties, knowledge about the tools	no need for visual control

Figure 4: The two instrumental deconstructions

Yes, but no, the point can be anywhere.; 17'44, C.: But you don't need to create the tetrahedrons to get the points, the intersection of the [planes] already made it.; 32'44, C.: No, but the aim is not the numerical stuff, for us...). Contrary to the other groups we mentioned, they anticipated and validated every strategy before the action:

6'06 Leelah: I'd like to put a plane like this, a plane like this, a plane like this. [...] By extending the truncated sides...

22'51 Catherine: Later I thought of a much easier solution! Symmetry with respect to this point: hop, done!

Then, a priori controls based on dimensional deconstruction and deductive geometry allowed these pupils to validate a strategy before action, and to design precisely their procedure by transforming the geometrical information into an operational process. One great consequence is that visual control is no longer required, as Catherine expressed it very clearly: "Middle of this segment... We can't see it, but it's done! " (21'59) Eventually, we can describe the differences this way:

CONCLUSION

Many studies about teaching geometry underline how difficult it is to make pupils use axiomatic geometry and proof, and consider that there is no continuity of the cognitive process (Duval, 2005). We showed here that in particular cases, such as construction tasks with 3D DGEs, a continuous evolution is possible. This is linked to a more general statement: there are in fact two instrumental deconstructions, which are at the same time very different cognitive process, but very close ways of acting. Eventually, characterising the differences needs a very precise tool combining epistemological and cognitive points of view, which was provided by cK¢. We only could underline the similarities between I.D.$_{iv}$ and I.D.$_{niv}$, and the evolution process between it remains to be studied.

Working with visually impaired students: Strategies developed in the transition from 2D geometrical objects to 3D geometrical objects

Chrysi Papadaki

University of Bremen, Bremen, Germany, chrysi@uni-bremen.de

In this paper, I will present some of the results of research that was carried out, during my master studies, that aimed to examine the strategies that visually impaired students develop while coping with the transition from 2-dimensional (2D) to 3-dimensional (3D) geometrical objects, and also their correlation with the concepts of visualization, haptic perception, gestures and language. A teaching experiment took place in a support unit for visually impaired students. The results showed that the students develop geometrical thinking procedures that are influenced by the concepts of visualization, haptic perception, gestures and language.

Keywords: Geometry, visualization, haptic perception, visual impairment.

INTRODUCTION

The subject of geometry has always been and continues to be a "headache" for most students. For many years researchers in didactics of mathematics, have studied the levels of students' geometrical thinking (Van Hiele, 1986; Gutierrez, Jaime, & Fortuny, 1991), as well as the processes that students follow in geometry (Battista, 2007; Duval, 2011). But if geometry is one of the most demanding subjects for the "mainstream" students, what happens in the case of students with visual impairments? How does a student who doesn't have the luxury of vision, cope with the demands of geometry, which besides mathematical abilities also includes visualization and spatial abilities?

Such questions and concerns led us to address these issues and conduct research in order to observe how visually impaired students interact with the objects of geometry and what strategies they develop while solving geometrical problems that connect 2D with 3D geometry. The basic concepts I will use to examine the strategies developed by students are: visualization, gestures and language that students use in order to describe geometrical objects and also haptic perception. Through these concepts, I will observe the processes of reasoning developed by students during their transition from 2D to 3D geometry, in the context of two tasks.

THEORETICAL FRAMEWORK

Important theories on the evolution of geometrical thinking

Many researchers have studied students' geometrical thinking and here I will present some significant theories of the evolution of geometrical reasoning, as well as some other concepts that relate to it, such as similes. In the field of didactics of mathematics and especially as far as geometry is concerned, much research has been done regarding the levels of students' geometrical thinking. The Dutch mathematician Van Hiele proposed a widely accepted description of the development of students' geometrical thinking (Van Hiele, 1986) through five levels, which show the way students think about figures and other geometrical concepts. Gutierrez, Jaime & Fortuny (1991), extended the Van Hiele levels for the case of three-dimensional shapes. They describe four stages concerning students' thinking levels regarding the geometry of solid objects and their properties. Gutierrez (1992) extended these levels, examining them also from the perspective of visualization.

An important contribution to research concerning students' geometrical thinking is the research work of Duval. Duval (2011) argues that when observing a figure from a mathematical perspective, we should determine its figural units, depending on its dimen-

		Figural Units (Components)	
Shape	Cube (3D shape)	0D/3D	Vertices (zero-dimensional components)
		1D/3D	Edges (one-dimensional components)
		2D/3D	Faces (two-dimensional components)
		3D/3D	Cube (three-dimensional object)
	Square (2D shape)	0D/2D	Vertices (zero-dimensional components)
		1D/2D	Edges (one-dimensional components)
		2D/2D	Square (two-dimensional object)

Table 1: Figular units of cube and square

sions, i.e. its different dimensional components (see examples in Table 1). This procedure can help us see the same shape as a composition of different figural units. In this way we choose the composition that is useful for solving a specific problem.

Similes, haptic perception, gestures and geometry

Visually impaired students often use, phrases like: "I see it" or "I do not see that yet". These phrases are usually verbal expressions of their haptic experience. Another phenomenon in language is the great influence of everyday life on visually impaired students' vocabulary. It is many times that influence that makes it difficult for these students to describe their thoughts in the formal terms of geometry. The results of Potari, Diakogiorgi & Zanni (2003), showed that similes are an important tool for students' access to geometrical concepts, which were inaccessible only with the use of formal terminology.

According to Figueiras and Arcavi (2012), haptic perception provides us with access to spatial details that would not be easy to observe in another way. This is due to the fact that haptic exploration combines the process of visualizing an object and "action", since it actually is the translation of a haptic stimulus to a mental representation, without the existence of a visual stimulus. According to Triantafillidis (1995), when exploring an object by touch, a series of steps is required in order to identify its shape. As a first step, the key characteristics of the shape are identified, though without following any particular strategy. Then a more detailed exploration of the shape begins, which is this time based on some strategies that will reveal in greater detail its characteristics and properties. For students with visual impairments, haptic exploration of shapes or figures plays for them the role of vision. It is the way through which they can "see" the shapes. According to Williams (1983) and Millar (1981), blind students explore an object in such a way that provides them a comprehensive view of it, thus leading them to a more accurate mental representation of its figure. According to Triantafillidis (1995), there is a correlation between the strategies a student chooses to use and the level of his/her geometrical thinking (Van Hiele levels). As a consequence, vision is not the only source of mental images in mathematics. To "feel" some physical objects with our hands, without seeing them with our own eyes, is also a source of a rich production of mental images.

Our hands though, are not a tool useful only for our ability to perceive haptic stimuli. They can also be used as mediations of our thoughts, through the gestures they perform while we argue or think. McNeill (1992) categorizes gestures in Iconic, Metaphoric, Deictic and Beat gestures, depending on the role they had in the talk of the speaker. Radford (2009) argues that thinking is not something that occurs only in the mind, but also through language, body and the tools one has at his disposal. He argues that gestures are operative components of thought. This means that gestures do not only make apparent to us what someone thinks, but they are in fact the ones to generate ideas, the ones that incite thinking.

Visualization and geometry

Gutierrez (1996) describes visualization in mathematics, as the kind of reasoning activity based on the use of visual or spatial elements, mental or physical, in order to solve a problem or prove properties. But what happens in the case of students with visual impairments? If someone cannot see, how can (s)he visualize? Just because someone is blind, it does not mean that (s)he cannot "see". Miller (1987) argues that mathematical visualization also involves intuition through pictures formed in the eyes of the mind. As described by Jackson (2002), visualization may go far beyond the sense of vision, because it implies the kind of understanding that comes from the intuition described by Miller. However, in order to achieve this kind of understanding, we should not isolate visualization from a general mathematical context, but instead connect it with other kinds of reasoning.

Lohman (1988) correlates directly the concept of visualization to that of spatial ability, defining the concept of spatial visualization, which refers to the ability to comprehend imaginary movements in a three dimensional space or the ability to manipulate objects in imagination. According to Kospentaris and colleagues (2011), a student's visualization process can influence the strategies (s)he chooses in order to cope with a geometrical task, as also the way in which (s)he implements these strategies. It is therefore apparent that there is a strong correlation between visualization and the formation of geometrical thinking.

RESEARCH QUESTIONS – METHODOLOGY

My research questions in the study were the following:

1) What kind of strategies and procedures do the students follow during the transition from the 2D to 3D geometry?

2) What is the contribution of gestures, the use of similes, and visualization in the selection and implementation of these procedures?

Participants. The research took place in a support unit for students with visual impairments. Five students participated in the study. The students were chosen according to their age, visual ability and their mental ability (visually impaired students with mental disabilities did not take part in this research as its focus was on students with only visual impairments). The reason why we wanted to have students of different ages and grades is that at different ages, students have gathered different experiences from their everyday lives and different levels of geometry knowledge from school. The research was conducted within the frame of interviews. There was no classroom situation. During the interviews the researcher was alone with one or two of the participants at a time. Students M and A worked together (group 1) as also students D and T (group 2), while student B worked alone.

Tasks. For the purpose of the study, four tasks were given to the students. Here I will present and analyze the results of only two of these tasks.

Procedure – Aim of Task 1 (Plane figure Rotation). The students were asked to think about what kind of solids will be created by the rotation of a plane figure (Rectangle, Right triangle, Disk), around a vertical axis of their choice. They used 2D objects (plastic plane figures) which they could rotate and manipulate freely. The objects were neither attached nor fixed on the desk or anywhere else. The students did not use any 3D objects. The procedure of the task was that the students touch the plane figures, create a rotation, imagine the solid being "created" and finally identify it. Students' prior knowledge regarding rotation was related mainly to what they knew about the earth's rotation around its axis.

Procedure – Aim of Task 2 (Nets of Solids). The students were asked to identify a solids' nets that were given to them. They started with the net of a cube and I asked of them to construct as many different nets as they could, which when folded would create a cube. Later they also did the same for more solids (Triangular pyramid, Square pyramid). My aim was, through the nets of the solids, to see how students handle the properties of the above mentioned solids, as also if they could identify a solid by its net and the properties its net "reveals" at the levels 0D/3D, 1D/3D and 2D/3D.

The nets were consisted of hard plastic parts (squares and triangles) which were detachable. The connec-

VISUAL IMPAIRMENT	Low vision	Congenitally blind	Low vision	Congenitally blind	Congenitally blind

Table 2: Participants' profile

tions between the parts of the nets were flexible and could be folded in order to create the 3D objects. In a discussion with the students, which took place before the beginning of the teaching experiment I asked them some questions regarding their theoretical background in geometry. I learned that they all had knowledge of the basic plane figures and solids and their properties, from the school course of geometry. My goal was to "challenge" the students to identify the solids during their creation, either through the rotation of plane figures or by their nets.

The first step of the analysis was the transcription of the recordings of the interviews. At first, the recordings of the interviews' discussions were transcribed. Then some critical events in each group were identified and analyzed based on the concepts explicated in the theoretical framework of this study. The critical events were classified as such based on the following criteria: (a) haptic exploration of the figures and students' haptic perception about figures, (b) students' geometrical thinking and spatial perception regarding the task they performed, the figures these included and their properties, (c) the way in which students seem to visualize the plane figures and the solid objects and their properties through haptic exploration and geometrical thinking, (d) the students' gestures while trying to explain what they were thinking/doing or in their attempt to argue about their answers, (e) the students' reasoning processes in order to accomplish the transition from 2D to 3D geometry.

RESULTS

Task 1 – Plane figure rotation

During the rotation task, some students (A, M, D and T) chose to rotate the figure for a while and then stop, making the rotation a picture in their minds. Student B chose to rotate the figure nonstop, in order to identify the solid that was being created. The common factor in all cases was the haptic exploration of the invisible solid that was being created. All the students touched the plane figure during its rotation, as well as the trace that was imaginably left of it on the desk, forming the basis of the solid. All of the students recognized the solids created, moving from a part to the whole of the solid, that is starting from the bottom and then moving to other parts of the solid. The different ways of rotation (temporary or nonstop), and hence visualization and spatial perception of the plane figure's movement, combined with the haptic exploration of the formed solid, led students in different strategies of spatial visualization of the solid created (Table 3). All the visualization processes and the strategies were identified based on students' verbal and gestural descriptions. During the identification procedure the students were always asked by the researcher to describe loudly their thinking processes and also the

ROTATED PLANE FIGURE	ROTATION AXIS	SOLID	STRATEGIES
Rectangle	One of longer edges of the rectangle	Cylinder	– Identification of the base of the solid. Then identification of the whole solid by its net. (students A and M) – Infinite number of identical rectangles in circular array (one behind the other), with common edge the rotation axis. (student B) – Two horizontal disks, joined together by infinite vertical lines or two horizontal disks with height difference. (student D)
Right Triangle	The longer perpendicular edge of the triangle	Cone	– Infinite number of identical right triangles in circular array, with common edge the rotation axis. (student B) – A "cylinder" that narrows gradually towards the top. Instead of a base, the top of the solid is formed to a vertex. (students A, M, D and T)
Disk	One of the diameters of the disk	Sphere	– Infinite number of identical vertical semicircles in circular array, with common part the vertical diameter. (student B) – Infinite number of horizontal circles of different diameters, one above the other. The circle with the largest diameter is in the "middle", whereas moving above and below it the circles have gradually reduced diameters. (students A and M)

Table 3: Strategies of visualization process of solids

ways in which the images of the 3D objects were created in their minds.

Through these strategies we can distinguish the different ways in which students apprehend and conceptually manipulate the plane figures and solids. For instance, the strategy in which students visualize a solid as a composition/array of infinite number of identical plane figures is perhaps a result of their choice never to stop rotating the figure until they identify the solid that is being generated.

The students argued about the way of rotation and the figures they felt being created during the rotation, based on the properties of both the rotating plane figure and the created solid. For example, student B's decision regarding the rotation axis of the disk was based on his knowledge of the infinite number of its diameters. In the case of the cone, the students justified its creation by the rotation of a right triangle because of the existence of the hypotenuse, which "forces the solid to have a pointed top instead of a face top". By the end of the interview, all the students had successfully identified all the created solids.

While thinking or arguing, students used gestures and similes. The similes concerned familiar objects from their everyday lives, which had the same shape as the geometrical solids investigated. The cone was described as a funnel or the orange cone used in football workouts, the cylinder as a milk can and the sphere as a ball, the earth or a "round" egg. Student B and the students D and T (group 2) described the solids' shape in their own words. The use of gestures was particularly strong in describing the rotation of the plane figure and the creation of the solid. Students used gestures sometimes in order to describe what they said (iconic gestures, McNeill, 1992) and other times to highlight some specific features of the figures, like a vertex or an edge (deictic gestures, McNeill, 1992).

Task 2 – Nets of solids

In this task the procedure of visualization was based to a great degree on students' haptic perception. They touched and explored the units of a net and identified their shape and through tactile contact they created visual images in their minds, which allowed them to imagine the solid that would be created by the folding of the net. Also here students used a lot of gestures. While thinking and visualizing the folding of the nets, their thoughts were followed by iconic and beat gestures (ibid.) described the ways in which they were imagining the folding of the net. These gestures helped them get a better understanding of the final shape of the created solid. The students started identifying haptically the figural units of the nets (faces). The basic strategies the students followed to identify the solids, while manipulating their nets, were:

1) <u>Identification based on the properties of the figural units of the solid</u>

At first the students identified the solids based on their figural units, without following the process of the imaginary or real folding of the nets. Thus, the presence of six squares indicated the existence of a cube, while the presence of triangles in the net indicated the creation of a pyramid. For example, in the case of the nets of the pyramids, student D said something very enlightening about her working process: "The pyramids are the only solids having triangles in their nets". This statement emphasizes the importance of knowing the properties of a geometrical shape, which can help a student create connections between geometries of different dimensions, evolving his/her geometrical thinking not only on the level of just 2D or just 3D geometry, but most importantly between them.

2) <u>Identification by the imaginary folding of the net</u>

In this case the students started identifying the figural units of a net, but still that was not the "guide" in finding the solid that corresponded to the net. In order to identify the solid they started to fold the net mentally. At this point one can recognize the important contribution of the process of spatial visualization in geometry and the decisive nature of a student's ability to visualize geometrical shapes dynamically. Students managed to create, in their minds, dynamic images of the net, which they could manipulate and fold mentally thus resulting in the identification of the solid being formed. This is a complex process that requires the student to be familiar with the properties of the shapes and their manipulation, even in the absence of visual contact with the object. In our case, only student B managed to manipulate mentally and in a dynamic way the object that was given to him. After the identification of the net that was given to group 1 of students A and M (cube), I asked them if a change in the net would result again to the creation of a cube. Student M explained that not all nets with six squares result to the creation of a cube, but only those that do not "leave gaps" somewhere in the solid when being folded.

These two strategies may differ. However, both of them are of great importance since each one shows a different aspect of the transition from 2D to 3D geometry, indicating that not all students perceive the geometrical shapes in the same way.

CONCLUSIONS – DISCUSSION

Through the strategies they followed, the students were able to successfully perform transitions from 2D to 3D geometry. The strategies were formed as a combination of both students' everyday-life experiences with objects, both plane figures and solid shapes, and their knowledge regarding the geometrical properties of plane figures and solids from the school subject of geometry. Their tactile experiences of plane figures and solids both from everyday life and school also made a very important contribution to students' visualization processes and reasoning in the transition from 2D to 3D geometrical objects.

The students identified the geometrical solids created, starting from a part and moving to the whole of the solid. This way the students managed to gradually build an image of the object, which was the result of a synthesis of all its individual parts. This procedure was not limited only to the synthesis of an image of a plane figure or a solid, but also continued to the composition of the one through the manipulation of the other. This process is consistent with Duval's view, which supports the partial identification of a solid by its figural units, but is in contrast to the usual, and more holistic, procedure of solids' identification by sighted students.

In most cases students used gestures, such as those mentioned by McNeill (1992), in order to describe something they could not easily express with words or the formal mathematical terminology. Such was also the role of similes used by students. It was often difficult for students to verbally express their reasoning through formal mathematical terminology. Thus, they used similes from their everyday lives, in order to describe the shape or form of a geometrical object or even some of its properties.

In all tasks the visualization process of the geometrical objects and their manipulation by the students was most apparent. The students created images like the ones described by Presmeg (2006), calling them "mental images". These images were sometimes static while other times students assigned to them a dynamic character, by moving them mentally, creating new images. Thus, the contribution of visualization was particularly important both in manipulating and identifying geometrical objects, as also for the transition of geometrical reasoning between geometries of different dimensions. This bidirectional relationship between visualization and geometrical reasoning can help students develop their geometrical thinking.

In the field of didactics of mathematics, no research has yet been done as to the levels of visual impaired students' geometrical thinking. Thus, and mainly because of some parameters that do not exist in the case of sighted students (e.g. lack of real visual images for solids), we cannot be sure whether we are allowed to classify the levels of the participating students' geometrical thinking, using Gutierrez's levels classification (1992). What we can say though, based on these results, is that the strategies followed by the students, and also the way they chose to implement them and result to their responses, show that the students based their geometrical reasoning on the properties of both the plane figures and solids, as also on the relations between these properties. However, realizing the limitations mentioned above, and also the limitations of our research (e.g. limited time and number of students), we cannot but emphasize the importance of further research in this field of mathematics' education, so that we are able to draw clear conclusions.

Agreeing with Healy's view (2012), that if we manage to understand the similarities and differences in practices of blind students in relation to these of sighted students we will then be able to understand even better the correlation between experience and understanding, we think that it would be extremely helpful, not only for visually impaired students but for all students, that the examples these five students gave to us on how to cope with geometrical objects, find their role in the field of didactics of geometry and not be left unexploited.

Learning geometry through paper-based experiences

Marta Pytlak

University of Rzeszow, Rzeszow, Poland, mpytlak@ur.edu.pl

Teaching of geometry in the elementary school in Poland is carried out in a very static way. Students learn various geometrical concepts in concrete, typical situations. They rarely meet these concepts in less common situations or not directly related to the geometry. In this paper, I will present a part of activities that have been carried out among pupils in the fourth grade of primary school. During these courses, students had the opportunity to take a look at familiar geometric concepts (square, cube, perpendicular, parallelism) from a new perspective.

Keywords: Geometry, primary school education, spatial cards, teaching geometry, 2D and 3D geometry.

INTRODUCTION

In recent years, there has been a lot of discussion in Poland on changing the education system. The results achieved by Polish students in various tests and exams showed that this topic is a lot of catching up to do. The new curriculum for mathematics has pointed out that it is necessary to develop students' competencies, which are important not only during a math class, but also in everyday life. A lot of space was devoted to geometry, which so far has not been significantly present in teaching, especially at the lower levels of education. And often geometrical problems are ignored or treated unfavorably by teachers at a lower level of education (kindergarten education and I-III grades of primary school). Teaching geometry is confined to familiarize students with the basic geometric shapes, i.e. square, rectangle, triangle and circle. In addition, students learn to measure the length of a segment, draw straight lines and segments which are perpendicular or parallel. At the next level of education geometry appears as a separate branch of mathematics, where the student is expected to have a formal geometrical knowledge. This leap from the first to the second level of education meant that for many students geometry has become as a very difficult subject. An additional difficulty is also the fact that geometry requires a much different approach than other areas of mathematics, e.g., arithmetic or algebra. It cannot be "algorithm and routine" and put in rigid frames. Thus, few questions appear: How to help students in the transition between the levels? How to help students develop their geometric intuition, which will be the basis for their future formal knowledge? Trying to find the answer to these questions

I decided to organize a series of activities with the students, whose goal would be to develop their interest in geometry. The activities were organized in such a way so that the student would recognize geometric issues somehow by accident, while having fun.

THEORETICAL BACKGROUND

Geometry is an integral part of our daily life even if we do not realize it. Geometry teaches the basic skills of logical thinking and reasoning. We can observe that in the latest trends in early education a large emphasis is placed on developing the skills needed for a child to explore and understand the world and to cope with different situations of everyday life. The skills that are particularly useful in various situations include analyzing, critical thinking and putting and verifying hypotheses. The tasks of the school according the new curriculum include the care that a child could acquire the knowledge and skills needed to understand the world and the tools the child needs in math skills in real-life and school situations and for solving the problems.

The most important skills acquired by the student in the course of general education in elementary school should be, inter alia, mathematical thinking, comprehension as the ability to use the basic tools of mathematics in his or her daily live and carrying out elementary mathematical procedures. On the higher stages of education mathematics is presented as structured and ordered formal knowledge, with specified chapters of mathematics. This enables the advanced work both on exploring and developing mathematical knowledge and develop formal (symbolic) mathematical language. At lower levels of education (especially in the lower grades of primary school) students are not presented a finished, formal knowledge from different areas of mathematics, but are introduced them to the world of arithmetic and geometry (Hejný & Jirotková, 2006). The world of arithmetic is ultimately structured and governed by clear rules. Individual records and symbols used in this world are read by all in the same way. The presents the situation in the world of geometry is different, as Hejný and Jirotková (2006) write:

> The world of geometry is a community of individuals or small families and there is a large diversity in the linkages between them. From the didactic point of view, arithmetic is suitable for developing abilities systematically, and geometry is more suitable for abilities such as experimenting, discovering, concept creation, hypothesizing and creating mini-structures. (p. 394)

By analyzing the historical development of geometry we can notice that it was accompanied by human in his activities since the dawn of time (much like arithmetic). Initially, geometry was not a theoretical science, but appeared from the need and desire of people to arrange the space around them, solve many practical problems - from construction by travelling to the ornamentation (Hejný, 1990). However, this geometry was the first "scientific field within mathematics" which was created by human. Its significance for the study of the ancient world was great. It had an important role in mathematics. This historical trait also points the way for didactical approaches to teaching school geometry: geometrical knowledge arises by action. Thus, it is important to gain experience, and practical problem solving.

The importance of geometry in the education of children and young people was the topic of many researchers' considerations. There is a belief that geometry can support the overall development of the child's competence in mathematics. Swoboda (2009) has written the importance of geometry in teaching children and adolescents. She emphasizes that a geometrical approach is closer to a child than an arithmetic one and can open doors to the world of mathematics. It is important that "Geometrical cognition starts from a reflection upon the perceived phenomena and in this way correlates with the basic ways of learning among children" (p. 29). In addition, geometry gives the opportunity to develop the mathematical ways of thinking such as generalization, abstraction, perceiving relations and understanding rules.

Although geometry has a great potential to develop mathematical thinking of students in the school teaching it is not treated with due care. It consists of a number of factors. As Karwowska-Paszkiewicz, Łyko, Mamczur and Swoboda (2001) write, one of them is the very limited number of lessons concerning geometry. It is the reason why during geometric lessons some "ready knowledge" is given and students "did not have the opportunity to learn the properties of the figures through manipulating and even if they had it, it was only apparent" (p. 86). Hence, there is no place in this teaching style for problem solving teaching, and there arise difficulties in the connection between the problem, the procedure of solving it and the solution.

To take advantage of the full capabilities of the geometry in the education of children and youth, you need to change the approach to its teaching. Geometry was born out of the action and of humans needs for development and structuring of space around them. Therefore, an important element in the teaching of geometry should be acting. As we can see in Swoboda (2001):

> Action play an important role in the formation of geometrical concept because there is always correlation between concept and the activity addressed to the concept. The object from the real world are perceived as the gestalt. The way of gathering information is perception, but after that the action with the object leads to the verbal description in their properties. (p.151)

So an important didactical issue is how to organize activity in mathematics lessons in such a way as to encourage students to actually participate in the lesson and to give them a chance to creative thinking and discovering mathematics.

The experience plays an important role in the learning process. Specifically writes about this Hejný in his theory of the General Model (Hejný, 2001). Children create their own knowledge primarily based on the experience they have. For a description of these experiences they use language - as it is close to them. The closest experience for a child is the language of gestures. It is the first language, how a child learns. This language is very helpful during learning of mathematics. Just as Cook and Goldin-Meadow (2006) say: "children who produce gestures modeled by the teacher during a lesson are more likely to profit from the lesson than children who do not produce the gestures". Only at a later stage of learning a child meets the formal language of mathematics. It is important that the experience and action in the acquisition of mathematical knowledge appears first, followed by language, and only at the end there is formal knowledge. According to Burton (2009), the human activity is the first and after that mathematics arise. And mathematical language (mathematical concepts, objects and relationship) arise through natural language, and within particular socio-cultural environments, in response to human thinking about quantity, relationship and space.

METHODOLOGY

Data for this paper were collected during classes with third grade students from primary school. It was a series of meetings, whose main purpose was to develop the students' interest and talents of mathematics. Classes took place once a week and last one school hour (45 minutes). Twenty students from the third grade of primary school (10–11 years old) took part in these meetings. They were students, who coped pretty well with school mathematics. They had no major problems with the mastery of the material carried in the classroom. They were students willing to undertake new challenges. During these meetings the students through fun developed their mathematical abilities. Much of the class was devoted to geometry. Students through play, by using paper and scissors, learn about various properties of figures in the plane and in space. The purpose of these meetings was to develop spatial imagination and the ability to perceive relationships and analogies between objects on the plane and space. Also worked on the development of students' mathematical language, and, in particular, to bring students the terms such as parallelism and perpendicularity.

During each class, students had access to colored cardboard, scissors, duct tape, crayons, markers. Classes were recorded with a video camera. After each meeting a protocol was prepared. The research materials consist of the works done by students, videos and chat records.

In this paper, I would like to present the classes concerning geometry called "play with geometry". The main purpose of the course was to develop spatial imagination and students' interest in geometry. In addition, I wanted to examine:

- How will students cope with the creation of three-dimensional models?
- How will they move between dimensions?
- Will they be able to notice the parallel and perpendicular elements in three-dimensional models?
- Will they be able to describe the work made by them in the mathematical language?

Activities under the name of "play with geometry" are divided into two parts. During the first of them students prepared spatial cards from pre-made templates. They cut out, filed and attached elements so that after unfolded their cards they received spatial composition. These classes were analyzed together, as making certain cuts or submit reflected in the final work. Students have tried to capture all the relationships that exist between objects.

After working with ready-made templates it was the time for students own creativity. They were given colored cards and scissors. Their task was to create any space card. Both themes of work and how to perform it completely belonged to students.

This task apparently had little to do with geometry. My aim was to show students that in such seemingly non-mathematics activities mathematical – geometrical ideas can be found. This kind of geometry we can find in our daily life.

Students began working on the worksheet in half. Then they began to mutilate the card. At first their work was very spontaneous and not targeted. After some time, students began to notice that the method of cutting and bending the paper affects how their work. So they began to think over each of the next move, already analyzed the resulting image and then decide on the next move. Very often the first work done was treated as a “training card”. After its execution students looked at it, analyzed it, in order to say what they managed to achieve. Only then they started working on the “final card”. When all the students had finished their work, everyone had the opportunity to present what he did. Also a discussion was conducted, in which all the students participated. During this discussion, the teacher drew attention to the manner of carrying out the cuts by the students. There were such concepts as “parallel”, “perpendicular”. Attention was also drawn to the properties of figures that appeared in the works.

ANALYSIS OF STUDENTS’ WORK

The work of Maks

Maks, a student of average ability, he made a very simple job. In an interview with the teacher noted that his foundation was to cut the “three squares”. Initially, however, he did not quite know what it really means.

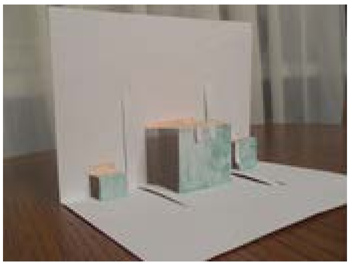

Figure 1: The card made by Maks

Teacher: Maks did the card and he colored it. Please, tell us about your work

Maks: I cut three squares.
Teacher: What does it mean?
Maks: I do not know.
Teacher: [goes to the Maks’ bench, takes his work consists in half and shows the class] Maks cut three squares. But how did you do it?
Maks: I fold it and cut here, here, here, here, here and here. [he shows a pair of scissors, how to carry out cutting]
Teacher: Ok, and what is next?
Maks: I opened it and pull out [he shows the way of making the card]. I watched how it looks and coloured.
Teacher: Ok.. And what were these cuts that created a square?
Maks: [silence]

No one in the class could answer the question posed by the teacher. Everyone knew how to make a “square”, most of the students had it in their work. They could not, however, describe how to construct this object using mathematical language. To help students teacher presented the experience. The teacher took a piece of paper and scissors and made a few cuts. Only then the students began to pay attention to the geometrical relationships.

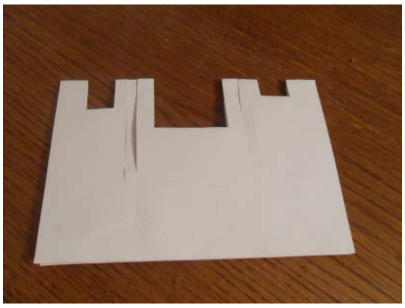

Figure 2: Squares in Maks’s work

Teacher: If cutting can be free? Well, look: I take the card, fold it in half and I will cut it. Here and here [holds the card in two places]. Maks said, that for every square he made two cuts. So I have two cuts and I put the cut piece to the center of my cards [he shows]. Look, did I leave the square?
Students: No.
Teacher: Look, if I want to make a square, the same as Maks did, how should I cut.
Student 1: Well... like a square.
Teacher: And what does it mean „like a square”?
Student 1: Well ... squarely.
Teacher: And what is characterized by square?
Student 2: Because it has all equal sides
Teacher: Well, what else can we say about the square?
Student 3: That is edgy.
Teacher: That is edgy?
Student 2: Because it has all sides perpendicular and the right angle.
Student 1: And it has four sides
Teacher: Very well. So now let’s get it all together: a square has four sides. You said that it has right angle.
Student 2: All sides are equal.

Teacher: Yes, all sides are the same length. And what else can we say about the square?
Maks: [he is looking at his work and pointing to the opposite sides of the cut square] And these are parallel.
Teacher: Great Maks. So what had to be done?
Maks: You have to make two parallel cuts of the same length.
Student 2: Why had not I thought of it?

Square is the first figure, faced by students. It is well known to them, everyone can indicate a square and describe its properties. However, during their work students forgot about the "mathematical" side of a square. In everyday language the square "is such a squared (edgy) thing, which has equal sides". Such a description is sufficient for students at some stage. And this one students applied during the class. The parallelism of the opposite sides and the perpendicularity of the adjacent sides was a secondary issue for them. Both concepts have been widely discussed during the lessons of mathematics. Students had drawn perpendicular and parallel segments. They even marked on the square (using colored pencils) which the sides are parallel and perpendicular.. However, these situations were "pure mathematical". Students know that now they are talking about perpendicularity and parallelism. During the course of creating the spatial cards nobody pointed them that "this is math". They initially did not see the mathematical context in what they were doing. It was for them just a normal execution of simple art work. Only a common conversation with the teacher allowed students to call in an appropriate way what they have made. Only then they began to use mathematical language in their descriptions. These experiences have allowed students to realize new opportunities for creating future cards.

Filip's work

Filip first created a "test card". He worked quickly, did not pay attention to accuracy. When the card was ready, he looked at it, analyzed the arrangement of individual elements, and then created a new card. This time, however, he proceeded very carefully. The effect of his work is presented in picture 3.

Figure 3: Filip's work

The boy was also aware of how it should carry out further cuts to achieve the desired end result. The following conversation with the teacher in an evidence of this:

Teacher: Great job, Filip. Tell us, how did you make it?
Filip: I cut strips
Teacher: And how did you cut these strips?
Filip: Getting shorter. Once a thinner, once a wider.
Teacher: Ok.. And on what more do you pay attention while preparing the work?
Filip: [silence]
Teacher: Well, how do these cuts take place?
Filip: Well ... straight
Teacher: Straight? What does it mean straight, Filip?
Filip: [long break, he looks at his work] Perpendicular to this line [he puts on the edge of the sheet] (...)
Teacher: And how are these cuts are related to each other?
Filip: Parallel.

The boy knew the concept of perpendicularity and parallelism. He could also use in practice the relationship of the perpendicularity and parallelism of objects. However, initially he could not name these concepts. He used the terms "straight, equally". These are the terms taken from everyday life, from everyday language. During creating the cards, it was enough for him. Just in describing what he did, he had to start using mathematical language. Students initially treated the task posed to them as a typical manual-plastic one: I have to make a spatial card. In their work they were rather to the directed to the visual aspect and did not refer to geometrical knowledge (although classes were held in the framework of mathematics lessons). A common discussion on the work made by students made them realize that what they were doing was hidden geometry.

Students were very surprised about that. Often appeared the statements: "oh, here is also a mathematics" or "Can we use the geometry here?" Therefore, in their further work they tried to use knowledge from geometry to create new spatial cards.

CONCLUSION

For 9–10 years old students the classes were in a new form. During the classes the students turned out to be open to new challenges. They approached the problem creatively. The care taken on the details of the created cards can prove the huge interest in the presented subject.

Although the concept of parallelism and perpendicularity were well known for pupils, they had problems with the indication of perpendicular or parallel objects. It seems that there are two different aspects: knowing concept definition and using it in practice. An additional difficulty was also a movement between two planes: the students during cutting worked on a flat plane, and the effect of their work was viewed in three dimensional space. When students were cutting out a "square" they received as a result a "cube".

When discussing the concepts of parallelism and perpendicularity during math class the focus was on two-dimensional geometry. On a flat sheet of paper the students were shown perpendicular and parallel segments and by using a ruler they drew perpendicular and parallel lines. Meanwhile, during the course presented here they "cut out" perpendicular and parallel lines which was a new experience for them.

Hejný (2004) in his theory of the development of student's mathematical knowledge writes that it is very important in the learning process to gain experiences, which are the basis for the creation of formal mathematical knowledge. The more different experiences, the better assimilation of knowledge. To the knowledge of students which is stable, flexible and operational, you need to provide them with as much variety of experiences related to a given concept, recorded in the different planes.

For primary school students the issues connected with geometry are not easy. The classes presented here were an attempt to find a way to present these issues in such a way that students could experience, see. By following the view that it is best to learn by experience, I tried to organize the activities in such a way that students can manipulate the materials given to them and solve the task by themselves. The open question is whether this is the right way to introduce the student to the world of three-dimensional geometry. In my opinion – yes, it is good direction. In my further work I would like to focus on the development of a geometrical environment which will be on the one hand appropriate and conductive for teaching and on the second hand - student-friendly. What should be this geometrical environment? What tools should be used in this environment? What kind of tasks and problems help to teaching and learning geometry?

Six year old pupils' intuitive knowledge about triangles

Maria Paula Rodrigues[1] *and Maria de Lurdes Serrazina*[2]

1 Universidade de Lisboa, Unidade de Investigação do Instituto de Educação, Lisboa, Portugal, mariapaular@campus.ul.pt

2 Universidade de Lisboa, Escola Superior de Educação de Lisboa, UIDEF, Lisboa, Portugal, lurdess@eselx.ipl.pt

This communication discusses the intuitive knowledge that six years old pupils reveal about triangles. Data is collected through a class group discussion, which was videotaped and transcribed. The results show that pupils articulate visual prototypes with known attributes to recognize triangles. Furthermore they identify nonexamples and its features to recognize this shape. Position didn't seem to be a problema to identify triangles, however, some features, as curved lines or topological properties, appear to be a problema on triangles recognition. Pupils used mainly a partitive classification type but, when they observed and discussed known attributes or properties, they can also use hierarchical classification type.

Keywords: Shapes, properties, classification.

INTRODUCTION

The research presented on this paper reports six years old pupils' intuitive knowledge about triangles when solving tasks, which were based on those presented in (Clements et al., 1999).

This is an exploratory study whose main goal is to get some clues about the intuitive knowledge that Portuguese six years old pupils have about shapes. It is a part of a larger PhD study of the first author, named *Shapes classification: a teaching experience in the early years*. The work reported on this paper intends to discuss what kind of intuitive knowledge Portuguese six years old pupils reveal about triangles.

All participating pupils are six years old and belong to a 1st grade class. The data collected addresses to intuitive knowledge about circles, squares, triangles and rectangles but, in this paper, we only focus on triangles.

CONCEPTUAL FRAMEWORK

When we presented a set of figures in order to identify the shapes which belong it is possible for pupils to reveal knowledge that is related to intuitive character thought, based on visual prototypes, without considering attributes or properties of those forms (Clements et al., 1999). This knowledge can be related to previous experiences and promotes different levels of development (Burger & Shaughnessy, 1986). Also, visual representations, impressions and experiences make up the initial concept image (Vinner & Hershkowitz, 1980).

Intuitive character thought can be related to major theories of concept formation: classical view and the prototypical view (Klausmeier & Sipple 1980; Smith, Shoben, & Rips 1974; Smith & Medin, 1981). According to the classical view, categories are represented by a set of defining features which are shared by all examples. The prototypical view proposes the existence of ideal examples, called prototypes, which are often acquired first and serve as a basis for comparison when categorizing additional examples and nonexamples (Attneave, 1957; Posner & Keele, 1968; Reed, 1972; Rosch, 1973).

Initially, the mental construct of a concept includes mostly visual images based on perceptual similarities of examples, also known as characteristic features (Smith et al., 1974). This initial discrimination may lead to only partial concept acquisition. Later on, examples serve as a basis for both perceptible and nonperceptible attributes, ultimately leading to a concept based on its defining features (Tsamir, Tirosh, & Levenson, 2008). Following this idea, some pupils may recognize shapes supported on the recognition of properties of those shapes and others will articulate visual prototypes with known attributes or properties to identify the same shapes (Clements et al., 1999).

Non-prototypical examples, are often regarded as nonexamples (Hershkowitz, 1989; Schwarz & Hershkowitz, 1999; Wilson, 1990) and specifically, "nonexamples serve to clarify boundaries" of a concept (Bills et al., 2006, p. 127). On the other hand, Fisher (1965) admits that topological properties, mental structures that enable shapes abstraction, such as the configuration or appearance, cannot leave some pupils arrive to the identification of a particular shape, because they can't consider specific properties of that shape.

Regarding to classification, Clements and Sarama (2007) mentioned that pupils tend to a partitive type of classification, where various subsets of concepts are disconnected from each other, into opposition to a hierarchy classification, where the most particular concepts integrates the general ones (de Villiers, 1994).

Tsamir and colleagues (2008) claim that concepts often serve as a means by which people may categorize different things, deciding whether or not something belongs to this class. In other words, one of the functions of a concept is to enable a person to identify both examples and nonexamples of the category.

At a partitive classification process pupils can identify the shapes name without ever having been the opportunity to reflect on their names, attributes or properties and only a small part will be able to provide nonexamples (de Villiers, 1994).

In front of a different figures sets, where the goal is to identify circles; squares; triangles and rectangles, Clements and colleagues (1999) and Sandhofer and Smith (1999) claim that, in order of difficulty, children identify the circle; square; rectangle and triangle.

METHODOLOGY

The exploratory study reported in this paper follows a qualitative interpretative approach (Denzin & Lincoln, 1989). Participants were all six years old and belong to the same 1st grade class, constituted by 21 pupils, of an elementary private school near Sintra, a small village of Lisbon area. All of them attended the kindergarten at the same school and belong to a socio-economical high level. All participants had had informal contact with different shapes during last school year and that fact influenced their intuitive knowledge of shapes.

The study started with four clinical interviews, carried out by the first author to four pupils to test a reworking of tasks used by Clements and colleagues (1999), whose goal was to identify all circles, squares, triangles and rectangles of figures sets. So, the task where children must identify triangles followed two different steps: on a first approach four pupils, two boys and two girls, in different four days, were taken out of the classroom and solved the tasks, as we want to experiment the task with pupils before taking it into classroom. Furthermore, the first four clinical interviews intended, on the one hand, identify the first knowledge about triangles of these four children, and, on the other hand, the given answers served as a starting point to all group discussion. The intention was to create a kind of game where pupils not interviewed should guess whose triangles had been chosen by their colleagues. This game was a motivation for a collective selection of triangles and a discussion about it. These interviews were videotaped. After this first step, the researcher took the task for the classroom and promoted a whole class discussion session, which was also videotaped. The researcher played a kind of game where pupils who did not participate in individual interviews tried to guess which shapes were chosen by the interviewed pupils. The data presented in this paper focus on this whole group discussion.

So, data collection was through a group discussion, by videotaping, where pupils could discuss different ideas, complete or disagree with arguments, creating new reasoning and clarify concepts. This group discussion intended to lead pupils to the possibility of inclusive classification through the construction of shape families that display equal or similar attributes or properties.

The work consisted on a chosen triangles task using a manipulative set of figures, placed in the same position as the one presented by Clements and colleagues (1999), each figure printed on a separate card allowed pupils compare, rotate, overlap, among others. On this set of manipulative figures, pupils had to choose all triangles, justifying their choices. During this stage we intended to understand what kind of knowledge pupils used to recognize triangles: visual prototypes; shape attributes or properties; nonexamples; among others. Besides, their justifications and new questions, related with their answers, we tried to forward them to the construction of shape families to look out to hierarchical classification.

The data were analyzed regarding to the pupils answers, based on visual prototypes, without considering attributes or properties of that forms (Clements et al., 1999), and when they claim that visual representations, impressions and experiences make up the initial concept image (Vinner & Hershkowitz, 1980).

Another aspect we considered on the analysis of data refers to a partitive type of classification influenced by Clements and Sarama (2007) and de Villiers (1994), which mentioned that pupils tend to a partitive type of classification, where various subsets of concepts are disconnected from each other, into opposition to a hierarchical classification, where the most particular concepts integrates the general ones.

Finally, we had in consideration that, probably, triangles, according to Clements and colleagues (1999) and Sandhofer and Smith (1999), will be a difficult shape to identify.

With this kind of methodology we wanted to get some clues about intuitive knowledge of six years old pupils about triangles; what kind of language they use to express this knowledge; understand how large group discussions can lead pupils to a better knowledge of triangles and their properties and, finally, understand if large group discussions facilitate the idea of hierarchical classification.

To preserve the identity of all pupils, on the analysis we used fictitious names initiated by the same capital letter of their real names.

PUPILS' INTUITIVE KNOWLEDGE ABOUT TRIANGLES

As we wrote before, the task where children must identify triangles followed two different steps: the first one we carried out individual interviews with four pupils out of their classroom. With the data collected on these interviews a group discussion session was organized. The researcher played a kind of game with the pupils who had not participated in individual interviews. They should try to guess which were the shapes chosen by the interviewed children. To start the researcher asked to all group which were the triangles they thought had been chosen by their colleagues.

Researcher: In front of these set of shapes, António; Geraldo; Marta and Mara should choose only triangles. Which ones do you think they chose?

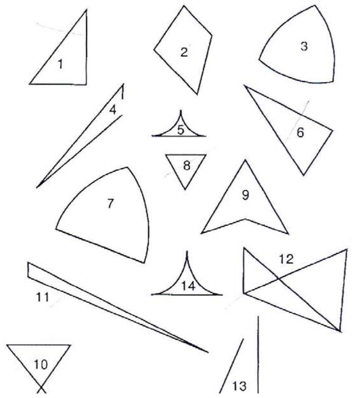

Figure 1: Set of shapes to identify triangles (Burger & Shaughnessy, 1986; Clements & Battista, 1992a)

Augusto: I think they didn't chose number 2. Because it has 4 sides and triangles only have 3 sides.

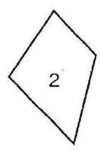

Figure 2: A nonexample of triangle given by Augusto

Some pupils, as Augusto, could recognize triangles identifying a nonexample of them, nominating attributes as the number of sides. Here he seemed regarded non-prototypical examples as nonexamples.

Joel: Picture 2 has 4 sides and 4 angles.
Researcher: So it can belongs to which family?
All group: Rhombus...
Augusto: ... and squares.
Researcher: Why?
Maria Manuela: Because it has 4 sides and 4 angles.
Researcher: So, square and rhombus can be part of which family?
Geraldo: Rectangles.

The group discussions conducted children to observe some attributes or properties and this observation, sometimes, led to comparisons between figures and their properties and offered a larger possibility to identify common attributes or properties that can produce a primary idea of hierarchical classification. However, last answer needs a different kind of work because all mentioned shapes don't have equal attributes or properties and can't be part of same family.

Researcher: What about you Geraldo... which triangles do you think your colleagues had chosen?
Geraldo: Pictures 1, 3, 4, 6, 7, 8, 11 e 13.

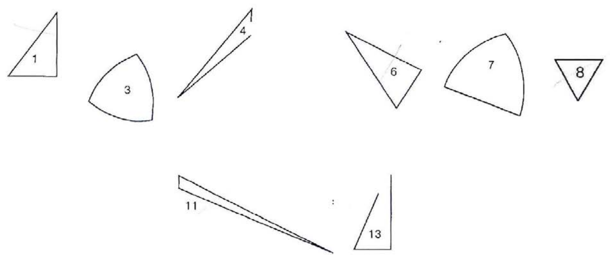

Figure 3: Triangles identified by Geraldo

Analyzing Geraldos's choices we can understand that when he had chosen figures number 3; 4; 7 and 13, his choices were based on topological properties, such configuration or appearance, without consider specific properties of triangles.

However, when he chose figures 6 and 8 he seemed recognize triangles articulating visual prototypes and known attributes. Already, when he identified figure 11 it is possible to say that he had identified some attributes and properties of triangles because the triangle identified by number 11 was a long and narrow scalene triangle which isn't a common representation of triangle represented on an unusual position.

Researcher: Augusto said that picture 10 has 6 sides but, António, you had identified it as a triangle. What do you think now, António?
António: It's a non triangle because it has 6 sides.

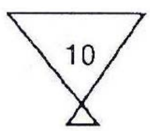

Figure 4: Figure identified as a triangle by António

When children were in group discussion they were encouraged to discuss shapes, attributes or properties, they could compare and integrate new concepts as the one showed on transcription "non triangle", which meant that these group discussions might become richer in terms of concepts. Moreover, the group discussions allowed all pupils participation, sharing, abstraction and reflection about triangles attributes or properties.

Researcher: António, you said that picture 14 is a triangle, but Geraldo, Mara and Marta said that is a non triangle. Who is right?
António: I think I was wrong..
Researcher: Why?
António: Because, now I can observe it has curved lines .
Researcher: So, do you think triangles shouldn't have curved lines?
[...]
Marta: Triangles only could have straight lines because they have 3 angles.
Lívia: I agree with Marta, triangles have angles because it doesn't have curved lines.
Researcher: So, picture 14 is a triangle or, like Marta and Geraldo said, a non triangle?
All group: A non triangle.

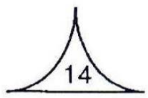

Figure 5: Figure identified as a triangle by António

Once more, group discussion seems to be a place where pupils can reflect about appearance, prototypes, attributes and properties and clarify concepts.

Researcher: António, now, you said that picture 14 is a non triangle because it has curved lines and because of that they can't have any angles.
Can you identify other pictures from the same family?
Mara: Pictures 3 and 7 are not triangles because they don't have any angles.

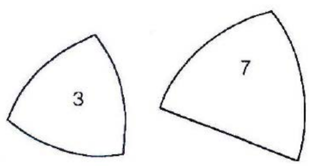

Figure 6: Figures identified as "zero" angles family

Lívia: I think they all can belong to "zero" angles family.

When pupils establish relations between different reasoning and identify necessary shape conditions, inclusive classification may emerge.

Researcher: Marco said that António, Geraldo, Marta and Mara probably had chosen picture 13.
Do you all agree?
Lívia: I didn't because it has open lines. All triangles should have 3 sides, all close. I think picture 13 is a non triangle.

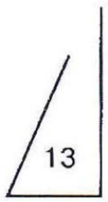

Figure 7: Figure identified as a triangle by Geraldo

During all discussion, Lívia seems to understand what are the necessary conditions to be a triangle and also a necessary condition to be a two dimension shape, when she considered the attribute "close lines".

Researcher: After all this discussion, who wants to tell me what pictures we are sure that represent triangles on this set?
Large group of pupils: Pictures 1; 6; 8 and 11.

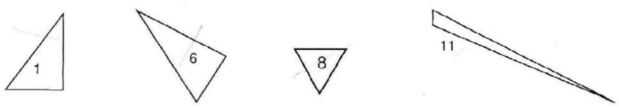

Figure 8: All triangles considered by a large group of pupils at the end of discussion

At the end of group discussion a very large number of pupils seemed to have clarified the concept of triangle and a strong concept image of this shape, while they were observing features of discussed figures and were articulating attributes and properties of triangles.

DISCUSSION

In this exploratory study the pupils articulated visual prototypes with known attributes, for instance, when they identify examples and nonexamples of triangles and were able to justify it, which is according to the results obtained by Clements and colleagues (1999).

In line with Rosch (1973) and other authors, few pupils used nonexamples to identify triangles and justify their choices. But in this study nonexamples served to clarify boundaries of a concept (Bills et al., 2006).

A group of pupils seems to have some difficulties to identify triangles because of some topological properties, as appearance or configuration that prevent the recognition of triangle specific properties. These results are according to those mentioned by Fisher (1995).

Contrary to what would be expected, some pupils recognized triangles independently of the figures position, which may be related with their previous experiences. Burger and Shaughnessy (1986) reveal that experiences and informal contacts with different shapes are very important factors at children intuitive knowledge of shapes.

Finally, we think it's possible to say that when pupils of 1st grade were encouraged to discuss shapes attributes or properties, in group discussions, they can observe differences and similarities and hierarchical classification could emerge (de Villiers, 1994). Furthermore, they seemed to be able to clarify concepts and construct new ones (Tsamir et al., 2008).

Mathematization of rotation as a didactic task

Ewa Swoboda

University of Rzeszów, Rzeszów, Poland, eswoboda@ur.edu.pl

The inspiration for observation was an idea of getting movement to a static school geometry. In the school curriculum, the only area where you can consciously refer to the movement are questions related to isometrics. I took the premise that the mathematization of movement should be based on student perceptions related to the physical movement of objects. Conducted observation shows that the mathematization of rotation might not be so obvious.

Keywords: Dynamic geometric reasoning, mathematization of physical movement, rotation.

RATIONALE

The process of solving geometrical problems needs an idea of the action. Almost every geometric problem requires focusing attention on certain compounds for their mental transformation. Hence, thinking in geometry requires mental skills to manipulate objects or its fragments. Such approach is visible also in many places of Euclid 'Elements'. Despite the formal expulsion of the movement from Greek geometry, reasoning were based, without doubt, on the imagination of making movement.

In Duval (1998, p. 38), "geometry involves three kinds of cognitive processes which fulfil specific epistemological functions: *visualisation*, (...) *construction*, (...) *reasoning* (...)". I understand this statement very widely: cognitive processes are elements of thought processes, and constructions act as *actions*.

Theories about the formation of geometrical concepts emphasize that the origins of geometrical knowledge proceed without words and rely mainly on visual perception of static phenomena (van Hiele, 1986; Hejný, 2001). Therefore, the problem of bringing students to the ability of making mental transformations I treat as an educational task. In the literature, there is no explicit opinion on what educational level there is possible to create such skills.

Today, while solving geometric problems in school, special computer programs that allow to receive dynamic images are often used (Ferrara & Mammana, 2013). Without doubt, they support not only visualisation, but also construction and reasoning. They facilitate experimentation – students can check certain assumptions, verify the hypothesis. Imagination at the screen shows what happens to the object when changing certain parameters – students can watch the following phases of these changes. Sometimes the student decides what action to perform (like dragging a specific point to make deformation of the figure). In the other situation the whole actions are defined: symmetrical reflection with respect to a particular line, parallel movement to another location, turning about a specific angle relatively to a fixed point. Student sees the overall effect of the change, without going into the mechanism beneath this. These two types of action are different, because they give student the opportunity to experiment in other ways, either through the use of ready-made tools without going into their mode of action, or through planning action based on a conscious determination of conditions governing the changes.

These tools were absent at the time when the geometry was created as a scientific discipline. Mathematicians were able to imagine some of the compounds without seeing them, predict the outcome of actions performed only mentally. How did they develop this ability in them? Can we develop the same in the traditional way of teaching? And maybe today only dynamic computer programs give the opportunity for the creation of dynamic representations of geometric objects?

For me, the starting point for using action in *geometrical thinking* is the problem of turning attention on movement as such. In the Polish school curriculum, the only area where we can consciously refer to the movement in geometry are topics related to isometrics. Isometries are most often introduced as a static relation figure to figure. Names of geometric transformations suggest that isometric transformations are the result of interiorization of rigid movements that take place in a physical space. This trend can be treated as didactic suggestion how to teach isometries at school. Mathematical concepts undoubtedly have a relationship with reality as the result of mathematization. But preparing students to the mathematization of movement raises many questions. Here there are some of them:

— How does the mathematization is done by a young student – shouldn't we attempt to correct some of the dependencies that a child draws attention to?

— Maybe some properties are so deeply rooted in intuitions that the child does not even recognize that they operate? So what is the role of the teacher - what behaviours should he be sensitive about in order not to impose a ready-made mathematical formulas to students, but develop spontaneous knowledge and skills; what to talk about, what to indicate, what to question?

— Don't we commit abuses assuming that the mathematization of movements is based on the experiences gained in physical experiments? A mathematician and a physicist look otherwise on the physical movement of the object, regardless of the fact that both base on their own experiences in physical reality. Both must, therefore, focus attention on different observed phenomena. Which of them are important for making mathematization?

My previous research suggests that students frequently use a rotary movement in solving geometrical problems (Swoboda, 2013), are even are able to bring the configuration of the figures which can be described in the language of mathematical transformations (Jagoda & Swoboda, 2011). The results of these observations, however, do not provide answers on how close the student is able to get in order to underline terms which define such a movement.

Marchini & Vighi (2011), describing their own research aimed on building intuition of geometric transformations among young students, they relates their observations to the Duval theory on different perception of geometric phenomena (Duval, 2006). They emphasize that the mathematical representations of isometrics can be read in two different registers. Mathematical concepts such as parallel shift, rotation, axial symmetry, can be defined both as the static relationships between objects or as transformations. In the light of the Duval theory, this known mathematical fact takes a new didactic interpretation. Not only that the position of the object to the object can function as a relation or as a transformation - perhaps the mental abilities of students mean that some will opt more towards static perception, and others - in a static image can easily see a movement. In Marchini and Vighi's experiment, children spontaneously were able to give the dynamism to the static arrangement of the two objects. In addition, students have used the words from the everyday language which can be treated as the equivalent of parallel displacement, axial symmetry, rotation. To what extent is this interpretation possible for another group of children? How do these results bring us closer to the process of movement's mathematization?

METHODOLOGY

The described research was conducted among 12–13 year old students in two schools in Rzeszów (Poland), in May 2014. So far their geometrical knowledge was associated mainly with geometrical figures. They also had many opportunities to deal with axial symmetry treated as a static relation, although for them there was the only isometric transformation they knew. On the other hand, it is worth mentioning that these students should not use computer animation in the process of learning geometry. Students worked in pairs. They were those students who cope with mathematics without problems and were open in their cooperation with others. The teacher leading the conversation with the students attended the research session as well [1]. At this stage, our goal was to observe and analyze the spontaneous behavior of the students working in the learning environment. That could be the basis for the understanding of isometric transformations on the plane.

Analysis of students' actions should lead to:

— identification of spontaneous student's behavior related to the representation of movement on the plane,

- capture those elements that may be included in the mathematical image of isometrics, and those that should be ousted during the development of mathematical concepts,

- diagnose how the proposed activities can be used as a starting point for talking with students about movements in geometry.

In this article we analyze the work of two students - Eliza and Gabriela. They had to create an animation of a moving triangle. Schoolgirls had a small book (size 10cm × 10cm) with 30 clean sheets for their disposal, to create animations. For facilitate drawing, they got a template of acute-angled triangle. They also had basic geometrical instruments (ruler, set square, compass, protractor) on the table. Girls could draw with a pencil or marker.

Purpose of the meeting was presented to the girls by their colleagues who had previously participated in a similar session. Using ready-made booklet, they showed to the girls how you can get the effect of moving the wings of a butterfly through a quick thumb through books.

A teacher, participating in the study, formulated a task:

Teacher: We'd like you draw a triangle in your booklet and make animations that it changed its position.

A formulation of the request does not dictate the way in which the figure is to be moved. The entire session was filmed. Film and prepared transcripts became the basis for the study.

RESULTS OF OBSERVATION

Determine the type of movement

The girls started their work by determining what kind of movement they will animate. They moved the triangle across the table, alternately offering various moves. All proposals were close to the rotation, and the whole course of this part of the meeting led to clarification how the movement will run. Girls were getting closer and closer to the idea of rotation around a clearly defined point - one of the vertices of the triangle. The first proposal (Figure 1a) – is a circular movement around the closed wheel, with the comment: something like this; the second (Figure 1b) – parallel motion showing by hand on the counter, with the arc trajectory, the third (Figure 1c) – the rotation of the triangle with one fixed point placed rather somewhere inside of the triangle, the fourth (Figure 1d) – rotation of the triangle with respect to one of the vertices.

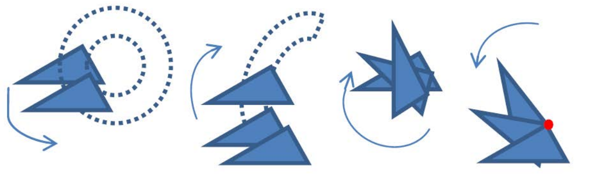

Figure 1: Four approximations leading to determination the type of the movement

The latter choice was commented, and the medium to convey thoughts were the movements:

Eliza: and I like it more like this: *she keeps the triangle with the fingers of one hand and with the other hand she is trying to rotate the figure relative to one vertex, in counter clockwise direction.*

In the next step girls have discussed the initial position of a triangle. Finally they decided (through appropriate arrangement) that the longest side would be parallel to the lateral edge of the page.

This first phase of work revealed rotation as such from intuition and the feeling that it is done with respect to a particular point. This point became more and more clear, it marked the organization of the whole movement. In the next stage, the discussion has been subjected to the initial orientation of the triangle. This position is also taken as the reference for determining the angle of rotation.

The centre of rotation

It seems that girls could not knowingly benefit from the center of rotation, till the end of their work. Although in their intentions triangle had to move in relation to one of the vertices, they do not feel the need to highlight this point – to tick, to discuss, to establish as a point of reference.

The beginning of their work indicates that the location of the triangle in the following slides is very problematic for students. Girls outlined the template of triangle on the first sheet of paper, turned a card in the booklet – and stopped embarrassed. They tried to find a way how to repeat the previous triangle position. Their first idea was to use the parallel shift: one of the girls tried to slip triangle out of the books (Figure 2a), then the second girl turned the page and they tried to push the triangle on this new card (Figure 2b, 2c) repeating its earlier position. Quickly they stated that it is not a good idea because the shift was not parallel and in their movements girls went as far as the "left side" of the earlier page (Figure 2d).

Gabriela found the other solution. She puts the triangle on the left side of the first contour (Figure 3a), closes the book (Figure 3b), turns it on the opposite side so that the triangle in the booklet falls down onto a second card (Figure 3c, 3d). These manipulations can be seen as the use of intuition of the axial symmetry, or folding. The girl uses it for placing a figure onto another plane in the same distance from the edges of the paper.

Later, the next few slides were drawn by using Gabriela's method. Then the girls have perfected their work – noted that on the following pages you can see the outline of the previous triangle position. So she have used this contour as a point of reference, to create a change.

While drawing further slides, girls tried to rotate the template relatively to one of the vertices belonging to the longest side. Sometimes they kept the vertex with their finger, but mostly – after the initial placement of the template on the track they only have tilted the template and thus determined the new position. There were moments when the girls manipulated the template quite freely, and the center of rotation was located somewhere inside the triangle.

The analysis of position of one of the vertices of the triangle through the following slides – that one, with respect to which the movement took place - shows how much this point was unstable. This is evident even in the pictures below (Figure 4, 5) and it is shown on the diagram beside, on which the arrangement (A) marks the position on the first "slide" and (B) – on the last one.

Comment: These first approaches prove that in attempts to perform the movement, the parallel shift and mirror reflection (understand as the tool) are closer to them than rotation. The girls mainly want to reconstruct the earlier position of the entire tri-

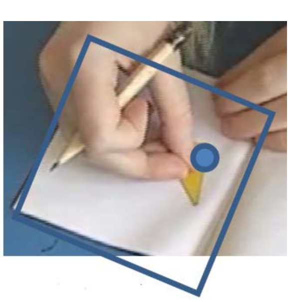

Figure 5

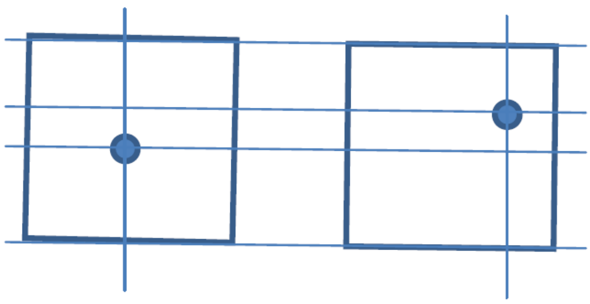

Figure 6

angle. In further work this position will be treated as a starting point for making changes in the position. Despite earlier manipulation on the table by hand, in which rooted movement at one fixed point was visible, they have no idea of the location of the center of rotation. What's more, the center of rotation escapes from their attention, it does not look not as an important constitutive element of movement.

Oriented angle

The first change of the triangle position was held after establishing its earlier position. When the girls dubbed the triangle's location from the first slide, carefully twisted template trying not to change the location of one vertex. Further stages of their work were similar - doubling the "old" position and light twist of template. It was evident that what was particularly important for them was the change of the placement of one of the triangle's sides (the longest - which end by the center of rotation) in relation to its previous position. Such action guided them from the very beginning of the work, which was confirmed in a conversation with the teacher:

Ex. 1

Teacher: What's your idea for the animation?
Students: Wow, that he would be so, so twisted (*both show by the hand the movement, in which it is clear that one vertex is stationary*). So around.
Teacher: So drawing the next steps, the next slides of you animation, you turn your attention to something? What do you pay attention to, because I see that Eliza draws a triangle, then she closes the book
Gabriela: that is, the first we make from that first contour...
Teacher: What, why so?
Students: In order to know *how it was before*, then we *move it a little bit so* (*Gabi is aided with her hands jammed into the table and one arm shows how to turn*)
Teacher: To move it a little further, or to rotate it a little bit?
Students: rotate
Teacher: Oh, do you move it in any way or just only rotate it?
Gabriela: just rotate (*Eliza is busy with another page*)
Teacher: aha.

Even when they discovered that there is an easier way of finding the proper position than the book manipulation, the essence of their work has not changed. The girls noticed that they can use the contour, which is reflected in the following pages. This location was used as the starting point for making changes.

Ex.2

Teacher: What now, Gabi, this facility will consist of?
Gabriela: So now you will not need to bounce it, but here it is already marked, and now only to apply (*she shows a position of the template on the track*) and to twist.

When the motion is realized, the most important is to change the position of one side of a triangle in relation to its position at an earlier slide. This change takes place in a specific way - as a change in slope. With this approach, the angle is understood as a measure, not as a geometrical figure. Thus, it refers to one of the oldest ways of describing the angle. The definition from the first book 'Elements' of Euclid, we have:

> Definition 8. And a plane angle is the inclination of the lines to one another, when two lines in a plane meet one another, and are not lying in a straight-line. [3]

For girls, it is enough 'to skew' a triangle. The existence of a fixed point is pushed aside. Such it looks in implementation, even in an interview the fixed point is marked, supported by gestures.

Size of the angle for the following 'slides' is taken intuitively, although girls try to make rotation rather on the same angle. At no time of their work were they interested by which total angle the triangle is rotated. Girls draw slide after slide, which can be explained by focusing only on the animation of movement; planned movement effect is the main goal of their work.

What you will observe, is a constant angle's orientation. This is evident in many moments of their work. While replacing themselves in drawing (they do it alternately) they remain continuously the same direction of rotation. At some point Gabi, taking the book for drawing, asks Eliza:

Gabriela: In which way it spins? so? (*she shows the movement by turning the template*).
Eliza: Oh, in this way (*shows movement by the hand on the bench*).
Gabriela: Oh (*turns her triangle in the same direction*).

FINAL REMARKS

'Mental rotation' is an issue multilaterally studied by psychologists. Sometimes their studies are used in the didactics of geometry (Steinwandel & Ludwig, 2011). However, these studies recognize the problem from a different side than the one that is presented in this essay. Generally, they are focused on solving tasks which require the mental rotation of three-dimensional figure or the mental movement in space. Our observations are not so much related to rotation usage, but to visualization of rotary motion with regard to its mathematical aspects. In such approach, we intend to realize two aims - the creation of geometrical concepts (here – a geometric transformations: rotation) and the formation of dynamic images in geometry. We are committed that the visualization emphasize those elements that are relevant to the mathematical definition of the rotation and underline the idea of motion.

During this meeting the teacher repeatedly posed the question to participated students, whether the task they perform can be offered to other students during a math class. The girls had no idea what relationship may these classes have with geometry. It is clear that paper geometry (even when learning use of physical models) does not create many opportunities to realize a movement that underlies conducting of the geometric reasoning.

Conducted observation shows that the mathematization of rotation might not be so obvious. The girls do not really have revealed these elements that define the rotation. Their activity gave a fairly imprecise effect of rotation, but did not allow to extract those elements that appear in the definition:

— Centre of rotation - the only fixed point in the transformation - is carried out in a quite fuzzy manner. The clash of what they want to do with what they actually realize shows that there are two different worlds. Action in the physical reality is not translated to the representation of the movement by the drawing. While creating a drawing they don't retain the features designated through physical action, and especially do not respect the stability of the center of rotation. The center of rotation stops being the most important point of reference in changing the position of the object.

— The angle of rotation is treated as a measure of the change of slope of the segment. This change is the essence of the functioning of the movement. It takes place in a weak relationship with the center of rotation. Perhaps this is the clearest element in this movement, showing the change. It seems likely that children are more focused on what is changed, and not on what is fixed. After all – the movement lies in the change.

— Orientation of rotated angle was accented in a very clear way. The initial position and the final position are always indicated. In subsequent stages, the final position moves into initial position - this causes that the movement is smooth, still directed in the same way.

— The measurement of the entire angle was not significant for girls. Only the initial position and fixed side of the triangle was scheduled, which was to define the first arm of the angle. Further work was regulated by the amount of sheets in the booklet – the amount of slides in the animation. Each subsequent turn was held by a small angle – about 5 degrees – but at no stage of their work this value was specified in a conscious way. It can be assumed that for the girls it was enough to have a situation where the following slides' layout was noticeably different from the initial position.

All these conclusions are related to the work of only one pair of students. Therefore they can't be the base for any generalizations. However, it should be noted, that they were students who work well with the school mathematics. For me, collected observations are the starting point for a critical analysis of the other students' work, dealing in the same learning environment.

The meaning of isometries as function of a set of points and the process of understanding of geometric transformation

Xhevdet Thaqi[1], Joaquim Gimenez[2] and Ekrem Aljimi[1]

1 University "Kadri Zeka" Gjilan, Gjilan, Republic of Kosovo, xhevdet.thaqi@uni-pr.edu, ekremhalimi@hotmail.com

2 Unversity of Barcelona, Barcelona, Spain, quimgimenez@ub.edu

In this paper, we try to show that in the process of understanding of isometric transformations, the meaning of isometric transformations is characterized as a function of whole figure to whole figure, as a function of the parts of the figure to the correspondent parts of the figure, and as a function of the set of points of figure to set of points of the same or other figures. This perception of isometric transformation has been observed in an experimental study which enabled us to define and understand different levels of difficulties in recognition of isometric transformation, from which the details are presented in this paper.

Keyword: Geometric transformation, function, teaching geometry, concept images.

INTRODUCTION

Considering low level of geometric reasoning of future teachers observed in the experiences and showed by different investigations (Thaqi, 2009), our interest is the foundations of the professional development of the prospective teacher of mathematical education. For that reason we have to design, plan and implement a practice on learning to teach the mathematics; to analyze elements of the constructions of personal meanings of future teachers about mathematics and, to recognize the difficulties of the students to understand, relate and organize mathematical contents, terms and properties associated to that content. During last years with my colleges we tried to contribute in this process focused concretely in geometrical transformations (Thaqi, Gimenez, & Rosich, 2011; Thaqi & Gimenez, 2012). In this paper we research nature and causes of difficulties in teaching/learning geometrical transformation and the relation of such difficulties with concept images constructed about geometrical transformation.

Some investigations have highlighted the reasons and advantages that provide the study of geometrical transformations (Jackson, 1975; Küchemann, 1980; Jaime, 1993; Harper, 2003; Jagoda & Swoboda, 2011; Thaqi, 2009). A main reason to study the transformation is curricular, since "The transformations are applications of the geometrical functions, and this treatment is fundamental for all the mathematics" (Jackson, 1975, p. 554). Other reason is that the transformations provide geometrical dynamic task. Despite these reasons and advantages that the transformations teaching offers, generally we know that the students show a low level of learning about the transformations (Thaqi, Gimenez, & Rosich, 2011) and we highlight that a program for the education of the teachers must integrate the same objectives that the scholar geometries classes have; the need of additional formation in formal geometry and empathize the conceptual understanding, starting from the analysis of the geometrical environment with conceptual explorations. The study of how prospective teachers build a meaning of the concept of isometrics transformation in process of understanding of geometrical properties and their relation with difficulties is one of the aims of this research.

THEORETICAL FRAMEWORK

Sundry authors have distinguished the everyday concepts (known as spontaneous) and so did the scientific (Piaget, 1970; Vygotsky, 1987). Fischbein (1993) considered that there have been seen three types of conceptual constructions in the investigation: inductive, deductive and inventive building of concept. Later on, the same author tells us that the concepts are the results of accumulated social experiences (Fischbein, 1993). We consider that there has to be built the conceptual meaning in interaction with contexts grounded in the experiences, to later build images and abstractions. Some authors like Sowder (1996) proposed that what characterizes a concept is to state an idea that is given like an answer to non similar stimulation (to varnish the understood like examples). In the opinion of Fischbein (1993) what characterizes the concept is the fact to state a idea, general representation of a class that is based in common characteristics.

The conceptual construction rests on a set of processes of construction, visualization, exploration of properties, elaboration of explanations and classifications, within others. Among more and better experiences we have, the conceptual image gets closer to the concept because, like Vinner and Hershkowitz states:

> to acquire a concept means, to acquire a mechanism of construction and identification through what will be possible to identify and build all the examples of the concept, the same way as that is conceived from the mathematical community [Cited for Jaime & Gutierrez, 1995].

As it concerns to the various investigations about the subject (Jaime & Gutiérrez, 1995; Pearman, 1990) generally they put the manifest that between the Piagetian concept of conservation of the length and the invariance there is a tight relation that they can be saved (Jaime & Gutiérrez, 1995).

The constructs "concept image" and "concept definition" (Tall & Vinner, 1981) will be useful to us also to describe the status of the knowledge of the individual fellow with a relation to a mathematical concept. It is meant to the mental entities that are introduced to distinguish the mathematical concepts formally defined and the cognitive concepts through which they are conceived. With the expression:

> concept image describes that the cognitive structure is totally associated to a concept, that includes the mental images and associated processes and properties (Tall & Vinner, 1981, p. 152).

Jaime & Gutiérrez (1995) state that in the formation of images of a concept that a person has, the experience and the examples that has been seen or used, both in a scholar and extra-scholar context have a basic role. Frequently the examples are few and the students convert them in prototypes. Jagoda & Swoboda (2011) study the process of construction of the concept in rotation spotlighting that "recognition of a specific figure to figure position is only a static image of this relationship, not connected with the movement of one object onto the other". In fact they confirm that the idea of geometrical transformation is necessary to conceive the specific movement that is transforming the initial figure into the final one, through which it is important that such conception stems from mental reflection on the phenomenon of movement. Our position is based on the meaning of the concept of geometrical transformation as a function of (whole) figure to (whole) figure that is the basic level of knowledge about geometrical transformations. It has also been shown by several authors that pre-service elementary teachers have difficulties in determining: (1) the correct attributes of transformation and motion to move an object from one point to another; (2) the results of transformations involving multiple combinations of figures; (3) the use of transformations as mathematically-general operations which require the specification of inputs, but as particular actions, each with given prototypical parameters (Harper 2003).

A recent study concerning prospective teachers' knowledge of rigid transformations (Yanik & Flores 2009) revealed that scholars: (1) started by referring to *transformations as undefined motions of a single object* which is equivalent with *Static Arrangement Figure To Figure* (Jagoda & Swoboda, 2011), followed by (2) using *transformations as defined motions of a single object*, and (3) the understanding of *transformations as defined motions of all points on the plane* which is equivalent with *transformation as function of set of points to set of points*. In our research we will try to explain that precisely these three ways of change of concept images of geometrical transformations enable us to explain and understand the difficulties of the understanding of the concept of geometrical transformation. A head we will show the relationship between the process of construction of the concept of geometrical transformation and the function of the set of the points of figure to the set of points of the (same or) another figure.

METHODOLOGY

The methodology was adapted to several techniques that allowed to approach the construction of the goals of the investigation and allowed to rate it as a theoretical formal study within the interpretative focus. In this way we have elaborated a design in which was combined the own techniques of the studies with case studies. Considering our own experience in the mathematical education of the teachers, we considered adults who acquire a professional scientific knowledge, and our work that has transformed a vision of the processes in the creation of a meaning, we identify that the investigation, action and formation are the three sides of a same methodological triangle. So, the investigation comprises theoretical component with epistemological and cultural character, also an experimental type component. These two parts of the investigation are intimately related giving the product - analysis of the speech and analysis of the personal constructions, to be able to form the conclusions of the investigation.

Participants of the study were 18 students of Faculty of Education in University of Gjilan – Kosovo. This is because two authors of this study have worked in regular lectures with these students in the program of preparing prospective teachers. Participants where purposefully chosen, and voluntary participated for this study. They are 20–22 years old students – from different, rural and urban places, from both sexes and with different studies done in prior studies. A previous curricular-cultural analysis based on textbooks, official curricular proposals and teachers' training materials, of these context is the same as showed in the deep study (Thaqi, 2009), not detailed in this paper.

During the development of the practical sessions dedicated learning to teach geometrical transformations, there has been prepared for every student, work sheets, to be able to have their productions and later analyze them. The quantity of the practical sessions and their length is what we present in the following table (see the main ideas in Table 1).

The results of a final semi structured questionnaire, was the basic data considered in this paper. Data were collected from descriptive notes, reflective notes, interviews and video records. The collected data was analysed using method described by Strauss & Corbin (1998) along with analytic induction. Such a questionnaire is the last step for a more wide developmental study in which group of students have the same training about learning to teach geometrical transformations (Thaqi, 2009).

The activities have been realized in usual classrooms of the Faculty of Education. In the group there were 18 students of 3rd grade of the study program of primary education. Some other questions were added to identify reasoning and specific cultural elements about geometric transformations, ideas about teaching and learning, and about their thinking about future classrooms in teaching geometrical transformations. The students come to the final test after having taken training course (Table 1) about teaching geometric transformations in the school, during spring semester 2013 course. The students were given the question-

Aspect of meaning of geometric transformation	Identified Activities
Isometrics and the everyday life (SI)	Presentation: An experience about isometric transformation - (SIP)
	1.2. The activities about the isometric transformations (SIA)
	1.3. Didactical activity: Presentation - video of teaching symmetry (SID).
Learning the usage and the value of the sources to teach the transformations (SR)	2.1.Presentation: *Scientific article as resource for teacher education* (SRP)
	2.2. Activities about didactical sources and geometrical transformations (SRA)
Projections and shadow (SP)	3.1. Recognition of work about shadow in primary school (SPP)
	3.2. Properties of shadow (SPA)
Reasoning, arguing and justification of geometric transformations (SA)	4.1. Presentation of topics (SAP)
	4.2. Activities about reasoning, proof and justification of geometr. transformations. (SAA)

Table 1: Sets of questions related to mathematical ideas about transformations

naire the last day of the course, and all students have responded to the questionnaire. The issue in focus is the identification of the prospective teachers' concept images and the way they make use of their images and the mathematical definition of certain concepts for geometric transformations that they will find central when they begin their professional life as mathematics teachers. The selection of questions in the questionnaire is closely related to the realized, the same four sessions of didactic practice on learning to teach geometric transformations, in the Faculty of Education in Gjilan.

In the sessions showed in Table 1, there are presented activities that one of the investigation goal was to prepare activities where, the basic knowledge of geometrical transformations are based in the intuitive teaching and experiences about the search, the discovery and the comprehension from the prospective teacher. In this way, the prospective teacher learns the knowledge and geometrical properties from the everyday world aspects constructing them as the concept image. In the first sessions (SI and SR) there is realised the treatment of the isometrics, the development of activities of using various resources. In the session SP there is developing activities to learn how to teach the non-isometric transformations (deformations, projections), while the session SA holds activities of the development of the capacity of arguing, justifying and reasoning in the process of personal construction of the meaning of geometrical transformation.

The students were asked to give an explanation to the following aspects: terminology and type of transformations, properties and relations on transformations, processes of changes, and other aspects about geometric transformations as reasoning, teaching, attitude, etc. We analyzed how the prospective teacher approaches to recognize isometric transformation and construct concept images during the process of a practice of learning isometric transformation; how is the level of recognition of the relationships and the hierarchy between different properties, and levels of difficulties in reasoning about the isometric transformations and communication of the results.

RESULTS

In the analysis of the context (Thaqi, 2009) we have seen that the Program of Geometry in Faculty of Education, talks about the formative teaching, and plans the contents as a set of knowledge and procedures. The study of geometry in this program has as a goal the mathematical knowledge, that basing on the qualified posture as formalist it can be understood as the rules that from some affirmations logically are followed some others. We present now the analysis of the moments of progress or difficulties of the student for future teacher of Primary school, in the process of building the idea of geometrical transformation that figure A is transformed in figure B, the usage of the adequate terminology in every case and identification of different types of transformations. Few students talk explicitly about the isometrics as a transformation that conserve the size and shape. Instead, they do identify the symmetries, rotations and translations as transformation as such property. Anyhow, in some cases, the activity makes the intuitive go ahead the structured knowledge. In that way, when we are in front of the observation of the embroidery, some students show rotation as a unique isometric, since they identify it as the only transformation that acts on the module that is marked (Figure 1). So, the conceptual image of the geometrical transformation is build basing on visual properties (transform=deform), and movement (Isometric=displacement).

Firstly, let´s say that in some cases the transformation is seen as a function of a set of points to the other one, but that function isn´t identified between the posi-

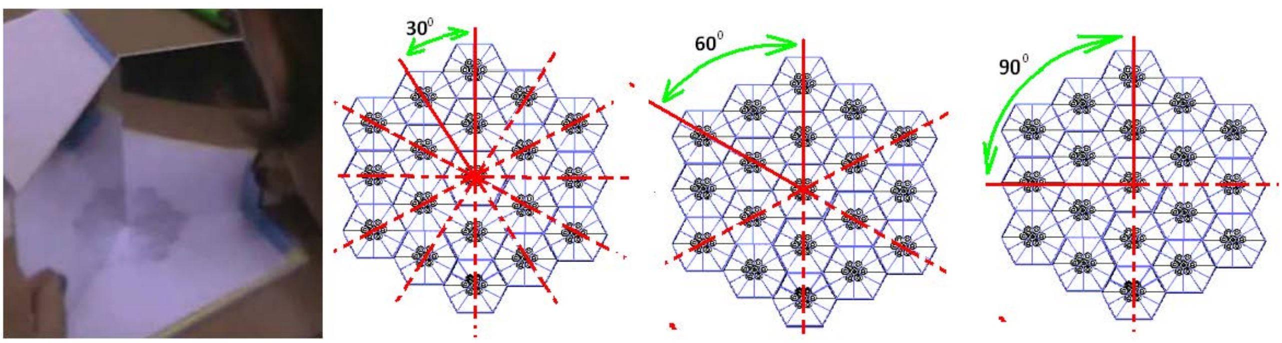

Figure 1: Reproduction embroidery using mirrors

tions of the objects in two different places. This can be explained with the symmetric figures, because it gets established easily the correspondence between the two parts of the figure or object. Instead, for other types of transformations, they should imagine the initial and final position of the transformed figure to be able to establish the idea of transformation as function or correspondence between parts of figure. We got convinced that it´s that way when we analyzed the answer to the problem where there is asked to explain the transformation of the figure A in the figure B, when Blerina (participant of investigation) explains it using transformation of set of points in the figure A on the correspondent points of the figure B. Only one of all participants' talks about isometric transformation as a transformation that conserves the shape and size – conservation of shape and size is the definition of function; while the others identify it as a repetition - which is associated with difficulties on identifying properties of transformations. We find that considering transformation with identification of invariants (form and size) is better level than considering transformation as simple repetitions.

Indeed, in the cases of considering transformation as simple repetition (that is equivalent with considering transformation as a function of whole figure to whole figure) they do not reach to precise the angle of the rotation, around what point or axis, etc. Actually, as the Figure 2 shows, to consider transformation as a function of set of point of figure A to set of points of figure B, they feel the need of naming the vertex of the triangle, and later on, they expresses the functional dependence:

Blerina: .... firstly there has been a displacement of the point A, and during the movement of the point A, the point B and C get the position presented as in the figure.....

In that way, it is constructed the idea of rotation as a function of three points in other three points under the condition:

Blerina: ... so the point C has gone out of the column of the point A one row lower, the point B has gone on point´s A place.

The second step of this process will be to indicate the axial symmetry with the axes of the symmetry instead of the mirror: "...we would see it better if we would imagine a mirror placed in the column of the point A, where the point A is not reflected (moved) and instead, the points B and C are reflected" (explain Blerina). We observe now the findings in the case of the deformations. The activity SAA5 shows the dynamic transformation of a triangle – two stable vertexes and the third one move horizontally inside a segment (Figure 3a). The students have to explain the properties that are observed in this transformation.

About the transformation with the property of invariance of the surface and the variables; it´s interesting for us that the students first identify these properties

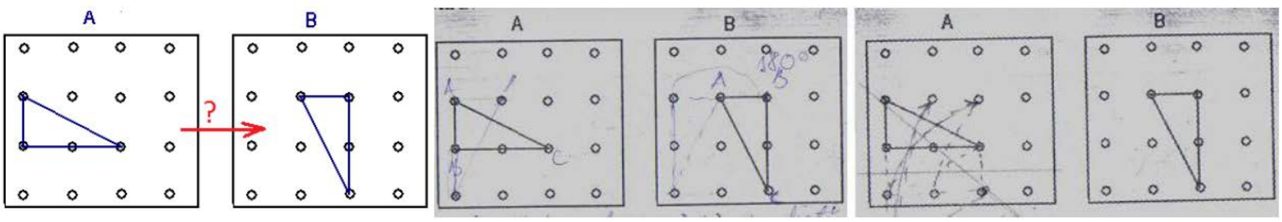

Figure 2: Transformation of triangle as function

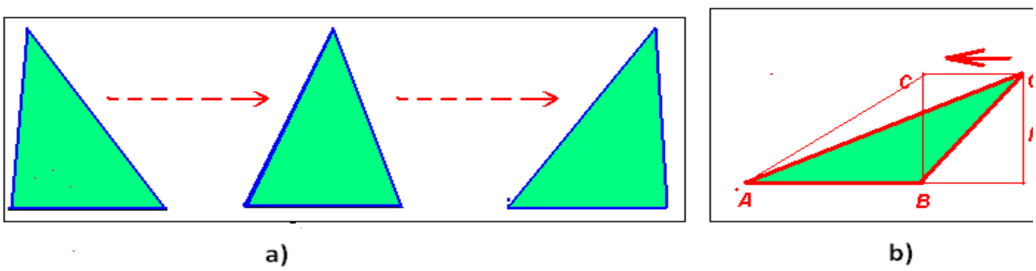

Figure 3: Dynamic transformation of triangle. Invariance and variable

and then justify the announced result. We find that Blerina identifies correctly the elements of the triangle that change and the elements of triangle that don´t change. She identifies the change of the shape, perimeter, position and what does not change like surface, base of the triangle and the height of the triangle. As an illustration we show the part of the dialogue with Blerina, who does a correct justification that the surface of the triangle does not change using the correct symbolization (the formula for the calculation of the surface of triangle: ($S = \frac{bh}{2}$) basing on the definition of the surface of triangle as a product of the base and the height (Figure 3b):

Blerina: The triangle gets converted in a rectangle triangle...
Tutor: What does change in this process? What does not?
Blerina: The height of the triangle doesn´t change.
Tutor: What other changes do we have?.
Blerina: The angles and the sides change and, the surface and height do not.
Tutor: How can you argue that the surface does not change?
Blerina: The surface of the triangle is in function of the base and the height. As said, the base and height does not change and either does the height ... so the surface is constant independently of the position of the upper vertex.

With the development of this and of the activity SAA4 we identify that the dynamic presentation of a deformation makes it possible that the students approach to recognize and build the concept of geometric transformation as a function of variables and constants $S=b{\cdot}h/2$ (this is to identify the elements of deformation that are conserved and variables). In the activities SRA3 there is asked to draw a symmetric image of the figure, having as a symmetric axis the straight line drawn (activity SRA3, Figure 4). The students have mirrors as a didactic resource for their activity. We haven´t noticed in the observation that any of the students didn´t reach to reproduce the symmetric figure from the given one. In the video recordings we have found important to describe the process of reproduction for some students. Before Blerina started to do the construction of the symmetric figure gives the comment: "I draw any figure in the plot of points. Later I draw a straight line in that way that it touches one vertex of the given figure. After that, I count that the straight line has to be the axis of the symmetry. Is it so? .... This means that I do an function of each vertex of the figure counting little squares in the other side of the axis..." Blerina does the symmetry using the properties of the symmetry: the axis, the same distances to the axis and the process of the application point-to-point. It is not needed to determine each point of the figure, she finds the vertexes of the figure and later, she uses the property of the aligned points: aligned points get transformed in aligned points (Figure 4).

High grade students recognize the transformation if they recognize the relevant elements of geometric transformation using the process of the function point-to-point, and the property of the aligned points: aligned points get transformed in aligned points.

CONCLUSION

Analyzing this findings we can say that in the program of mathematics for prospective teachers the main goal of the teaching of geometrical transformation is the informative knowledge, while is necessary program for the teacher education, intended to cultivate and practice the logical reasoning. We consider that the best is an equilibrating education between thinking and acting, or between the cultivated knowledge and

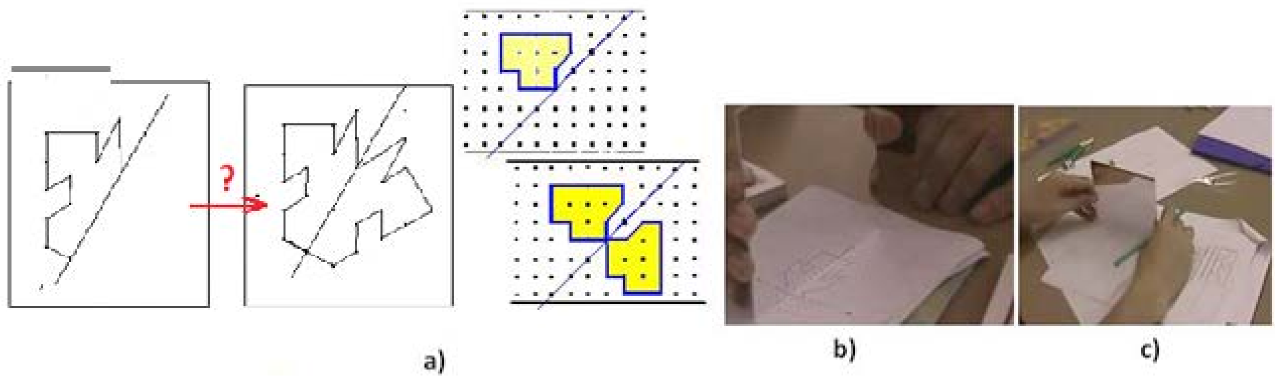

Figure 4: The process of construing symmetric figure

practical knowledge. In the cases that students recognize the transformation as a process of function of points to points, it is easy to identify the functional dependence between positions, the important properties of the transformation such as symmetry axis, vector of translation, center and angle of rotation, etc. and it established the complete concept image about isometric transformation. In cases when students consider isometric transformation as a fold, changing position or repetition of an object or figure, they are confronted with difficulties to establish the important elements of the transformation process. In other words, those who construct the idea of transformation as correspondence between sets of points do not find it difficult to have the complete concept image about isometric transformation, correctly identifying the properties and elements of that transformation as the orientation of the image, the axis of symmetry, the angle of rotation, the translation vector, invariance and variables etc.

A meta-classification for students' selections of quadrilaterals: The case of trapezoid

Fadime Ulusoy

Middle East Technical University, Faculty of Education, Ankara, Turkey, fadimebayik@gmail.com

This study aimed to propose a meta-classification for middle school students' selections of quadrilaterals in terms of trapezoid. Data were collected from thirteen seventh grade students via a trapezoid selection instrument and semi-structured interviews. Data analyses were executed by using thematic coding of qualitative research methods by synthesising past and current theories about teaching geometry (figural concepts, concept image-definition, prototypical phenomenon etc.). Meta-classification was characterized considering the types of students' selections, concept images, and errors through seven special categories. This meta-classification shaded light on how students conceive a shape as trapezoid, what they notice their selection procedure and what influences their selections for trapezoids.

Keywords: Concept images, figural concepts, prototypes, quadrilaterals, trapezoid.

INTRODUCTION

NCTM (2000) implies the importance of analyzing characteristics and properties of two-and three-dimensional geometric figures and developing mathematical arguments about geometric relationships. In this regard, one of the basic topics of geometry is quadrilaterals which involve the concepts of rectangle, square, rhombus, parallelogram, kite and trapezoid. Among these 2D-figures, there have been two different definitions of trapezoid in geometry textbooks. While one is that *a quadrilateral with exactly one pair of parallel sides*, another is that *a quadrilaterals with at least one pair of parallel sides*. As the former one is an example of exclusive definitions (e.g. parallelograms are not also trapezoids), latter one is a type of inclusive definitions (e.g. parallelograms are also trapezoids). Since the trapezoids high up in the hierarch of quadrilaterals, the choice of the definition influences the derivation of properties both of trapezoid and parallelograms, rectangle, rhombuses, and squares (Usiskin & Griffin, 2008). Despite the importance of the concept, there are a few studies specifically focused on trapezoid (Manizade & Mason, 2012; Nakahara, 1995; Türnüklü, 2014). Among them, Türnüklü (2014) conducted a qualitative study to determine middle school students' and prospective teachers' concept images regarding trapezoid. She reached that individuals used non-critical properties in non-formal and incorrect definitions and they made overgeneralizations. When considering conducted other studies, it can be claimed that scattered and limited literature related to trapezoid does not give a complete picture about students' conceptions. From this perspective, the aim of this study was to propose a comprehensive meta-classification model for students' selections regarding trapezoid. Thus, this study will put forth more complete and well-coordinated structure shedding light on how students select a shape as trapezoid, what they notice their selections and what influences their selections for trapezoids.

THEORETICAL BACKROUND

In this study, it is necessary to clarify the meaning of essential terms that used when classifying and explaining students' selections, statements, and drawings. All the required terms within the current study were described in the following.

Concept Image/Definition: *Concept image* is the set of all the mental representations associated in the students' mind with the concept name. The image might be nonverbal and implicit. On the other hand, *concept definition* constitutes a form of words which are used to specify the concept (Vinner, 1991). According to this framework, suitable and robust interactions between concept definition and concept image might guarantee the conceptual learning rather than instrumental ones. Unfortunately, learners do not make sense to link between the two elements because there might be irrelevant properties about the concept evoking in students' mind specifically. For instance, the results of some studies indicate that many of students at different grade levels have a concept image of equilateral triangle having a right angle or slanted sides of equal length (Burger & Shaughnessy, 1992; Clements & Battista, 1992). In this sense, if students are encountered limited examples having common figural features of a geometric concept in school or other context, these examples lead to prototypes phenomenon (Hershkowitz,1989).

Prototypes Phenomenon: The *prototype examples* are usually the subset of examples that had the "longest" list of attributes all the critical attributes of the concept and those specific (noncritical) attributes that had strong visual characteristics" (Hershkowitz, 1990, p. 82). Students often see figures in a static way rather than in the dynamic way that would be necessary to understand the inclusion relations of the geometrical figures (de Villiers, 1994). For instance, students receive square is not a rectangle because of their misconception about the length of the opposite sides of rectangle. Consequently, a contradiction between concept images and concept definitions emerges, which may elicit misconceptions in students' mind when classifying quadrilaterals. In the current study context, although a student has learned trapezoid as quadrilaterals with at least one pair of parallel sides, she/he may not admitted parallelogram, rhombus, square, and rectangle as a trapezoid, which clearly asserts the influence of prototype examples on relationship between concept image and concept definition that was structured in student's mind.

Personal/formal figural concepts: Geometrical concepts are characterized as having double nature by two aspects: figural and conceptual (Mariotti & Fischbein, 1997; Fischbein, 1993) similar to the concept image and concept definition (Vinner, 1991) respectively. While figural aspect involves spatial properties like shape, position, and magnitude; conceptual aspect involves abstract and theoretical nature as ideality, abstractness, generality and perfection. According to Fischbein (1993), figural aspect is generally more dominant than conceptual one. For example, parallelograms do not look like a trapezoid, but they are formally trapezoids considering the formal exclusive definition of trapezoid in our context. Based on these ideas, Fujita and Jones (2007) proposed the ideas of personal and formal figural concepts. Formal figural concepts involve formal concept images and definitions in Euclidian geometry. However, personal figural concepts were constituted through individuals' own geometry learning experiences about geometric shapes. For instance, "rectangle is a parallelogram with four right angles" is a formal figural concept definition. Besides, the expression of "a rectangle is a quadrilateral with only opposite sides congruent and four 90° angles" in a student's mind reflects student's personal figural concept.

Undergeneralization and Overgeneralization: Two types of common errors that are exhibited by students have been described in the literature as *undergeneralization* and *overgeneralization* (Klausmeier & Allen, 1978). *Undergeneralization* occurs when examples of a concept are encountered but are not identified as examples. It results when the examples provided in instruction are not sufficiently different from one another in the variable attributes (Klausmeier & Allen, 1978, p. 217). In the context of this study, for example, a student who has experienced only right trapezoids having exactly one pair of parallel sides may not identify trapezoids not having right angle even it has exactly one pair of parallel sides. On the other hand, *overgeneralization* occurs when examples of other concepts treated as members of target concept (Klausmeier & Allen, 1978, p. 217). In the current context, a quadrilateral having no parallel sides and non-equal length of sides or a polygon having more than four sides may be treated as trapezoid because of some reasons as omitting key properties of the concept or focusing only language-related factors.

METHOD

In this study, basic qualitative design methods were utilized to classify students' selections of trapezoids such as semi-structured interviews for data collection and thematic coding for the data analysis.

Participants

Firstly, an elementary school located in the capital city of Turkey was selected in order to determine the participants. At the school, there were two seventh grade classes with 47 students in total. After determining the school, I had an interview with mathematics teachers of the both classes to get information about students' mathematics grades and personal characteristics (e.g., talkative). Furthermore, each class was observed for four hours in order to monitor students' behaviors. Based on the maximum variation sampling, I conducted semi-structured interviews with 13 seventh grade students aged thirteen who were enumerated from S1 to S13. Their achievement levels were categorized according to their average math note belonging to the first and second semester. Semester notes were categorized as 5-5 was *high*; 5-4, 4-5 4-4, 3-4 and 4-3 were *middle*; and 3-3 and lower ones were *low*. According to semester notes, three students (S1, S2 and S3) were attended low achievement level. Five students (from S4 to S8) were attended middle achievement level and five students (from S9 to S13) were attended to high achievement level.

Instrument and data collection procedure

To understand how students select trapezoids in various polygons, researcher generated an instrument of *"Which figures are trapezoid?"*(see Figure 1). The instrument was organized in a manner of containing prototype and non-prototype polygons having different sizes and orientations. While creating the instrument, similar questionnaires about parallelogram in the literature were analyzed (Fujita, 2012; Nakahara, 1995; Okazaki, 1995). Then, a preliminary study was conducted with 86 seventh grade students to understand what they think about trapezoid concept. In the preliminary study, they only defined trapezoid and drew three different trapezoids in a grid paper. After examining the results of the preliminary study, seven possible selection categories were formed (*Note*: Details were explained in the heading of *characteristic features of meta-classification*). According to seven possible categories, figures were added into the data collection tool. Finally, data collection tool was controlled by experts and pilotted with five seventh grade students throughout the interview sessions. Before the selection procedure, participants also asked to make definition and different drawings for trapezoids to support data coming from students' selections of trapezoid.

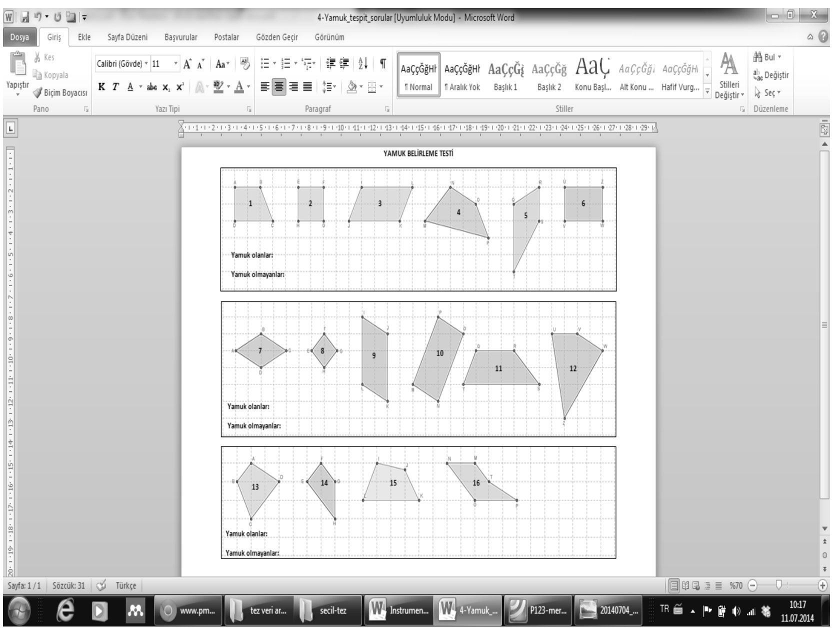

Figure 1: The instrument of "Which figures (1–16) are trapezoid?"

Data were collected via semi-structured individual interviews for in-depth analysis. Average time of an interview was twenty minutes. During interviews, participants explained their selections and the reasons why they select a figure as a trapezoid. Furthermore, they made definition and drawing of trapezoids. All interviews were videotaped and transcribed. To analyse the data, the researcher carefully examined the students' selections, drawings, and definitions. Then, thematic analysis was used to identify, analyse and report the themes in the data. For this purpose, all data were examined by taking account the phases of familiarization with data, generating initial codes, searching for themes among codes, reviewing themes, defining and naming themes, and producing the final report (Braun & Clarke, 2006).

Characteristic features of meta-classification

To propose a comprehensive meta-classification for students' selections of quadrilaterals in terms of trapezoid, I formed seven specific categories after the thematic analysis (see Table 1). The types of categories in meta-classification model were characterized considering the types of *errors*, and *concept images* with the *correctness* of students' selections, drawings, and definitions. To be more precise, the categories show the way in which students made to discriminate trapezoids in various polygons. *Error types* reflect whether students' errors have a character of undergeneralization or overgeneralization for each selection category. For instance, students either made undergeneralization by focusing only right trapezoid and exclusive selections or they made overgeneralization by selecting quadrilaterals with no parallel sides and irregular polygons. Since *types*

Category	Correctness	Image Types	Error types
Cat-1	Correct	Hierarchical	No error
Cat-2	Correct and incomplete	Partial hierarchical	Undergeneralization
Cat-3		Pure prototypical	
Cat-4		Partial prototypical	
Cat-5	Incorrect	Visual	Overgeneralization
Cat-6		Language-based	
Cat-7		Contradictive	

Table 1:* Classification of students' selections for trapezoid

*This table reflects the selections of students who learn inclusive definition of trapezoid in their lessons.

of the students' concept images changed throughout the categories, it was necessary to differentiate the concept images for each category. All other details were given in the following paragraph.

Category 1 reflects learners' correct selections of trapezoid according to hierarchical (inclusive) relation among quadrilaterals. This category indicates an ideal situation including a harmony between the two aspects of a figural concept (Fischbein, 1993). In other words, learners' personal figural concepts were completely and correctly consistent with formal figural concepts (Fujita & Jones, 2007). In *category 2*, learners can connect the correct relations between some quadrilaterals; however, they make their selections by considering partial hierarchical relations (e.g. they only select parallelograms as a trapezoid rather than selecting rhombus, rectangle etc.) even they know the geometric concept in terms of conceptual aspect. This situation supports the idea about the domination of figural aspect (Fischbein, 1993) which can be a result of encountering prototypes in learning process (Hershkowitz, 1990). *Category 3* reflects students' pure prototypical images because they select only all prototypical examples of trapezoids according to exclusive definition even they know the inclusive definition of trapezoid in written or verbal form. As a result, they do not select parallelogram, rhombus, rectangle and square as a trapezoid, which reflects undergeneralization error. According to the students, a square does not figurally a trapezoid, which reflects a conflict that may appear between the figural and the formal constraints as indicated in Fischbein and Nachlieli's study (1998). In a similar vein, *category 4* reflects students' partial prototypical concept images about trapezoid because they think only prototypical examples such as isosceles/right trapezoids, which leads the error of undergeneralization. In summary, *category 2-3-4* show students' personal figural concepts of trapezoid consist of correct concept definition and limited images. In *category 5*, learners make incorrect selections considering only similarity of the shapes in terms of position and visual appearance without thinking formal definition and critical attributes of the figure. This situation causes overgeneralization error because they treat irrelevant figures as a trapezoid. *Category 6* reflects students' language-based images because they think the meaning of the word of "*trapezoid*" in Turkish ordinary language with the meaning of "*oblique*". As a result, they image trapezoid as a figure having more than 4 sides. In other words, they treat some non-examples as examples by extending their knowledge to another context in an inappropriate way, which indicates overgeneralization error. Finally, *category 7* reflects the consistency of students' selections based on the contradiction in their between definition, drawings and selections. To sum, *category 5-6-7* indicate students' personal figural concepts of trapezoid consist of incorrect concept image and concept definition.

RESULTS AND DISCUSSION

In a general sense, results of the current study indicated that although higher level students generally selected shapes according to exclusive relations of quadrilaterals nobody made a selection on inclusive relations without a mistake. In other words, there were no students classified in *category 1&2* in which learners require connecting even partially hierarchical relations among quadrilaterals.

Category 3&4: Generally higher level students (S7-S12-S13) selected trapezoids based on exclusive relations of quadrilaterals and they attended in *category 3*. As a result, they did not think that parallelogram, rhombus, rectangle and square were also a trapezoid, which showed undergeneralization that students made with pure prototypical concept images. Students explained the selection procedure as below:

S12: (By *referring prototype trapezoid shape*) we drew trapezoid as a quadrilateral having only two parallel sides in our lessons.

S13: I remembered trapezoid as a shape having different angles and sides but top and bottom sides must be parallel.

On the other hand, two middle level students' answers (S5 and S8) were placed in the fourth category. Students chose only figures of 1 and 14 as trapezoids. They stated that there must be one pair of parallel sides in a trapezoid and they added unnecessary conditions as having two right angles. To understand their pre-existing concept images, I asked them to construct and to define trapezoid before the selection procedure. Their definitions and drawings also indicated that they had a concept image of trapezoid as a right trapezoid, which was the presence of the undergeneralization due to the restricted prototypical concept image development.

Specifically, the selections attended *category 3&4* showed students' limited understanding based on prototypical concept images of trapezoid (Fujita, 2012; Hershkowitz, 1990). Yet, their selections were interestingly based on exclusive definitions although they learned inclusive definition of trapezoid in their lessons. As a result, students tried to explain the concept based on critical attributes less than required. In other words, they made *undergeneralization*. The reason may be associated with the influence of giving prototype examples of trapezoid in the classroom and textbooks. In the textbooks, while trapezoid was defined a quadrilaterals with at least one pair of parallel sides, prototype trapezoid shapes were heavily given to illustrate the concept. Additionally, when the researcher examined students' notebooks to understand how their teachers explained trapezoid, it was received that teachers gave only prototype trapezoids. To prevent the formation of prototype concept images, it is recommended that teachers need to focus on the definitions by giving examples (e.g. quadrilaterals with at least one pair of parallel sides) and non-examples (e.g. five-sided shape or a quadrilateral with no parallel sides) of the concept (Bills et al., 2006; Petty & Jansson, 1987).

Category 5: Different from the situation in *category 3&4* students (S9, S10 and S11) having high achievement level selected the quadrilaterals with no parallel sides as trapezoid in addition to all prototypes trapezoid shapes in *category 5*. Students noticed only similarity of the shapes in terms of position and visual appearance rather than having at least one pair of parallel sides. Additionally, when researcher asked them to explain the reasons why they selected that shapes as trapezoid, their explanations indicated that they also perceived trapezoid as a quadrilateral having non-equal sides. Students' concept images were limited only visual representation of trapezoid with personal definitions rather than a formation of formal definition and properties. In this way, they reached overgeneralization for special cases by extending their information to special cases in an inappropriate way rather than considering the parallelism property as a critical attribute. At this point, Chazan (1993) proposed various reasons for overgeneralization in mathematics such as use of an insufficient set of examples, prevalent concept images and beliefs. To overcome students' overgeneralizations, the definition and critical attributes of the shape should be stressed. In this regard, using geometry software might be useful since they involve dynamic manipulations such as dragging that preserves critical attributes of the shape in the hierarchical perspective (Erez &Yerushalmy, 2006).

Category 6: Lower (S2-S3) and middle (S4-S6) level students selected an irregular polygon (the shape of 16)

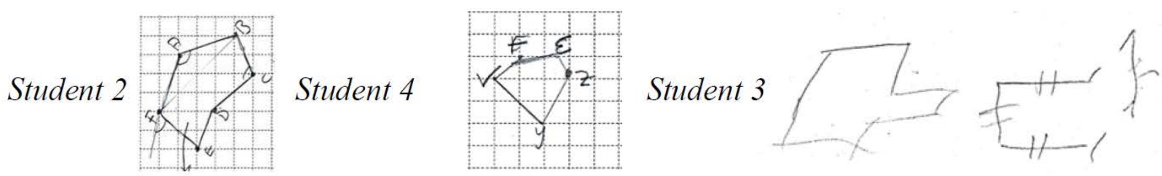

Figure 2: Students' drawings for the trapezoid in category 6

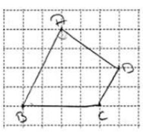
as a trapezoid with language-based concept images, which was supported by the results of similar national studies (Erşen & Karakuş, 2013; Türnüklü, 2014). Students in this category were not able to identify attributes of a trapezoid. Students' drawings were given in Figure 2 to reflect their concept images about trapezoid.

Furthermore, students written and verbal definitions indicated that they did not know the formal definition and properties of trapezoid (e.g. the number of sides) of a trapezoid. In Turkish language, the word of "*yamuk*" is used instead of "*trapezoid*" in all textbooks and teachers' instruction. However, "*yamuk*" is synonym and also means "*oblique*" in Turkish ordinary language. As a result, they made drawings under the influence of linguistic factors rather than focusing on definition and properties of the concept. Because language influences students' knowledge, ability and images about mathematical concepts (Monaghan, 2000; Silfverberg & Matsuo, 2008) teachers and curriculum developers must be more careful about whether they use both necessary and sufficient mathematical and linguistic structure for definitions of the concepts.

Category 7: This category showed the complexity of a lower level student's (S1) concept image and concept definition of trapezoid. Student's selections, definition and drawing of trapezoid contradicted themselves. Although student appeared to make a partial connection with inclusive relations by selecting parallelograms and rectangles as trapezoid, her drawing and definition of trapezoid revealed the imperfect nature of concept images in her mind.

As seen in Figure 3, although student stated there are no parallel sides of trapezoid, she drew a figure having a pair of parallel sides, but $|AB| \parallel |DC|$, and selected all parallelograms and rectangles as trapezoids, which showed student's insufficient knowledge about prerequisite concepts such as parallelism of two lines. Moreover, she drew a figure having four sides, but she selected irregular polygons having more than four sides. As a result, it can be inferred student had contradictive concept images and she did not know what trapezoid and its properties are. This result has reflected the importance of having prior knowledge about basic geometric concepts. Students' inadequate knowledge on geometric concepts may influence their concept images about quadrilaterals because many properties of quadrilaterals are based on basic geometric concepts such as parallelism and perpendicularity (Monaghan, 2000). For this reason, teachers should give more attention to whether their students obtained all required prior knowledge before introducing a new mathematical concept. As a final point, in-depth analysis of this study was limited to examination of thirteen seventh grade students' trapezoid selections. However, the idea of meta-classification of learners' selections can be applied and extended to other classes of quadrilaterals. Thus, the similarity and difference between the structures of meta-classification model may be analysed on the basis of different quadrilateral concepts. Furthermore, it will be more interesting to compare methods of teaching quadrilaterals classification in different mathematics curriculum.



S1's definition: Trapezoid is a figure. The sides of it have different length. It has no parallel sides.

Figure 3: S1's drawing and definition for the trapezoid

Signs and validation in the teaching of geometry at the end of compulsory schooling in France: A case analysis

Assia Nechache

Université Paris Diderot, Laboratoire de Didactique André Revuz, Paris, France, assia.nechache@hotmail.fr

In the first part of the communication, we present the research question, as well as the theoretical framework and methodology used to answer this question. In the second part, we describe a task given to students and provide a detailed analysis of some extracts from the session we observed. Based on the results obtained from the analysis, the last part provides a practical answer to our research question.

Keywords: *Geometry, geometric work space, validation.*

DESCRIPTION OF THE POSTER CONTENT

Section 1 – Introduction and the research aim

What is the place of signs in the validation process in geometry at the end of compulsory schooling? This question is the starting point for my communication. From the beginning of primary school, students are confronted with various geometric situations, such as: recognition and comparison of geometric forms, and reproduction of figures with drawing tools. Through these activities, they can identify invariants which are directly perceived on figures and then develop a conceptualization of geometric objects through characteristic properties. Then when they enter college, students are initiated to deductive reasoning, and thereafter engage in the transcription of this reasoning as a demonstration.

Section 2 – Research questions

- What is the place of signs in the process of validation in geometry in ninth grade?
- How does the teacher use the semiotic approach in the process of validation?

In French secondary education, teaching and learning validation (reasoning, argumentation, evidence and demonstration) represent a specific central mathematical issue (Balacheff, 1982). This teaching is initiated into the geometry field from the entry to college. Moreover, the teaching of validation is mainly based on the various registers of semiotic representation as a support to help build up a proof. This is where we use the theoretical framework. On one hand, it is necessary to consider the place of signs in the process of validation in geometry. On the other hand, we will analyze how the teacher uses the semiotic dimension in the process of validation.

Section 3 – Theoretical framework

Our analysis is mainly based on the theoretical framework of Mathematical Working Spaces (Kuzniak, 2011) and the use of the concepts of geometrical paradigms (Houdement & Kuzniak, 2006). With this framework, "style" validation adopted by teachers will be described, and particularly the way they integrate the semiotic approach in the discursive and deductive reasoning.

Section 4 – Data collection methodology

Our central question is the use of signs in the process of validation in geometry by secondary school teachers. To answer this question, we have chosen to analyze a ninth grade class session. In this session, students have to solve an exercise (chosen from the textbook used in class) using the concept of Thales' theorem and its reciprocal.

This session analysis is conducted in two steps: an "a priori" task analysis to identify paradigms at stake, as well as the validation process expected by the textbook authors. Secondly, using the geometric working spaces diagram (Kuzniak, 2013) the geometric work done during the activity is identified, allowing to see how the teacher leads the validation.

Section 5 – Results analysis

A specific working was highlighted during the validation process. In fact, the teacher uses the semiotic dimension (in a particular figure) and sets up a "maieutics" didactical contract in order to carry out his teaching project. We also notice that the mathematical work of validation put in place by the teacher himself is different than the one suggested in the textbook. This difference of validation work leads to a misunderstanding and mental blocks among students.

2 Anadolu University, Faculty of Education, Eskişehir, Turkey, nyavuzsoy@anadolu.edu.tr, dtanisli@anadolu.edu.tr

Geometrical transformations is one of the basic learning domains of geometry and mathematics teachers' content knowledge has a big impact on construction of middle school students' knowledge in this context. For this reason, the purpose of this study was to research preservice mathematics teachers' content knowledge and to design a teaching process including an appropriate scaffolding tool to provide participants to shift from informal thinking to formal thinking on geometrical transformations. According to results it was revealed that acetate could be designed as an effective scaffolding tool for developing the view of "bijective function", exploring relations, and making generalizations regarding the geometric transformations.

Keywords: Geometrical transformations, geometric habits of mind, preservice mathematics teachers.

INTRODUCTION

Unit of Geometrical Transformations, one of the basic learning domains of geometry, takes part in the Turkish Middle School Mathematics Curriculum including translation, reflection and rotation (MoNE, 2013). However, mathematics teachers' content knowledge about geometrical transformations has a big impact on the construction of middle school students' knowledge at this unit (Li, 2013). Starting from this point, we researched preservice mathematics teachers' content knowledge on geometrical transformations and what kind of scaffolding tools and learning activities can be designed with intent to improve their knowledge in this context.

METHODOLOGY

In this study designed as a teaching experiment research, participants are 28 preservice teachers enrolled in elementary mathematics education undergraduate program at a public university from middle region of Turkey. Two participants, coded as Ayse and Fatma, were selected as focal participants who would attend to clinical interviews among 28 participants.

Teaching experiment and design of a scaffolding tool

According to data obtained from pre-clinical interviews, it was seen that participants explained transformations with informal words as "moving", "folding" and they used trial-error strategies while solving problems. Starting from the constructivist approach, researchers discussed about appropriate learning tools that can provide participants to explore geometrical relations in transformations with informal experiments as "moving", "folding" and "rotating" the materials. Finally researchers decided that an acetate can be used as a scaffolding tool presenting both physical movement and one to one correspondence of points in the context. In addition to this, geometry activities were designed according to Geometric Habits of Mind (Driscoll et al., 2007) and the teaching process focused on visualization of geometrical transformations, exploring "function" meaning of transformations, generalizing strategies and discovering relationships between reflection and perpendicular bisector as well as between rotation and circle (Figure 1).

Figure 1: Using acetate for visualizing and analyzing reflection and rotation

RESULTS

During the posterior clinical interviews held, it was seen that the participants stated the role of "parameters" of geometric transformations within the context of "function". In addition, the participants, in their strategies, referred to their generalizations based on the isosceles trapezoid, radius, chord and perpendicular bisector. According to results, preservice mathematics teachers' content knowledge evolved from movement-based informal thinking to formal thinking in the context of geometrical transformations within teaching episodes including acetate mediated activities. Therefore it was seen that acetate could be designed as an effective scaffolding tool presenting both physical movement and one to one correspondence of points for developing the view of "bijective function", exploring relations, and making generalizations regarding the geometrical transformations.

OVERVIEW

TWG gathered 37 participants from 16 countries. 22 papers and 11 posters were accepted.

We started with two ice-breaker activities. The first one allowed participants to introduce themselves. During the second activity, we collected answers to two questions and organized a debate from their answers. The questions and the main answers are gathered in Figure 1.

The papers were organized into five groups, each of which was managed and chaired by one of the co-leaders.

1) KNOWLEDGE AND ATTITUDES (AISLING LEAVY)

This subtheme explored the nature of the knowledge and understandings of statistics held by *particular groups* (middle grade students, pre-service teachers) when engaged in particular tasks and activities (comparing data sets, examining data displays), or communicated in textbooks.

It identified the attitudes of learners towards statistics and identified and/or categorized knowledge and attitudes using a variety of frameworks, scales and perspectives (qualitative content analysis, procedu-

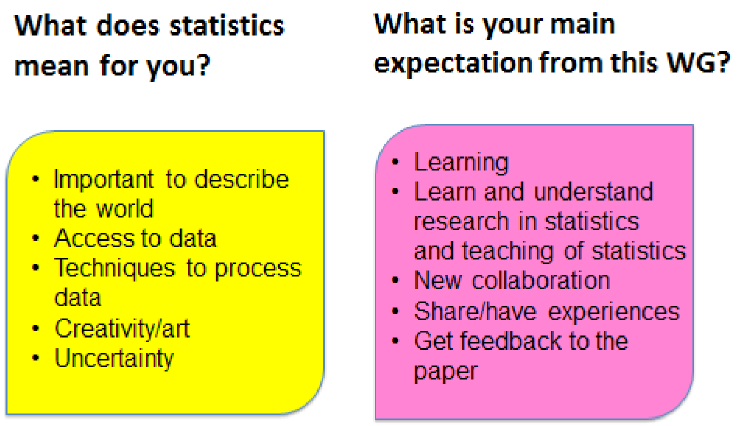

Figure 1: Ice-breaker activity responses

ral vs conceptual distinctions, Vergnaud's Theory of Conceptual Fields, Onto-semiotic approach, SATS).

2) PROBABILITY EDUCATION (CATERINA PRIMI)

This subtheme was about the relation between probability and statistics.

It addressed the questions of probabilistic reasoning and statistical literacy:

— How to integrate the different theoretical perspectives?

— When to start to teach probability?

— Which content is more suitable for different age groups?

A major question was the question of the use of simulation to teach probability and of its strengths and weaknesses.

3) INFORMAL STATISTICAL INFERENCE (SIBEL KAZAK)

The third subtheme was about informal statistical inference.

The discussion of the papers in this session focused on the key elements supporting students'/teachers' reasoning that leads to making informal statistical inferences based on data (cf. Makar, Bakker, & Ben-Zvi, 2011). These included:

— Knowledge of statistics: Statistical concepts, i.e., sampling, sample representativeness, sample size, uncertainty

— Knowledge of context given in the problem/task

— Design of learning environment: Task (i.e., use of physical objects, open-ended investigations), computer tools (i.e., TinkerPlots), students' age/level, teacher-student interaction, student-student interaction

— Transition from informal to formal statistical inference

4) STOCHASTIC THINKING AND TEACHERS (ANDREAS EICHLER)

The perspective of teachers in terms of teachers' knowledge and beliefs was the main topic in the fourth subtheme. This topic is important when researching the daily practice of teaching statistics and probability. Thus, teachers' knowledge and beliefs strongly impact on their instructional planning, their classroom practice and also impact on their students' learning. Not surprisingly, several papers at CERME9 refer to the teachers' knowledge and beliefs. Three papers concern the teachers' knowledge and beliefs before the teachers' classroom practice referring to teachers' knowledge about variability (Jacob, Lee, Tran, & Doerr), simulation approaches for informal inference (Lee, Tran, Nickel, & Doerr), and teachers' strategies for fostering decision making (Gonzales). One paper focuses on the relationship of teachers' espoused beliefs and the teachers' classroom practice (Bakogianni). Many important questions came out from the debates. For example, since research often yield shortcomings in teachers' knowledge, a challenge of research in mathematics education could be to develop a clear concept of what teachers have to know. Based on such a concept it could be possible to describe further the considerable corpus of the teachers' knowledge.

5) STATISTICS, CONTEXT AND REALITY (CORINNE HAHN)

The four papers presented in this group raise the question of the critical dimension of statistics education. These papers explore how we interpret statistical information from authentic contexts (newspaper articles mainly). The research works presented were conducted with a variety of audiences: teachers (Ozen & Cakiroglu), high school students in mathematics classrooms (Sturm & Eichler) or biology (Plicht et al.), tertiary students (Monteiro et al.).

They showed the influence of beliefs and affective aspects in the interpretation of statistical information. They raise the question of what can be considered as statistical as well as the question of the authenticity of the activities.

CONCLUSION

In this working group, we challenged current frameworks and perspectives on statistics education research.

Some important issues emerged from the discussions: The role of technology in statistical teaching and research, the relationship between statistics and probability, the goals for teacher education:

(What are the big ideas in teaching statistics?), the question of attitudes, motivation and efficacy in teaching statistics, the role of context in statistics, the question of methods and approaches to research in teaching statistics ...

We also anticipated directions of change: New role of technology, new topics (e.g., Big data...)

Studying the process of transforming a statistical inquiry-based task in the context of a teacher study group

Dionysia Bakogianni

University of Athens, Athens, Greece, dbakogianni@math.uoa.gr

Statistical inquiry, although beneficial for developing students' statistical thinking, constitutes a quite demanding task for the mathematics teacher. In this paper, I focus on the transformation of a statistical inquiry-based task. In the context of a study group of five secondary mathematics teachers, I investigate the various stages that the task passes through (set up phase, implementation phase, reflection) and explore factors that seem to frame the process of transformation. The emerging factors related to teachers' familiarity with the content and the teaching of statistics, students' prior statistical knowledge, classroom reality issues and issues related to the stochastic context of statistical problems are presented and further discussed.

Keywords: Statistics education, secondary mathematics education, teaching practice, task transformation, statistical enquiry cycle.

INTRODUCTION

Last years, statistics has increased its role in mathematics education (e.g. NCTM, 2000). The stochastic nature of statistics and the complexity of the underlying concepts and procedures require teaching approaches that promote active involvement of the students, personal investigation, experiences with meaningful contexts and explorations with real data (Jones et al., 2004).

Regarding the particularities of the statistical content, many researchers have turned their lens on the characteristics of teachers' knowledge related to the teaching of statistics (e.g., Burgess, 2007). Although the interest on teachers and teachers' knowledge for teaching statistics is growing rapidly in the statistics education research field, we still know very little on how this knowledge is transformed in the actual teaching. Rowland and his team (Rowland et al., 2009) define the *transformation* of knowledge as the ability of teachers to transfer what they know in a way that can be appropriate and accessible to students and they set transformation as one of the four categories in the *knowledge quartet* of mathematics teaching. The study of the process of transformation can contribute not only to the process of students' learning but also to the professional development of teachers. This study aims to get insight into the process of transformation in the context of teaching statistics and explore factors that seem to frame this process.

THEORETICAL BACKGROUND

Statistical tasks that promote inquiry in the classroom, engage students in a dynamic context where they explore, negotiate, make interpretations, search for solutions, communicate their results and proceed to informal inference. Such tasks are considered as essential learning experience for the students (Garfield, 1995).

Chapman (2013) argues that the way teachers transform what they know into tasks for their students, determines students' opportunities to engage in a meaningful way with mathematical activities and develop a conceptual understanding of concepts and procedures. Stein and Lane (1996) state that, the structural characteristics of a mathematical task (features, cognitive demands) can be changed through the process of transformation, often failing to achieve its learning potential. According to their findings, the transformation process of a mathematical task can be affected by various factors, such as teachers' learning goals, teachers' knowledge related to the content and to the students, factors related to the classroom norms and students' behaviour, which alter the high-demanding character of the task to a low one.

Regarding statistical inquiry tasks, Makar (2008) refers to some teaching skills that are almost rare in mathematics classroom but remain essential for statistical activities. Among these skills are: the ability to cope with ambiguity and uncertainty, the re-balance between teacher guidance and students' independence, the recognition of opportunities for learning in unexpected outcomes, flexible and creative thinking, deep understanding of disciplinary content and tolerance for periods of noise and disorganization. Considering the particularities of the statistical context, my aim is to study the process of transformation in the case of inquiry-based statistical tasks and identify factors that seem to affect the learning potential of such tasks.

I see the transformation process in the context of a study group. Many researchers emphasize the utility of study groups as form of professional development for teachers and refer to how the educational community can benefit from the research of study groups in order to get insight into how teaching practices are developed and changed (e.g., Arbaugh, 2003). I also explore the potentiality of this context to study the process of transformation in the case of statistical inquiry tasks, and investigate factors that seem to frame this process.

THE STUDY

In the context of a study group, 10 secondary mathematics teachers and two researchers worked together voluntarily for a period of two academic years (2012–2014). The groups' work focuses on the teaching and learning of statistics through a sequence of (a) deepening in a specific topic (b) design a task for the classroom-*design phase* (c) implement the task in the classroom-*implementation phase* (d) reflect on this experience-*reflection phase*. The role of the researchers in the study is mainly to finalize the groups' meetings' agenda and support the teachers by giving them particular tasks, materials and resources. Collaboration and interaction among the teachers was encouraged in all phases of their work.

In this paper I focus on five teachers who worked as a team on the design and implementation of the statistical investigation cycle in the mathematics classroom.

The participants of the study

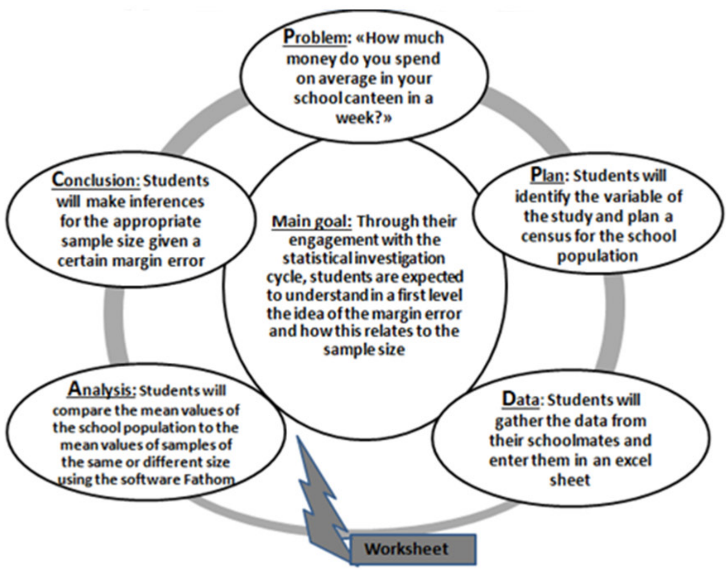
All five teachers have a mathematics degree and postgraduate studies in mathematics education. Dinos, is a practising teacher with 10 years of teaching experience while the others, Sofi, Cloe, Anna and Ersi are novice teachers with little teaching experience. Although the practising teacher has no particular experience in teaching statistics, he is quite familiar with the statistical content due to personal involvement in statistical methods, while novice teachers' involvement with the statistical content is limited to their university experience. Due to the lack of teaching experience and to their unfamiliarity with the statistical content, the four novice teachers consider Dinos as a team leader.

The work of the group

The five teachers were asked to design a task for the classroom and implement it. For the design, the teachers were supposed to build on the former phase of the study groups' work in which they had focused on sample and sampling notions and their relation to the concept of probability. For this phase the teachers met seven times, each meeting lasted about two and a half hours. The author was present in all meetings, and the wider group met in the four of the seven meetings (10 teachers and 2 researchers), exchanging views and giving support to one another.

The task was intended for the 8th Grade students with no background in statistics. The main learning goal, as set up by the teachers, was to help students understand in a first level the idea of the margin error in statistical results and how it relates to the sample size. The teachers decided to engage students with all the steps of a statistical investigation cycle based on the PPDAC (Problem-Plan-Data-Analysis-Conclusions) model (see Wild & Phannkuch, 1999) transformed as seen in Figure 1. As seen in the picture, a worksheet was designed between the steps of Data and Analysis. This worksheet aimed to introduce students to the concepts of mean value, sample and margin error that were necessary for the last steps of the statistical investigation.

The task was implemented in Dinos' classroom. Although all the members of the team were present in the implementation, Dinos had the leading role while the others (including the author) were mainly observers, taking field notes and supporting the various stages of the task. The implementation covered 5



Mathematical aspects

- Ability to calculate the mean value
- Ability to construct and read tables and graphs
- Ability to find from a given set of numbers all possible combinations of given size subset
- Conceptual understanding of the concept of probability and connecting it with the sample concept

Stochastic aspects

- Understand sources of variability in a sampling method
- Organize and manage real data
- Making interpretations of the data displays in relation to the reference problem
- Use statistical tools to answer to posed questions
- Make (informal) inferences for the reliability of a given sample

Figure 1: The investigation cycle as performed by the teachers and the related skills

didactical hours (1hour for PPD steps, 2hours for AC steps and 2 hours for the worksheet between).

After the implementation the group met two more times for feedback and reflection. The first time the discussion was based on their impressions regarding students' reactions and an overall assessment for the teams' work. In the second meeting, the teachers were asked to analyze more systematically the characteristics and the cognitive demands of the designed task and to evaluate the consistency with the initial goals and demands in the implementation phase. The group had a three-hour meeting discussing on their analysis and reflecting on their practice.

The data of the study consist of the audio and video recordings from the seven meetings' regarding the design phase, the field notes from the implementation and audio recordings from the two meetings of the reflection phase.

Analysis of the data

The first analysis of the data was conducted in collaboration with the teachers. We used the Stein's & Lane's (1996) framework for the relationship between instructional tasks and students' learning outcomes. Stein & Lane identify three stages that instructional tasks pass through: (a) instructional task as represented in curricular/instructional material (b) instructional task as set up by teachers in the classroom and (c) instructional task as implemented by students in the classroom. In each of these stages, they define two interrelated dimensions, the task features and the cognitive demands. The task features refer to characteristics of the task that are related to the engagement of students' reasoning, thinking and sense making, such as the extent to which the task lends itself to multiple solution strategies, the extent to which the task encourages multiple representations or the extent to which the task demands explanations from the students. The cognitive demands refer to the kind of thinking processes contained in the task, such as use of complex, non-algorithmic thinking or use of procedures with connection to underlying conceptual ideas.

Following this framework as a guide of analysis, we identified the task's features and cognitive demands and analyzed them in the set up and the implementation stage. For the set up, based on the audio recordings of the groups' meetings and the final worksheet intended for the students, we made a characterization of the extent to which these features and cognitive demands were supported by the design of the task. This characterization was mainly on a Small/Big note. Afterwards, using the field notes from inside the classroom, we studied the consistency of the design in the implementation phase. For example, if we note as Big the extent to which the task demands explanations from the students, we then explored if, through the implementation, this demand remained in a big extent or declined or supported more than expected. For every change identified between the set up and the implementation we further discussed possible factors that may influence such a change. The analysis of the task was part of the study's group work.

	Features and Cognitive Demands as identified in the task designed by the teachers	Extent of demand in the various steps of the PPDAC cycle SET UP PHASE					Extent of demand in the various steps of the PPDAC cycle IMPLEMENTATION PHASE				
		P	P	D	A	C	P	P	D	A	C
FEATURES	multiple representations				B					√	
	explanations from students	B	B	B	B	B	√	√	√	–	–

Table 1: Features and Cognitive Demands in the various phases of the task

In a second analysis, using the transcriptions of the groups' discussions from the design and the reflection phase, I focused on the process of transformation. The data were analysed with respect to the two dimensions as explored in the first part of the analysis, namely tasks' features and cognitive demands, focusing on factors that seem to frame the observed consistency or shift on the various elements of the task.

FINDINGS

The results from the first analysis, which was conducted in collaboration with the teachers, are described on Table 1.

As seen on the above table, in the set up stage the teachers aimed at large extent features and cognitive demands that set the task as a high-level activity for the students.

The fact that the teachers worked as a team during the design phase combined with the fact that all of them supported the implementation phase, were conditions that could lead to the assumption that the demands of the activity would remain in a high-level through the implementation, contrariwise, things proved to be different. In the most cognitive demanding parts of the PPDAC, the most of the task demands show a decline in the extent to which they were sustained. Since the analysis of the features and demands of the task is not central in this paper, a more detailed description of this phase's results is available in our research report, regarding teacher's reflection on the of PPDAC in the mathematics classroom (see Efstathiou et al., 2014).

The group's discussions from the set up and reflection phase helped me to get insight into factors that seem to frame the transformation process. The factors emerged from the analysis regarding the two dimensions under study, tasks' features and cognitive demands, were grouped in terms of whether they indicate consistency or shift. In Table 2 there is a summary of the main factors as appeared in each group.

Shifts on tasks' features	Shifts on tasks' cognitive demands: Shifts on mathematical demands	Shifts on tasks' cognitive demands: Shifts on stochastic demands	Maintenance of learning potentials
• students prior knowledge • time limitations • lack of access in a computer room so that students can experiment on an appropriate software tool	• students' prior knowledge • difficulty in the management of alternations from the mathematical to the realistic context • inappropriate ammount of time	• overemphasis on mathematical ideas • lack of balance between teacher's guidance and student independence • inappropriate amount of time alloted to the various parts of the task • disconnection of the reference context • inappropriateness of tasks and examples • time limitations	• strengthening of teachers' subject matter knowledge • teachers' flexibility and availability to act in the moment • collaboration among teachers

Table 2: Factors that frame the process of transformation in the case of a statistical investigation cycle

Shifts on task features

On the left column of the table, I refer to factors that seem to cause a decline into the features of the task through the process of transformation. The first factor that seems to be essential is the prior knowledge of students. The fact that students did not have any previous statistical knowledge, resulted in the teachers' decision to limit students' engagement in several parts of the task at the set up phase (e.g., on the decision of the statistical variable or the method of the investigation). The same factor compared with time limitations led to a decline on giving students space for explanations and active engagement. Moreover, in our case students did not have access to a computer room and this proved to be a crucial factor. According to the design of the task, the teachers were supposed to counterbalance this restriction by giving time to students to discuss and negotiate throughout the activity on the software, but due to time limitations there was no appropriate time for interaction and discussion causing a further decline in the engagement feature. Characteristically, Dinos admitted in his a posteriori analysis: "We didn't prevent students from being observers. I tried to engage them by asking questions, but the time was too limited, I am not sure that they could easily follow what was happening, the majority of them probably couldn't."

Shifts on task's cognitive demands

The factors regarding cognitive demands were separated into two subcategories, the cognitive demands related to mathematical issues and the cognitive demands related to stochastic issues (see Figure 1). The mathematical issues of the tasks refer to the first two demands as displayed on Table1 while the stochastic refer to the other three. The lack of students' prior knowledge in statistics resulted in dedicating time for constructing the necessary background for the goals of the task. Nonetheless, students seem to have coped well with the mathematical demands when they worked on the mathematical context but had difficulties when they needed to transfer their mathematical knowledge to the reference context of the problem. Moreover, due to time limitations there was not enough time for the teachers to make the appropriate connections and students remained to trust more their intuitions than their mathematical knowledge to make conclusions for their problem.

The cognitive demands related to stochastic issues proved to be the most challenging to maintain in a high-level during the process of transformation. First, the teachers' overemphasis on the mathematical ideas seems to act as barrier in their aim to help students develop statistical thinking. Characteristically, Dinos, in the discussion through the reflection phase, admitted: "In my view I could say that we succeed in helping students connect the sample notions with the concept of probability, but, the development of stochastic thinking proved to be difficult. I am not sure that we succeed in that."

In addition to this, another factor that seems to play a crucial role is the disconnection of the reference context of the problem. The disconnection of the reference context results in disorientating students from the underlying problem and they tend to think more in terms of what is right and what is wrong and less in terms of what is reasonable and acceptable. Although the teachers tried to restrict the effect of disconnection, they didn't spend adequate time on the necessary connections causing a decline in the cognitive demands of the task. The allocation of available time in the various parts of the task, is also an emerged factor in the transformation process. The above extract is indicative of the teachers' reconsidering the time allocation:

Dinos: If I were to implement it again, I would spend most of the time on the experimentation with the software. Students need to explore themselves, to see, to explore more and more samples. This is how they can start thinking in a different way.

Cloe: I totally agree with Dinos. We spent a lot of time in talking about combinations and we lost our goal. The point is the statistics. It is important for students to have the opportunity to make their own explorations. I don't think that the way we used the software was rather beneficial for the students. They needed more time in working on the software.

In the extract above, another factor is apparent, the balance between teacher guidance and student independence. The restriction of students' independence was something that results on a decline of the statistical thinking demand from the set up phase, and due to time limitations a further decline was caused in the implementation phase. The teachers seem to develop an awareness of the difficulty to encourage students' statistical thinking, and also an appreciation for the role of the exploration and personal engagement with data in this respect.

Another factor is the appropriateness of chosen examples. In this case, the teachers, in order to help students understand the variety of possible samples in a given population and understand better the meaning of the margin error of the mean in a sample with a given size, gave students an example of population with size 5 and asked them to explore all possible samples with size 3, but according to Dinos reflection: "this example gives students the impression of a certainty that does not exist in bigger populations, actually framing their stochastic thinking."

Finally, as in the previous category, time limitations seem to be dominant in this case as well. Students proved to need much time in order to develop statistical thinking, time for more explorations, more discussions and inquiry processes, but the time available was not the appropriate. For their attempt to challenge students in the way they use proportional reasoning when they think about samples they discussed:

Sofi: I think that we manage to make them conflict with the idea of proportionality.
Dinos: Yes, we actually did it, but, then what? You could see that there is nothing to come after. When they rejected the proportionality, they answered almost randomly. The development of an alternative thinking, more distributional, needs time, it requires more data explorations by the students themselves.

Although the teachers in the design phase had considered proportional reasoning as a potential obstacle, they didn't anticipate students' difficulty in proceeding to distributional reasoning. This difficulty appears to be unexpected and hard to handle.

Maintenance of learning potentials

In this last category I included factors that seem to act beneficially in the process of transformation. The first factor is the strengthening of teachers' subject matter knowledge. In the phase of the task design, the teachers discussed a lot on the statistical concepts and procedures, they read textbooks and research reports regarding the investigation cycle and they asked for help and clarifications in many instances. This route helped them to identify specific learning goals, to recognize the underlying concepts in the various steps of the PPDAC and to support challenging learning opportunities for the students. Moreover, the collaboration among the teachers seems to act as catalyst for the process of transformation. The interactions among them and the feeling of support in every step of the design and the implementation, seem to help them form and accomplish high-levels of statistical activity for the students. It is indicative that in the reflection phase, all the teachers mentioned that they wouldn't try such an activity if they didn't have the support of their colleagues.

Another factor that seems to be essential is teachers' flexibility and availability to act in the moment. In our case, the fact that the task was mainly implemented by Dinos, who is an experienced teacher with familiarity to the statistical content, had a great impact in the task's features. For example, in the extract below the teachers discuss on the questions that would be posed to the students in the part of the data analysis:

Anna: This part requires a lot of guiding by the teacher. Let's write down the questions step by step.
Sofi: We don't need to be so strict with the questions. It will be better to be more open, to give more space to students.
Anna: Don't we write the questions?
Sofi: Don't forget that Dinos is the one who will manage this. Dinos can handle it.

From this extract, we can see a feeling of insecurity regarding open questions. The fact that the team members seem to trust Dinos' ability to act in the moment affected the engagement of students during the implementation.

CONCLUSION

This study helped us to get insight into the transformation process of a statistical investigation task. Regarding the context of statistics, the management of the uncertainty proved to be, not only a difficult learning goal to achieve, but also a significant teaching challenge. The factors that appeared to affect the transformation process constitute an amalgam of teachers' subject matter knowledge, teachers' skills and abilities to confront with uncertainty and manage classroom discussions and teachers' knowledge of students in terms of students' prior knowledge and of ways students can be assisted in developing stochastic thinking as well. Many of the required skills and abilities, although determinant in statistical inquiry as mentioned by Makar (2008), are rare in mathematics classrooms. The collaboration among the teachers seems to encourage them to support statistical inquiry and promote high cognitive demands in the mathematics classroom. Through collaboration and interaction, teachers have the opportunity to understand deeper the statistical concepts and procedures, to define specific learning goals regarding the statistical content, and to be aware of learning difficulties that are related to them. Moreover, the support among the teachers in the implementation phase, and the collaborative management of classroom, can result in an increase regarding the use of open questions and inquiring strategies by the teachers.

On the other hand, an overemphasis on mathematical ideas and disconnections of the reference context of the problem, can result in a decline of the stochastic demands of the task. Furthermore, limitations regarding the time allocation in the various parts of the task, the use of inappropriate examples and the imbalance between teacher's guidance and students' engagement, can also cause a decline in the task's cognitive demands. Other factors that appeared to play a crucial role on shifts in the characteristics of the task are students' unfamiliarity with statistical concepts compared with the limited time available for exploration and development of conceptual understanding. Lack in access of statistical software, that allows students to interact with the data, is an additive obstacle to helping students develop stochastic thinking.

Stein's and Lane's (1996) framework proved to be useful not only as a tool for exploring the transformation process but also as a tool for teachers' reflection. The analysis of the characteristics of the task and the investigation of shifts through the various stages that instructional tasks pass, seemed to help the teachers evaluate their practice, identify sources of complexity and consider alternative strategies to develop more effective teaching.

Gender differences in attitudes toward statistics: Is there a case for a confidence gap?

Francesca Chiesi and Caterina Primi

University of Florence, Florence, Italy, francesca.chiesi@unifi.it

Female students tend to underestimate their abilities and to have more negative attitudes toward quantitative disciplines when compared to male students. In teaching statistics this concern has to be taken into account since it may create an obstacle for learning. The aim of the present study was twofold: to test if women had less confidence and more negative attitude than men regardless their actual abilities, and to investigate if achievement in statistics was affected by these factors controlling for gender. Results showed that women did not differ in their abilities but showed less confidence and more negative attitudes when compared to men. Moreover, confidence and attitude played a role on achievement in women but not in men. The importance of enhancing attitudes toward statistics in female students was discussed.

Keywords: Statistics education, attitudes toward statistics, gender differences.

INTRODUCTION

Since statistical literacy is a key ability expected of citizens in information-laden societies, and is deemed a necessary component of adults' numeracy and literacy (Gal, 2002), it is crucial to develop students' statistical learning. To accomplish this goal, i.e., to provide students with tools for understanding data-related arguments, building intuition about data, and making reasoned judgments and decisions in their professional and private lives, statistics has been included into a wide range of university programs. Thus, in many countries students progressing towards a degree other than statistics have to pass at least a compulsory statistics exam, and concerns related to teaching and learning statistics are internationally shared (for a review see, e.g., Zieffler et al., 2008).

In teaching statistics in postsecondary education gender might be a relevant factor since, although all students experience stress and difficulties in learning statistics, female students are more likely to feel uneasy in dealing with this discipline. Indeed, they tend to underestimate their abilities and to have more negative attitudes toward quantitative disciplines when compared to male students. For instance, referring to mathematics, it has been shown that women' self-efficacy is consistently and significantly lower than those of men (e.g., Pajares & Miller, 1994; Stevens, Wang, Olivarez, & Hamman, 2007) regardless their actual ability (Quest, Hyde, & Linn, 2010). This phenomenon, called the *confidence gap* (Sadker & Sadker, 1994), emerges during the high school years and impacts on the subsequent scholastic/academic choices, i.e. female students tend to avoid scientific secondary and postsecondary degrees and prefer non-mathematical ones (e.g., Halpern et al., 2007).

Nonetheless, female students enrolled in non-mathematical degrees such as Psychology, Education, and Health Sciences encounter statistics courses in their programs. Thus, it is likely that their *confidence gap* might affect their approach to a discipline like statistics. Indeed, it has been widely demonstrated that, along with cognitive components (e.g., mathematical knowledge and general scholastic background), non cognitive factors play a determinant role in learning statistics (Chiesi & Primi, 2010; Harlow, Burkholder, & Morrow, 2002; Nasser, 2004; Schutz, Drogsz, White, & Distefano, 1998; Tempelaar, Van Der Loeff, & Gijselaers, 2007; Tremblay, Gardner, & Heipel, 2000; Wisenbaker, Scott, & Nasser, 2000). Among the non cognitive factors, large attention has been paid to the attitudes toward statistics that include a self-confidence dimension (e.g., the trust in one's own knowledge and skills when applied to statistics) along with measures of feelings concerning statistics, and beliefs about the usefulness and the difficulty of statistics.

Starting from these premises, the present study aimed to investigate the relationship between attitudes toward statistics and achievement in male and female psychology students attending introductory statistics courses. In detail, the aim of the present study was twofold: to test if females showed more negative attitudes toward statistics (and, specifically, less self-confidence) than males, and to investigate if attitudes affected their achievement. These relationships were investigated controlling for the students' actual ability, i.e., mathematical basics deemed necessary for introductory statistics courses.

As refers to the first aim, literature on gender differences in attitudes toward statistics reports contradictory results. Some authors reported that men expressed more positive attitudes toward statistics than women (e.g., Auzmendi, 1991; Tempelaar & Nijhuis, 2007). Others found no gender differences (e.g., Estrada, Batanero, Fortuny, & Díaz, 2005; Judi, Ashaari, Mohamed, & Wook, 2011; Martins, Nascimento, & Estrada, 2011; Schau, Stevens, Dauphinee, & Del Vecchio, 1995; Wisenbaker et al., 2000). Some others have reported more positive attitudes for women (e.g., Mahmud & Zainol, 2008; Rhoads & Hubele, 2000). Assuming that those differences might be partially related to the sample characteristics (engineering students, economic students, psychology students, pre-service teachers), and referring to the above mentioned literature on the *confidence gap*, we hypothesized that psychology female students had more negative attitude toward statistics than their male counterpart, and, specifically, they show less confidence in their knowledge and skills when applied to statistics.

From a different perspective, i.e., the "stereotype threat" theory (Spencer, Steele, & Quinn, 1999), it could be argued that since psychology female students are not confronted with many male students, they should have higher confidence and more positive attitudes. Indeed, the "stereotype threat" refers to the concern that is experienced when one feels at risk of confirming, as self-characteristic, a negative stereotype about one's group. Given the stereotype concerning gender and math ability - that propose that women have less mathematical aptitude than men-, several studies suggest that gender differences in math performance occur in environments in which gender identity is salient, e.g., a class with a majority of male students is sufficient to create a threatening environment for female students. Nonetheless, in this stage of our research, we were interested in measuring students' competence and attitudes at the beginning of the course in order to highlight the way in which the students start to deal with statistics. As such, in line with previous studies (e.g., Chiesi & Primi, 2010; Nasser, 2004; Schutz et al., 1998) we assume that their initial attitudes do not depend on the current educational context, but on their previous experience with quantitative disciplines during the high school. Additionally, as reported by Hyde and colleagues (2008) and Quest and colleagues (2010) for mathematics, we hypothesized that, regardless gender similarities in abilities, women had less confidence and overall more negative attitude toward statistics than men.

Concerning the second aim, we investigated the relationships among mathematical competence, attitudes and achievement in men and women. Referring to literature on cognitive and non cognitive factors influencing statistics achievement, we hypothesized that mathematical knowledge has an effect on achievement (e.g., Chiesi & Primi, 2010; Harlow et al., 2002; Schutz et al., 1998; Tremblay et al., 2000; Wisenbaker et al., 2000), and, referring to the literature on female students' attitudes toward the quantitative disciplines (e.g., Hyde et al., 1990; McGraw et al., 2006; Pajares & Miller, 1994; Stevens et al., 2007), we hypothesised that attitudes, and especially self-perceived competence, might impact on women' performance differently than in men.

METHOD

Participants

Participants were 179 psychology students enrolled in an introductory statistics course at the University of Florence in Italy. The course was compulsory for first year students that represent the majority of the sample (91.3%). The course was scheduled to take place over 10 weeks, at 6 hours per week (for a total amount of 60 hours). It covered the usual introductory topics of descriptive and inferential statistics, and their application in psychological research. During each class some theoretical issues were introduced followed by examples and exercises. Students were requested to solve exercises by paper-and-pencil procedure (no computer package was used), and then solutions were presented and discussed.

Participants' age ranged from 19 to 54 with a mean age of 22.0 years (*SD* = 5.26). Female students were 113 (*mean age*= 21.9, *SD*=4.77) and male students were 68 (*mean age*= 22.7, *SD*=6.24). All students participated on a voluntary basis after they were given information about the general aim of the investigation (i.e., collecting information to improve students' statistics achievement).

Measures and procedure

In a previous study (Chiesi & Primi, 2010), we provided evidence that some mathematical basics are needed for introductory courses and to measure them we developed the *Prerequisiti di Matematica per la Psicometria (PMP)* scale (Galli, Chiesi, & Primi, 2011). The contents were defined on the basis of the basic mathematics abilities requested to solve descriptive and inferential statistics problems. The PMP is composed of 30 multiple choice (one correct out of four alternatives) questions including fractions, set theory (inclusion-exclusion, and intersection concepts), first order equations, relations (between numbers that range from 0 to 1 and numbers expressed in absolute values), and probability (base-rates, independence notion, disjunction and conjunction rules). Fractions are employed both in descriptive and inferential statistics tasks (e.g., to compute the standard deviation, as well as the *t* or *z* values). Equations are required, for instance, in the standardization procedure and in regression analysis. Establishing relations between numbers is necessary to compare the computed and critical value in the hypothesis testing. Set theory principles help to understand probability rules, and basics of probability are the prerequisite of the hypothesis testing. A single composite, based on the sum of correct answers, was calculated (range 0–30).

Attitude toward statistics was measured administering the 28-item version of the *Survey of Attitudes toward Statistics (SATS)* (Schau et al., 1995; Italian version: Chiesi & Primi, 2009). We chose SATS since it was proved to be invariant respect to gender (Hilton, Schau, & Olsen, 2004), i.e., equally suitable for male and female respondents, and because it assesses four attitudes dimensions including a self-confidence dimension. In detail, *Cognitive Competence* subscale (6 items) measures students' attitudes about their intellectual knowledge and skills when applied to statistics (e.g. "I can learn statistics"); *Affect* subscale (6 items) measures positive and negative feelings concerning statistics (e.g. "I feel insecure when I have to do statistics problems"); *Value* subscale (9 items) measures attitudes about the usefulness, relevance, and worth of statistics in personal and professional life (e.g. "Statistics is worthless"); *Difficulty* subscale (7 items) measures students' attitudes about the difficulty of statistics as a subject (e.g. "Statistics is a complicated subject"). The scale contains Likert-type items using a 7-point scale ranging from *strongly disagree* to *strongly agree*. Responses to negatively scored items were reversed, and then scores were obtained for each subscale, with higher ratings representing more positive attitudes. In the present sample, Cronbach's alphas for the four subscales were: *Cognitive Competence* = .76, *Affect* = .80, *Value* = .74 and *Difficulty* = .65.

Students were administered the SATS and the PMP in this order during the first day of class. The questionnaires were introduced briefly to the students and instructions for completion were given. Answers were collected in paper-and-pencil format and the time needed to complete them ranged from 25 to 40 minutes.

To measure achievement, we employed a midcourse test developed to monitor learning during the course and administered toward the end of the fifth week of the course. The test was composed as follow. Students were given a data matrix (3–4 variables, 10–12 cases) and referring to it they had to solve two problems (e.g., report frequency and percentage distributions, construct a two-way table, draw graphs, compute central tendency, spread and association measures) by paper-and-pencil procedure without the support of a statistics computer package. Additionally, they had to answer two open-ended questions (e.g., to define the measures of central tendency, to interpret the meaning of z values or percentiles). All the items pertained to contents covered in class. The test was timed (1 hour) and books and notes were not allowed to be used. For each problem the score ranged from 0 to 3: 0 = totally incorrect or not solved; 1 = partially solved; 2 = almost solved; 3 = completely solved. For each question the score ranged from 0 to 2: 0 = totally incorrect or no answer; 1 = partially answered; 2 = correctly answered. Two assistant teachers, preliminary trained, scored the tasks. The scores were aggregated in a single measure (range 0–10).

RESULTS

Gender difference in mathematical knowledge, attitudes, and achievement. All descriptives are reported in Table 1. No gender differences were found in mathematical knowledge ($t(177) = 1.10$, $p = .271$) and in the *Value* scores ($t(158) = -0.45$, $p = .97$). In contrast, differences were found in *Cognitive Competence* ($t(158) = 2.05$, $p < .05$, $d = .31$), *Affect* ($t(158) = 3.68$, $p < .001$, $d = .55$), and *Difficulty* scores ($t(158) = 2.13$, $p < .05$, $d = .32$) indicating that men were more confident about their own capabilities, had more positive feelings toward the discipline, and deemed the discipline less difficult than women. Concerning achievement, differences between male and female students were not statically significant ($t(155) = 1.38$, $p = .17$)

Gender difference in the relationships among mathematical knowledge, attitudes, and achievement. We investigated if mathematical knowledge and attitudes were related to achievement looking at the Pearson product-moment correlations separately in male and female students (Table 2). Males' achievement was related to mathematical knowledge whereas it was not related to attitudes toward statistics with the only exception of a small correlation with the *Cognitive Competence* dimension. Females' achievement was related to mathematical knowledge and to attitudes toward statistics with the exception of the *Value* dimension.

Since in both gender groups mathematical knowledge was related to attitudes and achievement, the correlations between them might be biased. Therefore, partial correlations were computed controlling for mathematical knowledge. For the male students the correlation with the *Cognitive Competence* score was not significant ($r = .04$, $p = .83$) once the effect of mathematical knowledge was controlled. Instead, for the female students the correlations between achievement and *Affect* ($r = .24$, $p < .05$) was still significant, as well as the correlations between achievement and *Cognitive Competence* ($r = .37$, $p < .01$).

Mathematical knowledge, Affect, and Cognitive Competence as predictors of achievement in female students. To establish the relative impact of mathematical knowledge, *Cognitive Competence*, and *Affect* on achievement in women, regression hierarchical analyses were run (Table 3). In the first step, the mathematical knowledge, and, in the second step *Cognitive Competence* and *Affect* were added as predictors. The

	Males		Females

two dimensions of attitudes toward statistics were kept separate to avoid multicollinearity due to the high correlation between them (r = .72) that makes difficult to estimate the single contribution of each one when kept together in the same analysis. Results showed that the mathematical knowledge was a significant predictor (F (1,79) = 29.35, p < .001) that accounted for the 27% of the variability in achievement. Adding separately at the two dimensions of attitudes, results showed that the model was significant both when *Cognitive Competence* was included (F (2,78) = 22.78, p < .001), and when *Affect* was included (F (2,78) = 17.53, p < .001). In both cases, they contributed significantly to explain achievement along with mathematical knowledge. Nonetheless, *Affect* explained only an additional 4% whereas *Cognitive Competence* accounted for an additional 10% of the variability in achievement.

DISCUSSION

The current study aimed at investigating the interplay among previous competence, attitudes, and achievement in statistics and taking into account gender-related differences. In detail, the first aim was investigating gender differences in attitudes toward statistics and the relationships with mathematical competences. As expected (and in line with Auzmendi, 1991; Tempelaar & Nijhuis, 2007), when compared to men, women were less confident about their own ability in dealing with statistics, perceived it more difficult, and had more negative feeling about the discipline. However, the present results shows that these differences were not related to different mathematical knowledge since any gender differences were detected in mathematical basics deemed necessary for introductory statistics courses. The second aim concerned the predictive role of mathematical knowledge and attitudes toward statistics on achievement. Confirming previous results, the *Cognitive Competence*, *Affect* and *Difficulty* components, but not the *Value* one, were related to achievement (Tempelaar et al., 2007; Wisenbaker et al., 2000), as well as mathematical knowledge (e.g., Chiesi & Primi, 2010; Harlow et al., 2002; Schutz et al., 1998; Tremblay et al., 2000; Wisenbaker et al., 2000). Concerning gender differences, as expected, gender induced changes in the relationships between achievement and its predictors. More in detail, mathematical knowledge was the only significant predictor for men, whereas – along with mathematical knowledge – the *Affect* and *Cognitive Competence* attitude components had an additional effect on performance for women. That is, low self-perceived abilities accounted for worse achievement, and more negative affect was associated to lower achievement (and vice versa). In particular, *Affect* had a smaller effect than *Cognitive Competence*.

Given these findings, it becomes important to identify methods for counteracting female students' tendency to underestimate their competence and to have negative feeling toward the discipline. In this way it could be possible to promote a better approach to the discipline and, as a consequence, a better performance. Specifically, it might be useful to arrange activities during the course in which students could realize that they can master the topics, develop confidence, perceive the subject easier, and reduce negative feelings toward the discipline. Thus, future researches might be conducted collecting repeated measures of attitudes from the beginning to the end of the course in order to monitor changes that might be due to the course itself and to specific activities implemented by teachers and tutors.

The present study has some limitations that we have to take into account when interpreting the results. First, we used the midcourse test score as indicator of achievement. For the purpose of the present investigation, we deemed this measure as an adequate indicator but it could be interesting to take into account the final examination's grades to better ascertain the role of attitudes on general achievement. In doing that, it should be necessary, as stated above, to monitor the changes in the attitudes that could occur during

Predictors	β	t	p	R^2	R^2 *change*	*F change*	p
Step 1: *PMP*	.52	5.42	<.001	.27	-	-	-
Step 2a: *PMP*	.45	4.52	<.001	.31	-	-	-
+ *SATS-A*	.21	2.10	<.05		.04	4.43	<.05
Step 2b: *PMP*	.40	4.20	<.001	.37	-	-	-
+ SATS-CC	.33	3.48	<.01		.10	12.09	<.01

Table 3: Hierarchical regression analyses on statistics achievement for Females. PMP = mathematical knowledge, SATS-A = Affect, SATS-CC = Cognitive Competence

the course, i.e., to have a measure of the student's attitudes at the end of the course, just before to take the final exam. Additionally, given the relevance of the self-confidence dimension (i.e., the trust in one's own knowledge and skills when applied to statistics) more attention should be paid in investigating more in detail this aspect, for instance using instrument to measure specifically the student's confidence in solving successfully typical statistic tasks. Finally, the present research was conducted with Italian psychology students and this may limit the generalizability of the current findings. Thus, future investigations should be conducted with different student populations to provide further evidence.

Enactive metaphoric approaches to randomness

Daniela Díaz-Rojas and Jorge Soto-Andrade

CIAE and Department of Mathematics, Faculty of Science, University of Chile, Santiago, Chile, sotoandrade@u.uchile.cl

Our work aims at developing means to facilitating the access to stochastic thinking, especially for non-mathematically oriented learners. To this end, we draw on metaphoric and enactive approaches to the teaching and learning of randomness. More precisely, we report on a challenging didactical situation implemented in various classrooms, with students and prospective and practicing teachers, concerning problem posing and solving in the context of randomness that is approached through enactive metaphoring. The findings suggest that this sort of approach allows non-mathematically oriented learners to make sense of and abduct otherwise inaccessible mathematical notions and facts.

Keywords: Enaction, metaphor, randomness, embodiment, waiting time.

INTRODUCTION

We are concerned about facilitating the access to stochastic thinking and its practice and appreciation by the learners as one way to make sense of the world. We are especially interested in approaches that might be meaningful and helpful for "general" non-mathematically oriented students in school, college and university.

The approaches we develop relay on metaphoring, enaction, embodied and situated cognition. Our main hypothesis is that most students – especially those with no special mathematical skills – can think mathematically if they *enact* first suitable didactical situations, involving problem posing and solving. Here enacting is meant in the most literal sense, as when enacting a role, bodily, on stage. In this way they may notice and "see" facts or relations that they may have trouble seeing in an abstract or symbolic setting. We put this into practice here in the context of probabilistic and statistical thinking, with challenging tasks like figuring out the expected waiting time for success in a dichotomic success-failure random experiment. Of course even learners with no probabilistic background can tackle this sort of task in a pure experimental statistical way, calculating the average waiting time for an increasingly larger number of repetitions of the experiment. Many of them may become sensitive nevertheless to the fact that they are calculating blindly without being able to anticipate, i.e., to "see" beforehand, what value the experimental average will be close to. We also aim at fostering the development of this sensitivity as an antidote to the common misconception of mathematics as just rote formula applying and calculating. These approaches have been tested with students and teachers with various backgrounds, ranging from elementary and secondary school students to university students majoring in science and humanities and to prospective and in service elementary and secondary school teachers.

THEORETICAL FRAMEWORK: METAPHORS, DIDACTICAL SITUATIONS AND ENACTION

Metaphors in cognitive science and mathematics education

Widespread agreement has been reached in cognitive sciences that metaphor serves as the often unknowing foundation for human thought (Gibbs 2008; Soto-Andrade 2014) since our ordinary conceptual system, in terms of which we both think and act, is fundamentally metaphorical in nature (Johnson & Lakoff, 2003)

We find remarkably theory-constitutive metaphors that do not "worn out" like literary metaphors and provide us with heuristics and guide our research (Boyd, 1993; Lakoff & Núñez, 1997). We might even claim metaphorically that a theory is just the unfolding of a metaphor! Recall the "tree of life" metaphor in Darwin's theory of evolution or the "encapsulation metaphor" in Dubinsky's APOS theory (Soto-Andrade, 2014). In what follows we will use the metaphorical approach as a meta-theory to describe the other theoretical frameworks we will use.

In mathematics education proper it has been progressively recognized during the last decade (Araya, 2000; Chiu, 2000; English, 1997; Johnson & Lakoff, 2003; Lakoff & Núñez, 2000; Presmeg, 1997; Sfard, 2009, Soto-Andrade, 2006, 2007, 2013 and many others) that metaphors are not just rhetorical devices, but powerful cognitive tools, that help us in building or grasping new concepts, as well as in solving problems in an efficient and friendly way. See also Soto-Andrade (2014) for a recent survey. We make use of conceptual metaphors (Lakoff & Núñez, 2000), that appear as mappings from a "source domain" into a "target domain", carrying the inferential structure of the source into the one of the target, enabling us to understand the latter, usually more abstract and opaque, in terms of the former, more down-to-earth and transparent. Our metaphoric approach to the learning of mathematics emphasizes their "poietic" role, that brings concepts into existence ("reification" in the terms of Sfard, 2009). For instance we may bring the concept of probability into existence when, studying a symmetric random walk on the integers, we see the walker *splitting* into 2 equal halves instead of going equally likely right or left (Soto-Andrade, 2013).

Didactical situations

The theory of didactical situations (Brousseau, 1998) might be described as an unfolding of the *emergence metaphor* for mathematical content: mathematical concepts or procedures we intend to teach should emerge in a suitable challenging situation the learner is enmeshed in, as the only means to "save his life". No real learning is possible if mathematical concepts "come out of the blue" or are "airborne" from Olympus.

Metaphors play an important role in didactical situations, that we describe with the help of a "voltaic metaphor": Key metaphors are likely to emerge, as sparking voltaic arcs, in and among the learners, when enough "didactical tension" builds up in a didactical situation for them. Typically this happens when students try hard and long enough, interacting with each other, to solve a challenging problematic situation. Suddenly a key metaphor to solving the problem emerges in one – or several – of them. Of course, to have the students sustain and endure the necessary didactical tension, is not an easy task in most classrooms...

Enaction

An unfolding metaphor for enaction is Antonio Machado's poem (Thompson, 2007; Malkemus, 2012):

"Caminante, son tus huellas el camino, y nada más; caminante, no hay camino, se hace camino al andar" [Wanderer, your footsteps are the path, nothing else; there is no path, you lay down a path in walking].

Indeed Varela had already metaphorized enaction as the laying down of a path in walking (Varela, 1987, p. 63), when he introduced the enactive approach in cognitive science (Varela, Thompson, & Rosch, 1991). In his own words: "The world is not something that is given to us but something we engage in by moving, touching, breathing, and eating. This is what I call cognition as enaction since enaction connotes this bringing forth by concrete handling" (Varela, 1999, p. 8).

Enaction in mathematics education may be traced back to Bruner (1953), who introduced it as "learning by doing". In fact he described *enactive representation* of a domain of knowledge (or a problem therein) as a set of actions appropriate for achieving a certain result, in contrast with *iconic representation*, where summary images or graphics are employed, or *symbolic representation*, based on symbols and their syntax. Later Bruner's ideas were successfully implemented and diffused via Singapore's CPA (Concrete-Pictorial-Abstract) methodology. For recent significant theoretical and practical developments of enaction in the field of education, which highlight the role of the teacher as an enactive practitioner acting in situation and prompt us to focus on the ways of being that can be fostered in the classroom rather than just monitoring the specific mathematical knowledge generated, see Masciotra, Roth, & Morel (2007) and Proulx & Simmt (2013).

ENACTIVE METAPHORIC APPROACHES TO MATHEMATICAL NOTIONS: THE EXPECTATION OF A WAITING TIME

We have discussed elsewhere (Soto-Andrade, 2013) an enactive metaphoric approach to the case of a symmetric 2D random walk (Brownie's walk). Here we will address the case of an important and ubiquitous family of random variables, to wit *waiting times*, and their expected values. The simplest case is that of the waiting time for success in a dichotomic success-failure random experiment, with success probability p and failure probability q. We specialize here to the simplest case $p = q = ½$, that can be modeled, or *metaphorized*, by tossing a coin and waiting for heads.

Methodology

The task (rather a problematic situation) proposed to the undergraduate students described below, was to figure out how long (how many tosses) they had to wait to get heads when tossing a coin. They had not been exposed to probability and statistics at the University and they were invited not to recall what they had heard about probability and statistics at school (where the subject is badly taught anyway). So they tackled this "impossible question" essentially bare handed. Notice that figuring out a sensible answer for our impossible question with no definite answer, is part of the task. We have then an "open task" that becomes stepwise more precise through the interactive work of the students (see a priori analysis below), accordingly with the enactive approach where problems are not "out there" waiting to be solved but are co-constructed by the cognitive subject and the world (Varela, 1987, 1999). It is our aim that the students learn to explore when tackling a problematic situation and then to conjecture and "see" beforehand ways of solution instead of blindly calculating the sum of an infinite series or computing an average over many repetitions.

Our experimentation regarding this task was carried out in the classroom with:

a. 1st year University of Chile students majoring in social sciences and humanities, from 2011 to 2014 (1 semester mathematics course, averaging 60 students per semester).

b. 25 University of Chile students enrolled in an optional one semester course in Post Modern Mathematics, majoring in mathematics or in pedagogy in physics and mathematics, in 2012.

c. 40 University of Chile prospective physics and mathematics secondary school teachers (one semester probability and statistics course) in 2014.

Students were observed by the authors during interactive 90 minute work sessions. They did group work splitting usually into two groups of no more than 20 each.

We describe now the mathematical analysis and the *a priori* and *a posteriori* analyses of this experimentation in the sense of didactical engineering (Artigue, 2009).

The mathematical situation

Notice that the experiment of flipping a coin until you get heads can be looked upon as a symmetric random walk on a truncated binary tree (you begin at the root and turn right if you get heads and to the left if you get tails, stopping when you get heads the first time), so that the question "How long will I have to wait for heads?" becomes "How long will it take the walker to get to one of the absorbing ends of the tree?" So flipping a coin or walking on the tree, are each one a metaphor for the other.

Since the random variable T = "waiting time for heads when flipping a coin" takes values n with probabilities $1/2^n$, its expectation E(T) is given by the series $\sum_1^\infty \frac{n}{2^n}$. Adding terms diagonally one can show that this series coincides with the geometric series $\sum_0^\infty \frac{1}{2^n}$, whose sum is 2.

The challenge we address below is whether the students could enactively "see" this result without calculating the corresponding series (symbolic approach, rather unfriendly for many) or averaging over an increasing number of repetitions of the experiment (statistical approach, also unfriendly for many). Notice that most students, and teachers, do not usually see another way to tackle the problem, besides the theoretical-symbolic one and the empirical-statistical one!

The didactical situation: Tentative script and a priori analysis of the enactment

The teacher flips a coin once and asks for interesting exploratory questions. Very likely some students suggest to flip it again. Various interesting questions may arise. In particular, if the teacher gets, say, 2 or 3 tails in a row, students may begin to wait for heads. Eventually the whole class may get interested in the question: How long has one to wait for heads?

Different answers may come up, the level 0 answer being: "Nobody knows, only Jesus knows!" Other answers are expressed in gestural language. Some students may suggest experimenting. Each of them flips a coin until he or she gets heads. They realize the variability of their waiting times. Some may find that the situation is hopeless. Others, more positively minded, may suggest to average. They average their waiting times and find, say, 1,7 or 2,6. So what?

This stirs usually a lot of discussion. Some students suggest further experimenting. Other make guesses, like "the average should tend to 3". One natural question is what average are we likely to get if we entice all students on campus to do the experiment?

Some become tired of experimenting and begin to look for a more theoretical approach. Eventually they draw the corresponding possibility tree (a truncated binary tree) and assign probabilities with the help of a hydraulic or pedestrian metaphor, as in Soto-Andrade (2013). Recall that in the first one we visualize the possibility tree in vertical position, root at the top, pour a litre of water at the root and let it drain evenly downwards. Probabilities are metaphorized as quantities of water. In the second one a suitable number of pedestrians (a power of 2 in this case) starts at the root splitting evenly at each junction. Probabilities appear now as proportions (ratios) of pedestrians reaching a node in the tree. This is easy, but then they realize that to calculate the theoretical average, i.e. the expected waiting time, they have to calculate the infinite sum $\sum_1^\infty \frac{n}{2^n}$, that is rather unwieldy for them. Some students begin to intuit that there should be something like a limiting value for the average (if all Chinese waited for heads...) or either an "ideal average". It is not clear for them however how to pin it down. The teacher prompts the students to suggest other approaches. If no new ideas arise, the teacher may suggest to *enact* the situation, all together.

More precisely, she suggests that all students stand up in a circle and each waits for heads when flipping a coin. She asks then how they would calculate the *average waiting time*. The students suggest the obvious way that entails asking each one of them how many times he had to flip the coin to obtain heads, add all these waiting times and divide by the number of players. The problem arises then however that this procedure does not allow them to guess or to estimate neither the experimental average waiting time nor the "ideal average waiting time". It is nevertheless clear for most of them that "ideally" half of them should get heads at the first flip. Then among those who failed, ideally one half will get heads at the second flip. This is an interesting idea that actually comes up from some students, but leads them to an infinite sum all the same (although simpler to evaluate than the sum above). So the students are still motivated to look for a friendlier approach.

At this point the teacher might suggest that to ask every player how long she had to wait for heads is a bit cumbersome. The question arises as to how could the students proceed in a friendlier and more concrete way, so that they really "see" what has happened to each one of them (notice the switch to a non verbal cognitive style). After some minutes thought at least one student suggests: flip several coins, one after the other, instead of just one! All appreciate this bright idea and begin to flip one coin after another (eventually the teacher has to lend coins to some students). After a while, each of them has a group of coins in front of her. If nothing happens, the teacher may ask them: what do you see? Some may say: "not very much, just a bunch of coins on the floor". But others remark quickly: "there is just one head in front of each of us". Other recall that to calculate the average we should count the total number of coins on the floor and divide by the number of players. Said that way however, the result is not easy to estimate beforehand. Then usually a few students realize that they will be dividing the total number of coins by the number of coins showing heads. But they "know" which is the "ideal ratio" here: if I see 17 coins showing heads on the floor, I would have expected "ideally" 34 coins in all. Of course there might be 37 coins instead. But this shows that "ideally" the average of all waiting times should be 2. After this breakthrough, usually the teacher invites the students to keep silent and quiet for a little while (one minute, say), in an introspective attitude, and to visualize the whole picture. After that she may prompt them to draw an image of the whole enactment (the circle of players, each with a bunch of coins in front of him...), so as to enter the iconic register. And then, according to the mathematical profile of the students, she can prompt them to formulate their conclusions in symbolic language.

An interesting fact that we have observed is that for most mathematicians this enactment *is* a proof while for most secondary school teachers it is not! Putting the whole situation on its head, we could even say that we have found an enactive metaphorical proof that the infinite sum $\sum_1^\infty \frac{n}{2^n}$ adds up to 2. We claim that this is closer to real mathematics that the usual purely symbolic, abstract and axiomatic approach, thst is just one genre among many possible ones (Manin, 2007; Soto -

Andrade, 2014). Finally we should remark that also the equality $\sum_{1}^{\infty}\frac{n}{2^n} = \sum_{0}^{\infty}\frac{1}{2^n}$ may be gleaned from our enactment: when students realize that they should collect all coins lying on the floor, the teacher may prompt them to suggest different ways to do it. Usually some students come up with the idea of the "common pot" (as in a soup-kitchen), like the one squatters occupying a school in protest would organize (a familiar experience for many students). The idea is that to collect all the coins, the teacher should ask first everyone to put one coin into the common pot. All can do that. Then she would ask for a second coin. Ideally only half of the players are able to do that. And so on. This shows immediately that the ideal average of waiting times coincides with the sum $\sum_{0}^{\infty}\frac{1}{2^n}$, hence the equality of the two infinite sums above.

The didactical situation: A posteriori analysis

The idea of flipping a new coin after each failure in getting heads came up as easily in students majoring in humanities and social sciences as in students majoring in mathematics or pedagogy in physics and mathematics. The fact that the number of students in the circle coincides with the number of coins showing heads did not come up very quickly, but we saw no significant difference between mathematically oriented students and humanists. Some of them realized this after contemplation of an iconic representation of their enactment, others did it after staring hard at the coins on the floor. A lot of discussion emerges as to how to register their results.

The relationship between the experimental average waiting time and the ideal one emerged rather slowly. Estimates of the experimental average of waiting times for millions of people varied in a significant way between students a and b, c. Recall that the former had previously flipped a coin 100 times and registered what they observed (not just the final result, but the whole process!). So they realized that the simplest avatar of randomness already creates shapes that look like mountain ridges and stock exchange charts. They were less prone than students b and c to think that in we cannot say anything sensible or even approximate about random experiment results. They also "saw" more easily that the ideal average waiting time should be 2, the inverse of the ideal relative frequency of heads when you flip many times a coin.

In all groups of students those who intuited that the ideal average waiting time should be 2 (out of statistical experimentation) related this immediately with the inverse of the ideal relative frequency of heads when flipping a coin many times. All students conjectured quickly after this experience that the ideal average waiting time for "ace" when tossing a dice should be 6. Further work in more advanced symbolic mode was easier with students b and c that had a more intensive mathematical training. Sometimes a game emerged after this enactment, that may suggest another approach to the expected waiting time: the teacher gives each student as many coins as necessary to get heads flipping them one after another. When a student finally gets heads, the game is over and he keeps all flipped coins. The natural question is: How much should the teacher charge for playing this game, so that it becomes a fair game?

DISCUSSION AND CONCLUSIONS

Crossing a priori and a posteriori analyses we see that several years of traditional mathematical training (students b and c) did not make a significant difference in performance in an enactment like the one we report here: students a, who come directly from high school, usually with a poor relationship to mathematics, did at least as well as students b and c, when trying to figure out enactively the value of the ideal average waiting time for heads. In fact they did even better regarding their intuition of the behaviour of the experimental average waiting time for an increasing number of flippers. We conjecture that this phenomenon is due to the fact that – in contrast to students b and c - they had made the enactive experience of flipping a coin 100 times and registering the whole stochastic process, realizing its relationship with everyday shapes like mountain ridges and stock exchange charts. This suggests that in some sense enactive experiences may concatenate and interact in a feedback loop in the life story of the learners, as suggested in Varela, Thompson and Rosch (1991): "cognition is not the representation of a pre-given world by a pre- given mind but is rather the enactment of a world and a mind on the basis of a *history* of the variety of actions that a being in the world performs" (emphasis is ours).

We also observed that learning enactively is not a one man (or woman) show, it is a collective social undertaking, that may be seen upon in some cases as an avatar of swarm intelligence. We have noticed, especially in group a, that among students reacting remarkably faster and better than the average in enactive situations, a high percentage of come from alternative Montessori or Waldorf schools.

We should remark that our enactive approach poses some significant challenges: teachers and students need to be able to play tightrope walkers and transit seamlessly between different cognitive styles (from symbolic to enactive particularly). Special support and dedication is needed for those who come from more formal and robotic school systems, so that they can progressively adapt to new ways of working and approaching mathematical experience and knowledge. If this sort of "cognitive therapy" is not provided (by a devoted highly qualified teacher assistant, for instance) the risk arises of a severe stratification in the classroom, that could demotivate many students. We see then that significant situational intelligence, in the sense of Masciotra, Roth, & Morel (2007) is required from teachers as enactive practitioners.

On the other hand, as pluses of our approach we have observed that is very often highly motivating for the students, involves surprise (a key factor for learning, according to Peirce and Freire), knowledge is constructed in a cooperative way in the classroom, space is given for questions to emerge from the students in experiential situations, instead of answers being given to them before they have a chance to ask the questions first (Freire, 2011; Tillich as cited by Brown, 1971; Mason, 2014) and finally, it fosters participation so that students become protagonists of their learning.

As open ends, we may mention, among others: the didactical study of histories of enactive experiences of the learners; the relation between enaction and intuition (first steps in this direction may be found in Diaz-Rojas, 2013); the systematic study of the emergence of enactive metaphoring in suitable didactical situations; the enactive exploration of the real meaning of being mathematical in the classroom in the sense of Mason (2014), research on curriculum reshaping motivated by the enactive approach in mathematics education.

Aspects of students' changing mental models when acting within statistical situations

Andreas Eichler[1] and Markus Vogel[2]

1 University of Kassel, Kassel, Germany, eichler@mathematik.uni-kassel.de

2 University of Education Heidelberg, Heidelberg, Germany

In the qualitative part of a larger research project aiming to investigate students mental modelling of statistical situations we found aspects of a statistical situation that provoke intended but also not intended (conceptual) changes of students' mental modelling. To describe these changes, we firstly outline the results of our former research followed by a brief discussion of our theoretical framework and our method. Then, we discuss results from the perspective of changing mental models.

Keywords: Statistical mental models, conceptual change, interview study.

INTRODUCTION

The contemporary educational research on statistics follows mostly the approach of intervention studies (Jones & Thornton, 2005). The amount of this research has grown in recent decades, since statistics become a crucial part of the curriculum of stochastics (statistics and probability) in many countries (Batanero, Burrill, & Reading, 2011). By contrast research referring unschooled students' acting and reasoning within data-centred statistical situations of uncertainty is sparsely developed (Eichler & Vogel, 2012). For this reason, we started a research project aiming to analyse non-schooled students' modelling and reasoning about statistical situations. The main aim of this research is to gather more information about young students' primary statistical thinking as an empirical based starting point for statistics education in school.

In this paper, we refer to the qualitative part of our research including interviews with young students, who act within statistical situations. For this, we outline our theoretical framework. Then, we briefly outline the main findings of our previous work and derive the research questions of this paper followed by a short report of our methodological approach. Finally, we give an account of research results, and particularly of both students' mental modelling when reflecting on comparable statistical situations given in paper-pencil-task, and a (conceptual) change of mental modelling when handling those situations in reality afterwards.

THEORETICAL FRAMEWORK

Students' conceptions are not always compatible with the intended statistical conceptions. This finding can often be explained by the influence of (naïve) prior conceptions and non-accomplished processes of their reconstruction. The mental model theory (Johnson-Laird, 1983) and a mental model oriented conceptual development approach (Vosniadou, 2002) meet the demands to capture this problem from a theoretical point of view. We outline briefly those aspects of our theoretical framework that are relevant for this paper.

Mental models

Johnson-Laird (1983, p. 156) states: "A mental model [...] plays a direct representational role since it is analogous to the structure of the corresponding state of affairs in the world – as we perceive or conceive it." From the perspective of information processing Schnotz and Bannert (1999) describe mental models as being constructed individually according to a task and its requirements within a specific situation. By this, they conclude that a mental model represents the structure as well as the function of the modelled situation that could be described as follows:

— Structure: An essential process of mentally modelling a situation's structure is recognising the observable or not observable physical objects of the situation, as well as the relationship of these objects that an individual identifies as mainly impacting on the situation. Given data are also to be seen as being part of a situation's structure because they represent results of a process having passed. For example a die, the characteristics of the die, the player throwing the die, the ground where the die will roll and even data representing results of the die having been thrown before are characteristics of the situation that an individual has to process when he build up a mental model of the situation.

— Function: Concerning the dynamic aspect of mental models, i.e. the function, Seel (2001) suggests that, when coping with demands of a specific situation, an individual constructs a mental model in order to simulate relevant aspects of the situation by anticipating possible results. The functional aspect of statistical situations is directly reasonable, since it represents a qualitative simulation of the situation in terms of making a prediction, for example of those numbers a die will show in the next throws. In general, such mental simulations cannot result in quantitatively exact conclusions – for example when a die with an unsymmetrical shape is given – but in qualitative ideas about reasonably expectable outcomes of such simulations (De Kleer & Brown, 1983). These "qualitative simulations" (ibid., p. 155) require sense making about the system or process that should be simulated, its constituent components and their relationships.

Conceptual development and change in terms of mental model theory

With regard to conceptual development mental models play different important roles: They serve as aids in the construction of explanations, are mediators in the interpretation and acquisition of new information, and provide tools that allow experimentation and theory revision (Vosniadou, 2002; Van Dooren et al., 2006).

Conceptual change in terms of mental model theory involves a validation of the model that necessitates a moderately changed or a fundamentally renewed model of a situation (Vosniadou, 2006). Posner and colleagues (1982) identify a disadvantage of existing models concerning new facts or phenomena as well as the existence of alternative models that seem to be – evidently or not – more promising to explain new facts or phenomena. In some sense an individual's conceptual change equals the acquirement of new pieces of knowledge. However, it is not necessary that this new knowledge eliminate the "old" knowledge (Vosniadou, 2006). Thus, students who conduct a conceptual change may construct different mental models of structural similar situations that were provoked dependent of the specific situation or task (Siegler, 1996). Because such different mental models occupy an autonomous role (Morgan & Morrison, 1999) they have not be consistent in an objective sense but they have to be experienced as being useful concerning their explanatory power in a subjective sense.

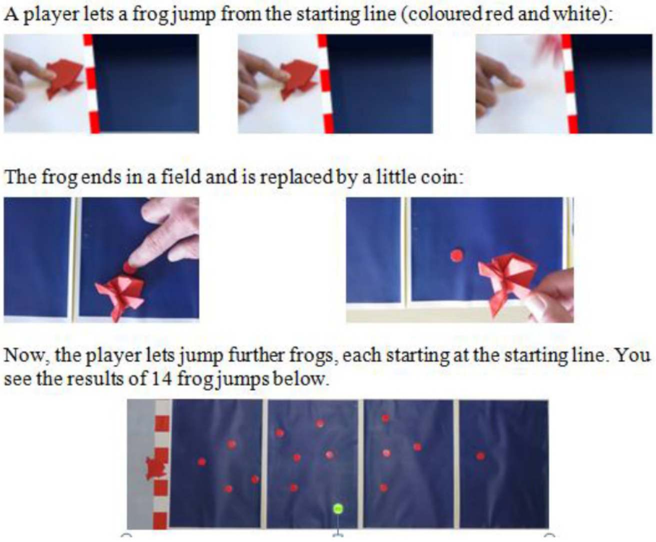
The situational perspective of mental model theories is closely connected with the approach of situated cognition: "Situations might be said to co-produce knowledge through activity. Learning and cognition, it is now possible to argue, are fundamentally situated." (Brown, Collins, & Duguid, 1989, p. 32) Amongst other theoretical approaches, the conceptual change approach refers fundamentally to situativity and mental model theory (Vosniadou, 2002). For this reason, we regard the change of a student's mental model from the perspective of conceptual change.

PREVIOUS WORK

Theoretical aspects

In our research we use the mental model approach for conceptual framing the aspects of students' modelling within specific statistical situations (Vogel & Eichler, 2014). Because we are especially interested in what Fischbein (1975) calls students' primary intuitions concerning statistics situations of everyday life we reduce ourselves to the descriptive mode (cf. Prediger, 2008) of mental modelling (referring to the interpretations students actually use) and leave out the prescriptive mode (referring to the mathematical interpretations intended to be learned). As an example, the situation of a frog jump is described in Figure 1.

The characteristics of the structure and the function of the mental model concept are provided in the situation of frog jumps: The structure consists of non-human objects (the frog, the fields, the starting line and so on), human objects (the player) and the relations among the objects. Further, the data (the shims on the fields; cf. Figure 1) are a part of the structure representing previous results of the situation. The function of a mental model is implicitly incorporated in the



The frog task:

The frog ends four times in field 1, six times in field 2, four times in field 3, and one time in field 4.

Make an estimation to the following experiments and justify your answer:

How often the frog will end in field 3 by 100 (in field 3 or in field 4 by 1000) jumps?

Figure 1: The situation of the frog jump

situation, i.e. a mental simulation of the situation, e.g. resulting in estimation for the next jump.

The situations and the mentioned characteristics of mental models allowed us to derive a theoretical model of task complexity with three influencing factors (Eichler & Vogel, 2012): The tasks could provide all the objects that potentially impact on the situation (or not), the tasks could provide data (or not), and the tasks could require a request of a mental simulation (or not).

Empirical aspects

Using the results of a questionnaire survey, the complexity model could be empirically backed up in a quantitative way (ibid.). Additional qualitative analyses of students' responses yield interesting insights in students thinking (ibid.): For example, students tend to show a bigger variation of mental models when there were situations to be judged in which random processes were apparently, at least partially, influenced by human. This assumption can be underlined for example by an overview of the analyses of 74 written student responses concerning a task using rolling dice on the one hand, and a task using jumping paper frogs (cf. ibid.). In the so-called die task no student mentioned the hand of the person which throws the dice whereas in the frog task (as well as in other tasks which not comprise dice) human influence was considered in different elaborated ways.

RESEARCH QUESTIONS

The research question referring the qualitative part of our research is a result of our previous findings and future aims.

In this qualitative part, the students work with the concrete material that is shown in the statistical situations in the tasks (e.g., the frogs, the fields and the starting line). Besides other (primary) goals of this part, it aims to disclose possible changes of students' mental modelling in specific statistical situation. This aim seems to be necessary to focus on how to engage students to change their mental models, e.g. as a result of an intervention. For this, beyond the mental model concept we use the conceptual change approach (see above). We are aware that the time span provided for the students to work within the statistical situations in our research might be not sufficient to get evidence for conceptual changes. However, if a student changes his mental model concerning a statistical situation this change could be interpreted as a beginning of a conceptual change that potentially took place on the long run.

We derive our research questions from these considerations: Confronted with a statistical situation (like the frog jump) a student could build up an initial mental model of this situation and conduct mental simulations only based on this model. When a student tackles the situation in reality and works with the concrete objects afterwards, it is possible that the student changes his mental models. Based on our previous work we are especially interested in the following two questions:

— When a student changes his notion of the objects from hardly to strongly impacting on the results of a situation of uncertainty (or rather the other way around), in which way will he or she express this by arguing and/or acting?

A student changing his notions of the impact of the objects could potentially also change his notion of the process of data generation and, accordingly, the function of the situation. In concrete, we ask:

— When a student start with the notion of a deterministic impact of one or more objects on the results of a situation and change this notion to a perception as a random situation (or rather the other way round), in which way will he or she express this by arguing and/or acting?

METHOD

The sample of the qualitative part of our research project consists of about 60 students grouped in pairs. We use pairs of students because we want them to solve a statistical problem situation together by arguing, discussing (cf. Dreher & Dreher, 1982) and thus, externalizing their ongoing mental modelling during this collaboration. 24 students (12 pairs) of this sample worked with the situation of the frog jump as it is shown in Figure 1. The students (grade 6; age 11–13) come from schools of urban and rural regions in Germany. We collected data in videotaped interviews with pairs of students lasting about 20 minutes and consisting of three steps:

1) Each student was asked to solve one of two tasks representing similar versions of the situation of the frog jump. In this step the students were asked to work alone and without any intervention of the interviewer.

2) The students were asked to explain their tasks and their solution to each other, and, further, to find consistent solutions for each task. The interviewer had the task to moderate the students' discussion and prompt the students to continue their explanations until the other student understand this explanation.

3) The interviewers used the physical objects of the situations represented in the tasks. The students were asked to re-enact the situation of the frog task and to conduct the experiment of the frog jumps. After this step, the students were asked to modify their collective solution.

The interviews were transcribed verbatim. The analysis of transcripts follows a coding approach close to Grounded Theory (cf. Kuckartz, 2012; Strauss & Corbin, 1998).

RESULTS

We firstly illustrate the diversity of students' mental models referring the structure when they explained their solutions in the pairs (step 2) after working alone on the paper and pencil tasks (step 1). This diversity replicates qualitatively the diversity that we found in our quantitative survey (Eichler & Vogel, 2012).

Chris: "If I let the frogs jump in the same way as showed on the picture then I will hit this field as well."
Gerd: "The frog is not able to jump that far."

Both students stem from different groups. The students mostly mentioned the player (human object) or the frog (non-human object) to have the main impact on the situation. Only few students also refer to the fields and the border between two fields. In all cases, the notion of the structure presupposes the mental simulation of the situation resulting in a prediction for the next jump.

According to results of former studies (ibid.), the students' rationales for a prediction of the next frog jumps differ considerably. Differences refer to the relevance and the number of situations' information represented by objects or data that the students used in their rationales. We want only to illustrate these differences by quoting the responses of two students. Both students predicted a certain field for the next jump of the frog and afterwards justified their prediction:

Ernest: "I made it in this field, because in the second field are the most of the coins [he points to the sheet with the task]."
George: "The frog is heavy. He will crash to the ground easily."

When the pairs of students were asked to conduct the experiment of the frog jumps (step 3), it was striking that all students were immediately able to re-enact the situation and to conduct the experiment as it is represented in the task. This result is crucial for our analysis since there is no evidence that the students misinterpreted the situation presented in a task on a paper sheet.

However, when the students experimented with the frogs, in some cases signs for a potential (conceptual) change concerning the situation's evaluation can be reconstructed. We illustrate exemplarily a change in mental modelling concerning the pair of Eva and Franka (in comparison to Figure 1, in this case, the tasks include a slightly different distribution of coins or rather frog jumps):

> Eva: "I believe that the frog will end 70 times by 100 attempts in the third field, because he ended in this field 7 times by 10 attempts. Thus, I have only added a 0, because concerning 100 there is also a 0 more at the end in comparison to 10."

Before they conducted the experiment, Eva and Franka seem to identify the frog (non-human object) to be mainly impacting on the situation. It is not decidable, if the students mentally model the situation randomly or in a deterministic way.

When dealing with the frogs, they changed their mental modelling by judging the human object (the player) instead of the non-human object (the frog) as having the main impact on the situation.

> Franka: "It depends of the force. If you let the frog jump with little force, the frog will not jump as far if you let him jump with more force."

After the first experiments, both students feel certain that they are able to produce any desired results. The reason of variation in the results seems to be determined only by the intention of the students. Thus, the mental simulation seems to be mostly of deterministic nature.

After a period, in which the students experiment several times with the frogs the answers of Eva and Franka provide indications of another (conceptual) change. Firstly, they re-changed their judgement of the object as mainly impacting on the situation and, further, changed their mental simulation from a more deterministic to a more stochastic way:

> Franka: "I think they [the frogs] approximately will jump equally."
> Eva: "I think this depends on fortune."
> Franka: "Yes. I think that there would not been many exceptions from that the frogs will jump equally. At most a little. I think the frogs will jump equal distances."

Like these both students, other pairs of students also seemed to change their mental models one or more times to yield a fit of the model and the situation. However, most of the students appear to consolidate one mental model at the end of the interview. A categorizing of all student pairs' answers yields the following change type (for which Eva and Franka are representatively standing):

> Change type I: From a deterministic model of a situation of uncertainty to a stochastic model that includes a pattern ("the frogs will jump equally") but also a first idea of variation ("fortune", "exceptions" from equal jumps).

If we hypothesise that these changes of mental modelling are the beginning of a conceptual change in the long run, the trajectory of changes is desirable. Referring the structure of the mental model this type includes a change from the human to the non-human object as mainly impacting factor and a change from a deterministic to a stochastic mental simulation.

Of course, the latter interpretation leads to a hypothesis that has to be proven in further situations, or similar argumentation have to be shown by other pairs of students. Actually, few of the pairs of students showed a change of mental modelling like Eva and Franka. In contrast, more pairs of students showed changes that are in contrast to the change type described above. We illustrate this other type with the case of Hubert and Ian.

> Hubert: "He will jump in this field because [he points to the sheet with the task] here are only four, here are much [coins], and here is only one."

Firstly, the frog was considered as mainly impacting on the situation thereby the data were taken into account. After jumping the frog several times, Ian and Hubert stated the following:

Ian: "I think I know it. The more I press at the back the farther the frog jumps."
Hubert: "But if you press to far at the end it does not work." […]
Ian: "The jump depends on who it makes."

Both students jumped the frog again and again resulting in different lengths of the jumps. They changed their position and made further frog jumps. They commented their results from time to time, consolidating that the jumper (the human object) has the main impact on the situation. They ended with the following assertion:

Ian: "The most important thing is, how I hold the frog and how I make it [the jump]"

Both students initially tended to favour a stochastic model of the situation based on an informal data analysis. When they jumped the frogs, each of the students showed a considerable variation of length that could potentially evoke a notion of a jumping distribution including a centre and variation. However, these students as well as other pairs of students represent another change type than Eva and Franka.

> Change type II: From a stochastic model of a situation of uncertainty that includes a pattern and a first idea of variation to a deterministic model.

This result condensed in the second change type was surprising on the one side and was not intended on the other. Following Fischbein (1975) this change type potentially show a trajectory from an appropriate primary intuition to a misleading secondary intuition.

DISCUSSION AND CONCLUSION

In this paper we reported the qualitative part of our research into young students' changing mental models when they act within statistical situations. The aim is to gather information about initial mental models of young students judging a statistical situation and changes of these models when they can tackle the situation. In an educational point of view the changes to sufficient mental models concerning statistical situations are especially interesting when they are stable over time. For this reason, we refer beyond the mental model concept also to the conceptual change approach. Of course we do not claim that working within a certain statistical situation will be followed by a conceptual change, this is never possible to state in general. But we consider reconstructed changed mental models as a potential initiation of a conceptual change that potentially endures. Under these theoretical conditions we derived two aspects, to which students' mental model changing possible refer to: the extent to which certain objects impact on the results of a statistical situation and the preference concerning a more deterministic or a more stochastic estimation of the situation.

In the qualitative interview study reported in this paper we found indications for both of these theoretically derived aspects of mental model changes. These indications were illustrated and discussed along the frog task, which was exemplarily presented in this paper. The analyses of students' responses and actions concerning this task's statistical situation yielded two change types: from a deterministic dominated interpretation of the situation to a stochastic dominated one (this was the intended one) and vice versa. Beyond the reason for getting deeper insights in young students' statistically mental modelling we conducted this qualitative interview study to generate hypotheses for the following research steps. In this point of view we assume based on our findings that the impact of the human-factor should be reduced in the statistical situations, with which the students are confronted when introduced to statistics. At the moment we investigate this assumption in more detail by changing the context of the frog task to a (in sense of the statistical situation) structural equivalent task using toy cars. The results of this current study will also be reported on the 9th Congress of European Research in Mathematics.

Preservice teachers' statistical reasoning when comparing groups facilitated by software

Daniel Frischemeier and Rolf Biehler

University of Paderborn, Paderborn, Germany, dafr@math.upb.de, biehler@math.upb.de

Comparing groups is a fundamental skill preservice teachers are supposed to gain after attending a statistics course at university level. Preferably these activities are embedded in the well-known PPDAC-Cycle and contain the exploration of real and motivating data. Adequate software such as TinkerPlots may support learners when exploring data and carving out differences between distributions of numerical variables. In this article we want to present first results of a study on statistical reasoning of preservice teachers while doing group comparisons with TinkerPlots.

Keywords: Preservice teacher education, statistical education, group comparisons, software use, tinkerplots.

INTRODUCTION

Comparing distributions of numerical variables lies in "the heart of statistics" (Konold & Higgins, 2003, p. 206). A question which may motivate a group comparison is for example "In which respect do men and women differ regarding their income?". This could be also posed in the daily-life media, so we see the importance of such an activity, not only for students but also for upcoming teachers. Preferably questions and activities are embedded in a cycle (like PPDAC, Wild & Pfannkuch, 1999) where students are enabled to generate their own statistical questions and hypotheses, to design a questionnaire for collecting data, to analyse their data and to draw conclusions from it. When analyzing large datasets, the use of adequate statistical software becomes inevitable. TinkerPlots (Konold & Miller, 2011) yields many requirements for statistical software for use at school and university level. At the one hand TinkerPlots can be seen as educational software supporting learners to learn data analysis, on the other hand it can be seen as a tool for exploring multivariate data. Additionally, the teacher can also use it as demonstration medium in the classroom. From our research point of view, we are primarily interested how preservice teachers compare groups with TinkerPlots. In this article we want to introduce a framework to rate preservice teachers´ skills when comparing groups in large datasets with TinkerPlots. Therefore we designed a course to deepen preservice teachers´ statistical knowledge and conducted an interview-video-study to evaluate in which way the participants are able to compare distributions with TinkerPlots in large datasets. First results of this study will be reported at the end of this article.

LITERATURE REVIEW

Comparing groups is an important domain in statistics education research: There are several empirical studies which concentrate on rating learners' statistical reasoning when comparing groups. We can differentiate between at least five different ideas in these studies (not in order).

A first idea is set by Watson and Moritz (1999) who investigated Australian 3–8 graders when comparing two data sets. The participants were given two data sets with test scores of two classes and were asked which class has done better in the test? The distributions of the variable test score was displayed as a stacked dot plot and the interview protocol offered different types of group comparisons, e.g. distributions which differed in the number of cases, in variation or in skew (Watson & Moritz, 1999, p. 151). The learners responses were rated via SOLO taxonomy where the responses where rated "unistructural", "multistructural" and "relational" and distinguished between the comparison of equal and unequal sizes. One major result of their study was, that students in higher grades tend to reason proportionally rather than younger students (for further details see Watson & Moritz, 1999, p. 153). A second main idea is displayed by Makar & Confrey (2002). They conducted a one semester professional course for preservice teachers including group comparison tasks with Fathom and developed a "taxonomy for classifying levels of reasoning when comparing two groups" to evaluate their participants reasoning from an interview task (concluding the course regarding to comparing groups). The participants were asked to compare two distributions of test scores of two schools given as a stacked dot plot in Fathom (with no use of software itself). A crucial point in their analysis was in which way inferential terms (like "evidence" and "significance") were used in the comparison process of the participants and in which way the participants draw conclusions from samples. A third idea of research on comparing groups is given by the work of Biehler (2001) and (2007). Biehler gives a normative view on comparing groups and expresses which elements shall be included in a "good" group comparison. He mentions that *p*-based [1] and *q*-based [2] comparisons (Biehler, 2001, p. 110) might offer intuitive strategies for students and he also emphasizes an interpretation of the difference in the skewness of distributions as a possible comparison element (Biehler, 2001, p. 101). There is also an idea (fourth) which covers the use of software when comparing groups. Biehler (1997, p. 175) has set up a cycle and gives an overview on four phases "statistical problem", "problem for the software", "results of software use" and "interpretation of results in statistics" which are run when doing data analysis with software. Maxara (2009) designed a framework for evaluating learner´s software competencies when simulating chance experiments with Fathom. This is not directly related to group comparisons but nonetheless adaptable for evaluating leaner´s competences when using software (such as TinkerPlots) when comparing groups. Overarching for the fifth idea might be the work of Pfannkuch and colleagues (2004; 2006; 2007). In these research papers a framework for evaluating learner's competencies when comparing two distributions was developed. Since Pfannkuch (2007) is a succeeding study of Pfannkuch and colleagues (2004) and Pfannkuch (2006), we want to refer to Pfannkuch (2007) only. In this empirical study she gave a boxplot comparison task (see Pfannkuch, 2007, p. 157) to "Year 10"- students. They were given two boxplots, asked to compare them in the sense of making three statements to explain differences or similarities between the distributions. Pfannkuch (2007, p. 159) had a look on different statistical aspects that were used by the participants and set up categories for the evaluation of statistical reasoning elements when comparing two distributions by boxplots. On a structural level she distinguished between "summary", "spread", "shift" and "signal". Then she rated each statement regarding to its quality: "point decoder" (level 0), "Shape comparison describer" (level 1), "shape comparison decoder" (level 2) and "shape comparison assessor" (level 3). Main results of this study were that the students mostly refer to summary and spread elements, but neglected elements on shift and signal. Furthermore they tended to stay mostly on the describing and decoding but not on the assessing level when pointing out differences and similarities between both distributions.

All in all, we can derive three dimensions having an influence on the group comparison process from the literature review: *Software cycle when comparing groups* (Biehler, 1997), *competence of using software (TinkerPlots) when comparing groups* (Maxara, 2009) and *"statistical reasoning" when comparing groups* (Watson & Moritz, 1999; Biehler, 2001; Makar & Confrey, 2002; Pfannkuch et al., 2004; Pfannkuch, 2006; Biehler, 2007 and Pfannkuch, 2007). In this study the work of Pfannkuch seems to be the most interesting aspect: Watson and Moritz (1999) deal with given data and given distributions (but in datasets with a small amount of cases) and a focus on counting strategies and proportional reasoning. Makar & Confrey (2002) have had their crucial research point of interest on how learners draw conclusions from samples to a population while comparing samples. Pfannkuch offers an open framework which firstly structures learners' outcome in regard to the statistical element used and secondly rates this in form of quality. Since working with software offers a broad spectrum of statistical elements (e.g. center, spread, shift, etc.) which can be used in group comparisons even in large datasets, the framework of Pfannkuch with enrichment of Biehler´s (2001) suggestions (skewness, *p*- and *q*-based comparisons) seems to offer possible and adequate comparison elements when comparing groups and a solid basis for evaluating the outcomes of learners when comparing groups. These ideas and aspects motivated us to design a course for the education of preservice teachers in statistics in which we want to teach the comparison of groups (with TinkerPlots) with the elements (such as center, spread, etc.) described above.

COURSE "DEVELOPING STATISTICAL REASONING WITH TP"

The authors of this article have designed a course for preservice teachers called "Developing statistical reasoning with using the software TinkerPlots" (Frischemeier & Biehler, 2012) in the sense of the design based research paradigm (Cobb et al., 2003). In this course, which goal is the development of statistical content (but not pedagogical) knowledge, the participants go through the whole PPDAC-cycle (Wild & Pfannkuch, 1999) which includes analysing self-collected data with TinkerPlots and writing down findings in statistical reports. In the analysing section the participants got to know about how they could compare distributions via different aspects (such as center, spread, shift (see Pfannkuch, 2007) and skewness, *p*-based- and *q*-based-comparisons (see Biehler, 2001)) with TinkerPlots. At first they were taught to identify differences between distributions (regarding to center, spread, etc.), then they were told to interpret these differences. A norm set by us was to work out as many differences regarding to center, spread, etc. between both distributions as possible. At this stage we firstly want our participants to work out as many differences as possible and to interpret them. In a next step, not reported in this paper, the participants are asked to synthesize their findings (e.g., in form of writing a statistical report). For further details see (Frischemeier & Biehler, 2012).

RESEACH QUESTIONS

Since the ability of handling a large set of real and multivariate data is important for upcoming teachers in statistics, we want to investigate how preservice teachers explore large datasets and compare distributions with TinkerPlots. In this article we want to concentrate on the "statistical reasoning" component of preservice teachers when comparing groups with TinkerPlots only, so two research questions arise: Which group comparison elements (which were taught in our course - such as center, spread, shift, etc.) are used by the participants when comparing groups? How is the quality level of these group comparison elements used by the preservice teachers?

DESIGN OF THE STUDY

As part of the Ph.D. study of the first author, an interview-video study was designed in which the participants were asked to compare two distributions with TinkerPlots in pairs of two. For the selection of task we chose a task which deals with the exploration of the income distributions of male and female employees, which has got a lot of publicity in Germany with regard to gender biases in monthly incomes. The dataset taken from the German Bureau of Statistics was imported in TinkerPlots and contains 861 cases and more than 20 variables (such as gender, monthly income, region, kind of employment, etc.). This was drawn as a random sample out of 60,552 which itself was sampled at random (stratified) from the population of all German employees. Furthermore we handed out a TinkerPlots file containing the dataset and an exercise sheet where the participants were asked to make notes on it. After motivating the problem of a "gender difference income" with a newspaper article, the task for the participants was: "*In which way do the men and women differ regarding their income? Carve out differences in both distributions!*" Some impulses which differences can be carved out between the distributions can be found in (Biehler & Frischemeier, 2015). The video study was two-phased adapted from the design of Busse & Borreomeo-Ferri (2003). In phase 1, the "working phase", the participants work on the task in pairs and were forced to communicate to each other while doing the task. Figure 1 shows a TinkerPlots graph which displays the differences between both distributions using boxplots (and the mean) produced in TinkerPlots by participants during the working phase.

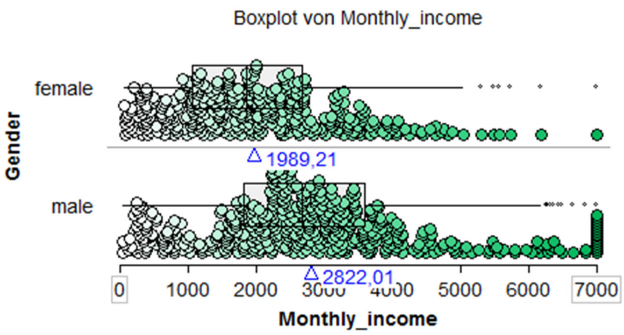

Figure 1: TinkerPlots Graph with boxplots and mean

In this phase there was no intervention by the interviewer (first author of this article). In phase 2 cognitive processes of the pairs should be revealed via "stimulated recall".

DATA, PARTICIPANTS AND METHODOLOGY

All in all 14 participants (7 pairs) took part in the study. All of them were preservice teachers for mathematics for primary and secondary school at the University of Paderborn and all of the participants attended the course "Developing statistical reasoning with TinkerPlots". The interviews were done 4–6 weeks after the last session of the course "Developing statistical reasoning with TinkerPlots". The participants were asked to work on the task in teams of two while they and their screen activities were video recorded. TinkerPlots files, exercise sheets and video recordings were also collected. The communication and action with TinkerPlots was transcribed. Our goal is to evaluate the whole communication of the participants regarding to their statistical reasoning elements when working on the task. So a large amount of data is to handle and there is also a need for an evaluation procedure which is comprehensible. The qualitative content analysis in the sense of Mayring (2010) "can be well applied in the case of having the intention to analyse a huge amount of transcribed data" and follows the "reduction of the huge amount of data in form of an analysis via category systems" (Kohlbacher, 2006). One main goal of this procedure is "to filter out a particular structure from the material" (Kohlbacher, 2006). Mayring (2010, p. 63) has pointed out different streams of the qualitative content analysis, such as "structural", "explicating" or "summarising". We want to structure the group comparison elements of the participants first and then scale (evaluate) them. The sequence of a structured-scaled qualitative content analysis (Mayring, 2010, p. 101) starts with choosing the analysis units (Step 1). In this case the analysis units are the transcribed data from the communication of the pairs when the participants were working on the task. As a second step the dimension of analysis is set up (step 2) – in our case this is *statistical reasoning when comparing groups*. In a further and third step we determine the characteristics of "dimensions of analysis" (Step 3) in form of setting up a category system, which is seen as the basis of this method where coding rules and key examples are given for an exact assignment between coding and data material and therefore define categories for evaluating the transcribed communication of the participants (Step 4). These categories can be defined deductively, inductively or mixed (Kuckartz, 2012, p. 62).

FRAMEWORK FOR COMPARING GROUPS

We used this construction of categories in the sense of Kuckartz (2012, p. 62) for our purpose. The aim was firstly to structure the transcribed data regarding the statistical elements used for group comparison and secondly to evaluate the quality of each element. So we took into account the elements "summary", "spread", "signal" and "shift" of the framework of Pfannkuch (2007) in the sense of a deductive approach. Since our participants were asked to find differences between both distributions and since they have had the possibility of a free data exploration with TinkerPlots, we have had to modify the categories of Pfannkuch (2007) for our purpose. Having a look on Biehler's (2001) normative point about group comparisons, where the comparison of skewness and *p*/*q*-based-comparisons also plays a huge part in the comparison process, we decide to add the elements "skewness", "*p*-based" and "*q*-based" to our framework. The further step sees an inductive refinement of the categories (Step 5) in the sense of Kuckartz (2012, p. 69). In this step 5 we have

	High quality	Medium quality	Low quality
Center	Measures of center (mean, median) are compared in a quantitative way and are interpreted.	Measures of center (mean, median) are compared in a qualitative way and are not interpreted.	Measures of center (mean, median) are compared in a wrong way.
Spread	Measures of spread (IQR) or informal descriptions of spread (such as "density", "close") are compared and interpreted.	Measures of spread (IQR) or informal descriptions of spread (such as "density", "close") are compared and not interpreted.	Spread is compared with inadequate measures (like range) and is wrongly interpreted.
Shift	Shift between both distributions is quantified correctly (with comparing the position of the middle 50% or with comparing non-corresponding numbers)	Shift between both distributions is described in a qualitative way.	Shift between both distributions is worked out in a wrong way.
Skewness	Skewness of both distributions is described correctly and the differences between the distributions are interpreted correctly.	Skewness of both distributions is described correctly but not interpreted.	Differences of skewness are worked out in a wrong way.
p-based	p-based differences are identified and interpreted	p-based differences are identified but not interpreted	p-based differences are worked out in a wrong way
q-based	q-based differences are identified and interpreted	q-based differences are identified but not interpreted	q-based differences are worked out in a wrong way

Figure 2: Definitions of codings

gone through the data with our deductively developed categories and refined them inductively. After this process, we added the elements "center" instead of "summary" because we wanted to concentrate on the comparison of mean and median and not on the comparison of all summary statistics and we have left out the category "signal" which is a special element for boxplot comparisons but not necessarily for group comparisons in general. We did not focus on the construction of plots in TinkerPlots, we just focus on working out as many differences with TinkerPlots as possible. Mostly standard displays, also primarily used in our course, like stacked dot plots, histograms and boxplots were used. All in all we finally have the following elements for our analysis: "center", "spread", "shift", "skewness", "*p*-based" and "*q*-based". We see these elements as our categories (see Figure 2).

As we see in Figure 2 we also generated for each of these categories the ratings "high quality", "medium quality" and "low quality" to evaluate the quality of the use of the elements in the comparison process. Generally we coded a group comparison element used by our participants with a "high" quality, if the difference of the distributions was worked out quantitatively and was also interpreted (in the idea of Pfannkuch's category "assessor"). An element is coded in the sense of a "medium" quality, if the difference is at least worked out on a qualitative level ("X is higher than Y") but not interpreted. Finally a "low"-quality code is given if the difference is worked out in a wrong or in an inadequate way. For illustrating the definition of codings we want to give examples (see Figure 3) arisen from our data.

When having set up the category system, we chose (in a sixth step) a word as minimal coding unit and a phrase as maximal coding unit. With this agenda we have coded the transcripts of four of the seven pairs so far. In this paper we refer only to codings belonging to the working phase, the codings of the transcripts of the stimulated recall phase are not reported here. If codings of passages were unclear, we had a look in the video to clarify the situation. A further step (step 7: Revision of codings) included the discussion of the codings with an independent researcher and in the following the revision of categories and definitions of categories. Finally a frequency analysis of the occurrence of the several categories was made (step 8: frequency-analysis of occurrence of steps).

RESULTS

Let us have a look which group comparison elements were used by the teams and how well they did in using them when working on the task with TinkerPlots.

At first we can say that we have 23 codings in total. The codings of the elements center, spread, skew and shift are at least at a medium quality level. All *p*-based comparions were rated with medium quality. There has been no team using *q*-based comparisons. All in all

	High quality	Medium quality	Low quality
Center	The men earn 29,5% more than women on average. (L & R)	The mean of men is higher than the mean of women (H & I)	No example.
Spread	The middle 50% of men spreads more than the middle 50% of the women. (H & I)	The Interquartile Ranges of the distributions are almost identical. (C & M)	No example.
Shift	The median of the distribution of men is almost equal to the first quartile of the distribution of women. (H & I)	The middle 50% of men are shifted right compared to the middle 50% of women. (H & I)	No example.
Skewness	The distribution of men seems to have some peaks but the distribution of women seems to be right skewed, so there might be more women earning little money compared to men. (L & R)	Here [distribution of salary of women] we can find a peak at 400€…the men [distribution of salary of men]…okay there is also a peak, but it is not so high. (L & R)	No example.
p-based	No example.	10% of the men earn more than 5000€, only 2% of the women earn more than 5000%. (S & L)	No example.
q-based	No example.	No example.	No example.

Figure 3: Key examples of codings of the group comparison elements

Overall	High quality	Medium quality	Low quality	Overall
Center	1 (33%)	2 (67%)	0 (0%)	3 (100%)
Spread	2 (40%)	3 (60%)	0 (0%)	5 (100%)
Skewness	2 (50%)	2 (50%)	0 (0%)	4 (100%)
Shift	3 (60%)	2 (40%)	0 (0%)	5 (100%)
p-based	0 (0%)	6 (100%)	0 (0%)	6 (100%)
q-based	0 (0%)	0 (0%)	0 (0%)	0 (100%)
Overall	8 (35%)	15 (65%)	0 (0%)	23 (100%)

Figure 4: Overwiew of all codings related to group comparison elements

Hilde & Iris	High quality	Medium quality	Low quality	Overall
Center	0	2	0	2
Spread	1	1	0	2
Skewness	0	0	0	0
Shift	3	0	0	3
p-based	0	1	0	1
q-based	0	0	0	0
Overall	4	4	0	8

Conrad & Maria	High quality	Medium quality	Low quality	Overall
Center	0	0	0	0
Spread	0	2	0	2
Skewness	0	0	0	0
Shift	0	1	0	1
p-based	0	0	0	0
q-based	0	0	0	0
Overall	0	3	0	3

Skewness	1	1	0	2
Shift	0	0	0	0
p-based	0	3	0	3
q-based	0	0	0	0
Overall	1	4	0	5

Figure 5: Codings (group comparison elements) distinguished by pairs

we can say that all of the statements and conclusions which were done by the pairs are at a high (35% of the codings) or medium (65% of the codings) quality level. Let us now have a look on the codings distinguished by pairs.

Hilde & Iris use amongst others center and spread elements - both of their statements using the group comparison element center were on a medium quality, one of their two elements regarding spread are on a high, the other on a medium quality. The conclusions regarding the comparison of shift of the both distributions are all on "high" quality. They also offer a medium quality *p*-based comparison, but they do not use a comparison of skewness or a *q*-based comparison. Conrad & Maria do not show any high quality statements in the whole solving process of the task. They offer at least three statements at medium quality. Conrad & Maria only use spread and shift elements but no center elements. They also do not use any skewness element neither do they use a *p*-based or a *q*-based comparison. Having a look on the codings of Laura & Ricarda we can say that they use every comparison element except *q*-based comparisons. They use center and spread (both in high quality) to compare the distributions and also shift and *p*-based comparisons (all in medium quality). Sandra & Luzie do not use center, spread or shift elements at all and work out differences from both distributions using skewness elements (one in high quality, one in medium quality) and *p*-based comparisons (all (3) in medium quality).

CONCLUSIONS

The statements of the pairs offer a broad variety of the use of comparison elements and none of the teams show low quality group comparison elements when working on the task. Most of the statements relating to the codings of "medium" quality could have been improved with the addition of an interpretation of the differences. Nevertheless we have to report some shortcomings which occurred: The amount of codings (overall: 23) is low. That means that all four teams made 23 comparison statements in total. On a first view this aspect is not necessarily negative, but in the course we have set up the norm that a group comparison should include as many investigations as possible. In this task there could have been found several differences along all aspects (center, spread, skewness, shift, *p*-based and *q*-based), so we finally expected some more codings relating to the comparison of both distributions. Whereas Hilde & Iris and Laura & Ricarda made eight respectively seven group comparison statements, Conrad & Maria only made three of them. *Q*-based comparisons were not used at all by the teams, although they played a big role when e.g. comparing boxplots in our course. Comparisons of skewness of both distributions were only done by two teams and apart from Hilde and Iris, the shift between both distributions was not worked out adequately. *P*-based comparisons were all done without interpreting the differences and are therefore all rated on a medium quality. As a further step in research we will take into account our findings from all three dimensions and search for relations between them. With these findings and the re-design of the course in mind we might conclude that our norm "to work out as many differences between two distributions as possible" should be made more explicit. A data analysis scheme, which structures the data analysis process and gives hints of possible comparison elements, might support learners when comparing groups. Furthermore we might conclude that there should be a closer focus on interpreting differences between the distributions regarding center, spread, shift, etc. This may be done with contrasting adequate and non-adequate examples in regard to comparisons via center, spread, etc. Additionally we might reemphasize comparing groups with q-based comparisons in an upcoming course.

ENDNOTES

1. Comparisons of two distributions of numerical variables are called p-based, if for x the relative frequencies $h(V \leq x)$ are $h(W \leq x)$compared. So in p-based comparisons a specific argument can be given (for example: 10 hours) und the proportion of cases which are equal or larger than 10 hours is compared in both groups. (see Biehler, 2001, p. 110)

2. Comparisons of two distributions of numerical variables are called *q*-based, if for a proportion p between 0 and 1 the matching quantiles of the variables V und W, $q_V(p)$ with $q_W(p)$, are compared. With $q(p)$ we mean the quantile regarding to p. For $p = 0.5$ this is a comparison of medians. (Since the comparisons of medians is also included in the category "center" we do not want to include this special case for $p = 0.5$ here). (see Biehler, 2001, p. 110)

An investigation of understanding of preservice elementary mathematics teachers (PEMT) about data displays

Kurt Gamze

Middle East Technical University in Ankara, Faculty of Education, Ankara, Turkey, gkurt@metu.edu.tr
Mersin University, Faculty of Education, Mersin, Turkey

Understanding to what extent preservice teachers are capable of conceptual and procedural knowledge of data displays is the aim of this study through analyzing a part of data collected during an independent study course. Change in the middle school curriculum in Turkey necessitates the study of examination of understanding of PEMT about statistics. Therefore, this study is significant in supporting the needs of teacher educators as well as it contributes to the consequences of curriculum efforts. In order to possess an understanding of statistical concepts for preservice mathematics teachers, they must have both conceptual and procedural knowledge (Hiebert & Lefevre, 1986), which is the main concern of this study.

Keywords: PEMT, data displays, conceptual knowledge, procedural knowledge.

INTRODUCTION

In our revised curriculum, which started to be instructed in middle-level schools in Turkey in September 2013, statistics has been the most emphasized subject. It was considered as a separate learning area named as data handling and it was included in all grades from the 5th grade through the 8th grade. However, the content of probability was reduced compared to previous curriculum, and it is placed into the 8th grade level only with a basic understanding of probability. These changes in the new curriculum could be identified as reflection of Moore's (1997, as cited in Biehler, Ben-Zvi, Bakker, & Makar, 2012) recommendation emphasizing that curriculum needs more statistics and less probability while leaving the deeper conceptual knowledge to the high-school level. The earlier studies showed that PEMT have less comprehension of statistics and probability compared with the other learning areas of curriculum, that I,; they found probability and statistics subjects difficult to teach especially because of their lack of content knowledge in probability and statistics (Quinn, 1997; Stohl, 2005). Contemporary efforts are addressing the same issue as well, so that teacher education should be enhanced through giving an attention to statistics and probability teaching for mathematics teachers (Stohl, 2005; Jones & Thornton, 2005).

Change in the elementary school curriculum necessitates the study of examination of understanding of PEMT about probability and statistics. It should be understood whether preservice elementary teachers have both conceptual and procedural levels of understanding of probability and statistics in order to teach them (Star, 2005). Thus, this study is significant in the above needs of the Turkish mathematics education literature as well as it contributes to the consequences of curriculum efforts and will be a light for future considerations of this issue. This study is part of a relatively larger study which was conducted by the researcher in spring semester in 2014. The research questions examined here are as follows: (a) to what extent are PEMT capable of conceptual and procedural knowledge of data displays? (b) what are the main strengths and weaknesses of PEMT in data displays?

REVIEW OF RELATED LITERATURE

Statistical knowledge for teaching can be interpreted under the framework of mathematical knowledge for teaching. This framework has two main dimensions for mathematical knowledge for teaching: first, subject matter knowledge which includes common content knowledge (CCK), specialized content knowledge (SCK) and knowledge at the mathematical horizon; second, pedagogical content knowledge which includes knowledge of content and students (KCS), knowledge of content and teaching (KCT) and knowledge of curriculum (Hill, Ball, & Schilling, 2008). From the statistics point of view, CCK is considered as computing and interpreting the most frequent measures of central tendency; SCK is considered as special for teaching as which is best for which statistics term; horizon knowledge is considered as working on populations will eventually emerge the working on samples, for example. For the second dimension, KCS can help teachers to catch the common strategies which students use in developing students' statistical reasoning; KCT deals with the content-specific strategies like knowing how to explain arithmetic mean as a fair share or as a balance point; and knowledge of curriculum can help teachers about structural properties that a curriculum possess (Groth, 2012). Therefore, Groth (2012) has developed a framework for combining above terminology and suggested the figure in his paper.

Based on the efforts in conducting the course which Groth (2012) was teaching, namely as Statistical Knowledge for Teaching (SKT), he has developed the framework for SKT, while adding two new constructs to the statistical knowledge for teaching framework, one of which is key developmental understandings and the second one is pedagogically powerful ideas. Key developmental understandings were defined as "cognitive landmarks in the learning of fundamental ideas needed to understand content" (Simon, 2006, as cited in Groth, 2013). Pedagogically powerful ideas can be defined as ideas that occur as the result of transforming key developmental understandings into ideas that facilitate students' learning of the key developmental understandings. Groth (2013) in his hypothesized framework relates these two dimensions with the other existing dimensions of mathematical knowledge of teaching.

According to above framework, subject matter knowledge needed for statistics and probability teaching is the concern of this study and its sub-dimensions such as conceptual and procedural knowledge types should be integrated to it as well. The terms were introduced by Scheffler (1965), but expanded by Hiebert and Lefevre (1986) and Star (2005), where "conceptual knowledge is characterized most clearly as knowledge that is rich in relationships, like a connected web of knowledge, a network in which the linking relationships are as prominent as the discrete pieces of information" (p. 3). They also categorize the conceptual knowledge as primary and reflective. The primary level of conceptual knowledge is formed as in "the relationship connecting the information is constructed at the same level of abstractness (or at a less abstract level) than that at which the information itself is represented" (Hiebert & Lefevre, 1986, p. 5). The reflective level of conceptual knowledge is constructed in 'a relationship which requires a higher, more abstract level than the pieces of information they connect' (p. 5). Apart from conceptual knowledge, Hiebert & Lefevre (1986) also explains the procedural knowledge in two types: "one kind of procedural knowledge is a familiarity with the individual symbols of the system and with the syntactic conventions for acceptable configurations of symbols; the second kind of procedural knowledge consists of rules or procedures for solving mathematical problems" (p. 7). In order to develop an understanding of statistical concepts for PEMT, they must have both conceptual and procedural knowledge (Hiebert & Lefevre, 1986). Ball (1988) described the subject matter knowledge similar to above; she names the procedural knowledge as substantive knowledge, which refers to "understanding of particular topics, procedures, concepts and relations among them" (p. 4), and secondarily, knowledge about mathematics is named in place of conceptual knowledge. Hence, this type of categorization fits with the above expressions and summarizes our theoretical framework.

METHODOLOGY

This study has a phenomenological approach which is categorized by one of the qualitative research designs (Creswell, 2007) since researcher tries to understand the shared experiences and understandings of a group of participants on data displays and their weaknesses/strengths as a phenomena.

In order to investigate its research questions, data were collected through face-to-face interviews (later transcribed verbatim). 23 participants from PEMT were interviewed voluntarily, 12 of whom are 4th year students and the rest are in their 3rd year of elementary mathematics teacher education. They have already attended to a statistics and probability course (which is a must course in their undergraduate education) in their second year and it includes the probability and statistics subjects in a very advanced and a theoretical form. Apart from that, six participants had taken the "methods for statistics teaching" (which is a fourth year must course in one of the universities studied) before the instrument and they specified especially that they learned statistics through that course.

In order to investigate the understanding of PEMT's knowledge of statistics and probability subjects framed by elementary school curriculum, an instrument was used. It involves open-ended questions as well as multiple-choice items which measure both procedural and conceptual types of knowledge required for understanding of statistics and probability. Specifically, it involves statistics questions related to measures of central tendency (mean, median and mode), measures of variation (range) and data displays; and probability questions related to probability of a basic event, certain, impossible and equally-likely events, theoretical and experimental probability. Some items are presented at the end of the paper as Appendix. The instrument is organized as most of the questions were taken from two tests written by Diagnostic Teacher Assessments in Mathematics and Science developed at the University of Louisville (CRiMSTeD- Center for research in Mathematics and Science Teacher Development) with their permission to use. There is also one question taken from Jacobbe's (2007) dissertation. These assessments have established high levels of reliability and validity (Bush et al, under review, as cited in Jacobbe, 2007). Since the instrument was implemented to the participants as face-to-face interviews, it is necessary to mention about the interviews summarized below.

Each interview is composed of three sections. In the first section, participants were asked questions related with their choice of being elementary mathematics teacher, interest of mathematics and mathematics teaching, subjects which they know as best and least covered in middle school mathematics curriculum, comments on change on curriculum regarding the statistics and probability subjects, interest of learning/using technological tools/materials needed for teaching and comments on test items at the end of the interview. In the second section, participants were directed to questions related with the measures of central tendency, measures of variation and probability, such as 'how do you define mean?' or 'what does mode of a group of data tell you?' in procedural and conceptual knowledge levels. Thus, the findings of this part were the results of test items according to the subjects. In the last part, participants were given the test and they were expected to solve open-ended questions as orally. Implementing the instrument as in this way provides us in order to learn how preservice mathematics teachers understood probability and statistics, more specifically their conceptual and procedural way of understanding on these subjects.

The last two sections consider the content knowledge of participants while taking its different types as procedural and conceptual into consideration comparatively. That is, these sections compensate for each other in order to investigate the understanding of participants on the subjects which analyzed.

The analysis of the data gathered from first and second part of the interviews was done according to themes and codes specified before the implementation. The evaluation of the data gathered from the instrument was performed according to a rubric which was prepared for only open-ended items. The evaluation of open-ended items was done in only three categories: full response, incomplete response and wrong response. A full response addresses that participant gives the best explanation using the right terminology and expected logical foundations in order to rationalize the subject whereas an incomplete response addresses that participant does not give a fully satisfying response or s/he cannot rationalize his/her response. A wrong response means that participant gives a completely wrong response without making any logical explanation or rationalization by using his/her understanding of the subject.

FINDINGS

Although the methodology part mentions about the parent study of the study framed here, only the findings for data displays will be presented in order to answer the research questions outlined above. The instrument included 22 items and 11 items were associated with data displays. The responses given to each item and the subject related with the item are given below in the table:

Most of the participants did not know about most of the graphical representations which directed as questions through the instrument. For example, all of the participants do not seem to have any idea about box-and-whiskers plot and they couldn't catch the me-

Question	Type	Related Subject	Ratio of Achievement
Item 1	Multiple Choice	Stem-and-leaf display	2 correct, 1 wrong, 20 of 23 have no information about topic.
Item 2	Multiple Choice	Graphical representations of data	2 correct, 5 have no information about the subject, 16 of 23 are wrong.
Item 3	Multiple Choice	Scatter-plot	13 of 23 are correct.
Item 4	Open-ended	Box-and-whiskers plot	All of them have no information about topic, and they analyzed graphic with their own understanding, and sometimes come up with correct answer. Hence, they answered incomplete.
Item 5	Open-ended	Biased graphic displays	2 of 23 responded full, 1 of 23 responded false, and 20 of them responded incomplete.
Item 6	Open-ended	Circle graph	13 of 23 responded full, 2 of them responded wrong, 8 of 23 responded incomplete.
Item 7	Multiple Choice	Line graph	10 of 23 are correct.
Item 8	Multiple Choice	Line graph	22 of 23 are correct.
Item 9	Multiple Choice	Frequency table	21 of 23 are correct.
Item 10	Open-ended	Line graph, bar graph, categorical variable	10 of 23 responded wrong, 10 of 23 responded full, 3 of 23 responded incomplete.
Item 11	Open-ended	Frequency distribution, mean, median, mode, range, normal distribution, data displays	8 of 23 responded incomplete, 15 of 23 responded full.

Table 1: Findings per item with respect to the subject and type

dian and percentiles from the representation given in the item 4 (in Appendix). Most of the participants do not know of stem-and-leaf display, either, as realized from the findings of item 1 (in Appendix) in the test. The item 2 is another item which has only 2 correct responses. Item 2 was asking the best description of the distribution of achievement test scores for all 4th graders in a school while choosing among scatter plot, box-and-whiskers plot, line graph and circle graph. This finding is expected since box-and-whiskers plot is not known by the participants so as in item 4.

The scatter-plot question (item 3) has a half success by the participants. Most of the participants cannot relate each dot with two axes onto the graph, many of the correct responses were given with an unclear explanation. Although, all of the participants could realize the difference between two different graphs with the same data, they couldn't explain its consequences correctly and their responses show a misunderstanding or inadequate knowledge of biased graphical data displays. Item 6 asks for reasons of mistakes made by a student who draws a circle graph of a given set of data and how to overcome those mistake. Most of the participants could easily found the mistake, however, nearly half of them could present ways to overcome it.

Item 7 (in Appendix) is having one of the most wrong respondents which is also an unexpected result compared with the result of other line graph question, item 8. Item 8 asks the true alternative for the difference of average salaries taken by university or high school graduated workers and it includes two line graphs on the same display. Item 9 presents the frequencies of data as a rotated bar graph and asks the true alternative among the other 3 false alternatives like in the previous item. The responses for this item are mostly correct and we can say that the most achieved items which the participants responded with a higher rate than others were the 8th and 9th items. Another item which nearly half of the participants responded correctly is the item 10 (in Appendix) since they could realize the importance of having a categorical variable (like in this item) for a bar graph in this item. The item 11, which was taken from the Jacobbe's (2007) dissertation, is the longest question in the instrument. Nearly two-thirds of the participants responded as full, the rest of them could neither grasp the dot plot display nor explain their choice with a satisfying rationale.

DISCUSSION

The findings of this study show some aspects mentioned in the theoretical framework for preservice mathematics teachers' understandings described by Groth (2013), Hiebert & Lefevre (1986) and Ball (1988). It can be said that the questions directed to participants during the interview, they could not show their conceptual knowledge about data displays since their answers were mostly in procedural knowledge base. In general, PEMT has a high achievement in procedural level of knowledge for data displays.

It is also worth to mention that the responses given to the items in the instrument shows also resemblance to the findings through interviews which investigates the understanding of the statistical concepts, specifically measures of central tendency and measures of variation. For definitions of mean, median and mode, participants seem to not know the difference between calculations and meanings of them, as emphasized before (McGatha, Cobb, & McClain, 1998, as cited in Jacobbe, 2007). This can be discussed that they don't know the foundations under mean, median and mode and can be explained as there is a difference between knowing how something is calculated and knowing why it is (Hiebert & Lefevre, 1986).

Moreover, based on the findings of the interviews, it can be claimed that participants has a high achievement in procedural level of knowledge for measures of central tendency. They mostly know concepts; but, most of the participants have difficulty in answering questions necessitating conceptual knowledge, which are connected with the subjects of meanings of measures of central tendency as related with data displays, difference or relation between those. It can be argued that participants have not enough ability to connect what they know about measures of central tendency and the associated data displays; besides, they have not a higher-order comprehension needed for knowledge answering to the questions (Ball, 1988; Hiebert & Lefevre, 1986; Groth, 2013).

When we consider the possible reasons of why conceptual knowledge of PEMT have been less-developed compared with procedural knowledge, the courses offered for teacher candidates during their university education are like 'recipe-type' or 'rule-bound' courses which only deals with the calculations and lead preservice teachers to memorize the subjects while underestimating the logic behind it, as Shaughnessy (1992) stressed out previously. He claims also that preservice teachers lack of opportunity to develop their stochastic reasoning in university courses due to their misunderstandings about statistics. Nearly half of the participants have stressed during interviews that they feel themselves not knowing very well about statistics although they have taken a course namely as "statistics and probability" which they took in their 2nd year. The other half of the students have mentioned that they have a course about "teaching probability and statistics in elementary level". However, unless they learned about statistics very well, they do not feel to be able to teach it. Hence, they first need to know it, as they expressed and eventually corresponds with the arguments of Shaughnessy (1992). Although it was not one of the interview questions, most of the participants mentioned about their complaints about "statistics and probability" course. They emphasized that the course have not included any practical implementation to a real-life example, but was mostly theory-based and proof-based. Therefore, most of them specified that they could not learn much about statistics or probability subjects in this course, for example, they did not meet even with a boxplot display during the course.

In brief, this study discussed the understanding of PEMT for statistics, specifically the issue of data displays. Findings implied that content knowledge assessed by the items in the instrument have two dimensions, procedural and conceptual knowledge, as discussed clearly by the researcher previously in the review of related literature part above (Hiebert & Lefevre, 1986; Ball, 1988; Groth; 2013) and corresponds to the framework which was bounded.

The implications of this study will be enlightening to the future research for the understanding of PEMT in Turkey. The discussion of the findings can have an impact on teacher education programs in the universities. While some universities have currently specific courses related with pedagogical content knowledge for statistics and probability including content knowledge needed for those subjects as well, some of them have not. As specified before, PEMT are not ready for teaching statistics because of lack of statistical knowledge (Greer & Ritson, 1994). Therefore, as the participants of this study stressed out that they should learn statistics very well while learning methods of teaching statistics. Having such consequences, this study can have positive influences on the development of elementary mathematics education programs, and might affect the perspectives of teacher educators, who are responsible for educating the teachers, as well.

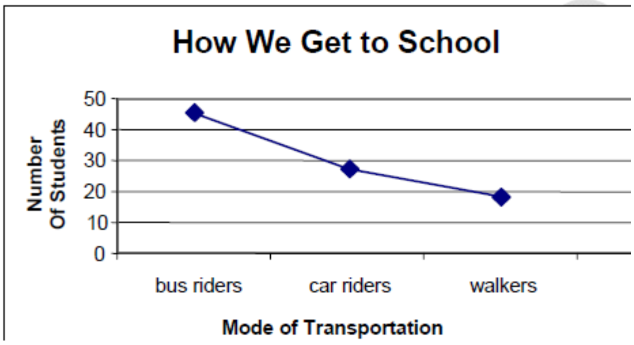
APPENDIX: SAMPLE ITEMS FROM THE INSTRUMENT

Item 7: Which of the following best describes a line graph?
a. A graph that visually represents the median, the quartiles, and the smallest and largest values of a data set.
b. A graph consisting of a horizontal number line with data points represented by X's.
c. A graph consisting of points, one for each item being measured. The two coordinates of a point represent the measures of two attributes of each item.
d. A graph with a vertical and horizontal axis that is primarily used to show changes over time.

Item 10: A student collected data from 90 fourth grade students about how each student traveled to and from school. The student created the following graph. How would you respond to this student?

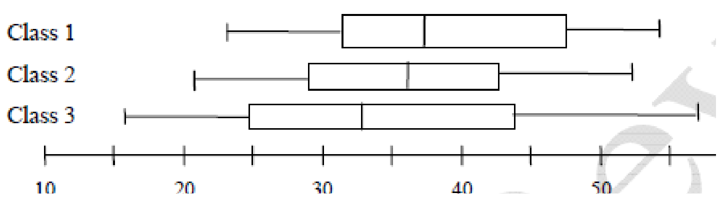


Item 1: The students in a sixth-grade class were timed to the nearest second for a run around the school's gymnasium. The times for the class are listed below in a stem-and-leaf plot. Which of the following is true?

2	4 8
3	1 3 4 5 6 7 8
4	1 2 3 7 7 8
6	0 1 4 8 9

a. The lowest time was 28 seconds
b. Half of the students had times above 41 seconds
c. The highest times was 60 seconds
d. 50% of the students had times below 38 seconds

Item 4: The box-and-whiskers plot below represents the test scores of three classes on the same test.
a. Which class performed the best and which class performed the worst.
b. Provide justifications for your choices with data from the box-and-whiskers plots.



Regression in high school: An empirical analysis of Spanish textbooks

María M. Gea, Carmen Batanero, Pedro Arteaga, J. Miguel Contreras and Gustavo R. Cañadas

University of Granada, Faculty of Education, Granada, Spain, mmgea@ugr.es

The aim of this study was to analyze the presentation of regression in Spanish school textbooks aimed at Social Sciences students. In a sample of eight textbooks we analyzed the problem-fields and suggested procedures, as well as the associated concepts, which are classified according to the way they are introduced and the properties associated with them. Our results suggest that these textbooks mostly reduce regression to lineal regression, present many properties at an operational level without deep discussion of their meaning, and there is a great variety between the textbooks. Some suggestions to improve the presentation of this topic are included.

Keywords: *Regression, textbooks, high school, mathematical objects.*

INTRODUCTION

Correlation and regression are fundamental statistical ideas, due to their usefulness to model phenomena in different fields (Engel & Sedlmeier, 2011). Previous research is mainly focused on students understanding of correlation and describes several misconceptions (Estepa & Batanero 1995; Estepa, 2008; Zieffler & Garfield, 2009). There has not been, however, much interest in the way the topic is taught or presented in the textbooks, even although textbooks are important educational tools. From the official curricular guidelines to the teaching implemented in the classroom, an important step is the written curriculum reflected in textbooks (Herbel, 2007). The selected textbook is an important part of teaching and learning mathematics at secondary and high school level, since the presentation of the topics and the problems proposed provide the main basis of why the topic is taught (Shield & Dole, 2013). Moreover, in other mathematical topics, textbooks receive increasing attention from the international community; see for example Fan, and Zhu (2007).

The aim of this research was to analyze the presentation of regression in high school Spanish textbooks aimed at Social Sciences students. It is part of a wider project where we compare the way in which correlation and regression are presented in the textbooks in Spain. Due to length limitation we only present here a part of our analysis; complementary results were published in (Gea, Batanero, Cañadas, & Contreras, 2013), and (Gea et al., 2014).

THEORETICAL BACKGROUND

According to Rittle-Johnson, Siegler and Alibali (2001) conceptual and procedural knowledge are the two extremes in a continuous; conceptual knowledge is more flexible and includes the implicit or explicit understanding of a domain and its interrelationships. Sfard (1991) suggests that a concept is a construct which corresponds to the mathematical universe and distinguishes two types of definitions of the same: structural (where concepts are introduced by describing their essential conditions or properties) and operational (when it is described by a formula) definitions. In our analysis we will take into account both types of definitions and will also describe in detail the properties associated with regression.

The division between conceptual and procedural knowledge is analyzed in the onto-semiotic approach to mathematics education (Godino & Batanero, 1998; Godino, 2002) where mathematical activity plays a central role. Knowledge in this framework is modelled in terms of systems of practices, in which different types of objects intervene when a subject faces the solution of a given problem. "Object" is understood in a broad sense for any entity which is involved in mathematical practice and can be identified separately. More specifically in our analysis we will consider the following types of mathematical objects: problem-situations; procedures; concepts and properties.

Previous research

In spite of the relevance of the topic, previous research suggests poor results in people's understanding of correlation. For example, Chapman and Chapman (1967) described *illusory correlation* where people are often guided by their theories rather than by data when estimating correlation. Estepa (1994) defined several misconceptions including the *deterministic conception*, where the student only considers whether functional dependence exists. Sánchez Cobo (1999) described students' failures in ordering correlation coefficients and in interpreting the relationship between the correlation coefficient and the slope of the regression line. As regards research on textbooks, Sánchez Cobo (1999) classified the definitions of concepts presented in 11 textbooks published in the period 1977–1990 as procedural, structural or a mixture of both. Lavalle, Micheli and Rubio (2006) analyzed the concepts and procedures included in 7 high school textbooks from Argentina.

As stated in the introduction, this paper is part of a more comprehensive project. In (Gea et al., 2013) we analyze the problem-situations used to contextualize correlation and regression in eight Spanish textbooks and in (Gea et al., 2014) the symbolic, verbal and graphical language used in this topic. The current paper complements these publications with the analysis of concepts, properties and procedures included in the study of regression in the same textbooks, which were not included in these papers. In each of these types of objects we analyzed all the categories that are relevant for the teaching of the topic.

METHOD

The sample consisted of eight mathematics high school textbooks aimed at Social Sciences students and that were published just after the current curricular guidelines were introduced (MEC, 2007). These particular textbooks have a wide diffusion in Spain due to the publishers' prestige and are still used in the schools (See Appendix). We performed a content analysis (Neuendorf, 2002) of the chapters devoted to correlation and regression with the following steps: a) following an inductive and cyclic procedure we first categorized all the different mathematical objects explicitly or implicitly included in the chapter (the different types of problems, concepts, properties and procedures); b) For each of them we analyzed the way in which they are described or used in the textbooks. In this paper we only describe the mathematical objects linked to regression; as the remaining results have been published elsewhere (Gea et al., 2013; 2014).

PROBLEMS AND PROCEDURES

Anthony and Walshaw (2009) reported on the different types of tasks that have been analysed in mathematics education research, that include problems focused on specific mathematical content; problems that promote mathematical modelling; others that require discussion of aspects that vary; those that ask students to interpret and criticise data and those that prompt sense making and justification of thinking. Gea and colleagues (2013) identified two main types of problems in the study of regression in which one of several of the above type of tasks may be combined: a) Fitting a model to the data requires sense making and criticism of data; mathematical modelling, discussion of variation and justification of thinking, b) Using the model to predict a value of the dependent variable is a more computational type of task; however, much of the time judgement of the goodness of fit involves criticism, decision making and justification. Both types of problems appear with different frequency in all the books; each of these types of problems range from 20% of all the problems posed in the chapter in [H4] to 35% in [H6] 1. To solve these two types of problems, the books introduce the following procedures:

P1. Fitting the least squares line. Lineal regression by the least squares method is included in all the books, with two different procedures to compute the line of best fit: a) Equation of the line which includes the gravity centre (point whose coordinates are the mean for the two variables); and b) General expression for the lineal function:

Regression line $Y = f(X)$
a) $y - \overline{y} = \mathrm{b}_{yx} \cdot (x - \overline{x})$ b) $y = a + b_{yx} \cdot x$

Regression line $X = f(Y)$
a) $x - \overline{x} = \mathrm{b}_{xy} \cdot (y - \overline{y})$ b) $x = a' + b_{xy} \cdot y$

1 All the books also introduced the analysis of the sign and strength of correlation between the variables as a previous problem as well as problems related to graphical representation of bivariate data. We are not including here these problems that were analyzed in (Gea et al., 2013).

P2. Fitting other regression models. Only [H8] includes the regression towards the median developed by Tukey, which is a robust method in the presence of outliers as well as variable transformation to fit exponential and polynomial models.

P3. Computing the determination coefficient and interpreting the goodness of fit. Only a few textbooks introduce the determination coefficient r^2 as a measure of the goodness of fit; in all of them the coefficient is previously defined.

P4. Prediction with the line of best fit and interpreting the goodness of prediction. All the books propose some tasks where the students have to estimate the response variable *Y* given a value for the explanatory variable *X*. Some of them ([H1], [H2]) suggest that when the correlation coefficient is strong it is possible to use the same line to predict *X* from a value of *Y*. Since this property is not general (as there are two different regression lines) students could make an incorrect generalization. Some books qualitatively evaluate the goodness of fit by comparing the estimated and observed values for isolated data. This informal method is not reliable, as the reliability of estimation depends on the goodness of fit (given by the determination coefficient) as well as on the closeness of the estimated value to the centre of the distribution of the explanatory variable.

In Table 1 we observe that all the books include the least square line, as well as its use for prediction, while only one includes the Tukey line and a few the evaluation of the goodness of fit. A missing point is the use of informal "eye fitting" methods that are useful to build the students' intuitions and can be implemented with applets (e.g., //docentes.educacion.navarra.es/msadaall/geogebra/figuras/e3regresion.htm). Results are better than those by Lavalle, Micheli and Rubio (2006); where only half the books include the line of best fit and 60% of the books include prediction activities.

CONCEPTS AND PROPERTIES

In our analysis we found the following concepts linked to regression:

C1. Dependent (response) and independent (explanatory) variable: While correlation is symmetric, regression is asymmetric; for this reason we should discriminate the response and explanatory variables (Estepa, 1994). Only a few books make the distinction explicit although in other books it is implicit when they introduce two different regression lines.

C2. Model of fit. The idea that the regression line is only a model (and therefore does not exactly coincide with all the data) is only implicitly introduced; a couple of books make this idea explicit: "*When there is strong correlation between X and Y the analysis of regression helps to find a mathematical function as a model to fit the data. This function can be a straight line, a parabola, exponential…*" ([H4], p.226).

C3. Line of best fit (linear model). All the textbooks include the definition and explanation of the minimum squares method (in an informal way); however, only a few of them justify the utility of the model to estimate values of *Y* in situations where the variable is difficult to measure. Moreover, as in Sánchez Cobo (1999), few texts highlight the predictive utility of the regression line.

C4. Regression coefficients. Since there are two possible lines of best fit (depending on which is the explanatory and response variable) there are two different regression coefficients, but only a few books make this explicit. They also include the interpretation of these coefficients: "*The line that minimizes the sum of residuals* Σd_i^2 *is given by the following expression:* $y = \overline{y} + \sigma_{xy}(x - \overline{x})/\sigma_x^2$. *The slope* σ_{xy}/σ_x^2, *is the regression coefficient*" ([H1], p. 230).

Procedures	H1	H2	H3	H4	H5	H6	H7	H8
P1. Fitting the least squares line	x	x	x	x	x	x	x	X
P2. Fitting other regression models								X
P3.Computing the determination coefficient and interpreting the goodness of fit					x	x		
P4. Prediction and interpretation (line of best fit)	x	x	x	x	x	x	x	X

Table 1: Regression analysis procedures included in the books

C5. Goodness of fit. Coefficient of determination. These concepts help the student understand the meaning of regression; however they are only included in [H5] and [H6], where the accuracy of the model is identified with the accuracy in the prediction for any particular point. This is not true, as the accuracy is higher when the point approaches the centre of the distribution of the explanatory variable.

C6. Non lineal models of fit. Regression is a general method for understanding relationships between variables (Moore, 2005), and therefore it is necessary to introduce different models of fit; however, only a few textbooks implicitly define non lineal models, where [H5] and [H6] define them explicitly.

We summarize the definition of concepts in Table 2, where we observe the predominance of adding examples to the definitions; usually the texts include scatter plots with the line of best fit added to show the residuals. The line of best fit is introduced in all the books and is generally defined both in a structural and operational way (Sfard, 1991). The presentation is very similar to that in Sánchez Cobo (1999). Other definitions (regression coefficients, dependent and independent variable, goodness of fit and non linear models) are missing in some textbooks or are only defined in an operational way. The definitions are introduced in different orders; sometimes the examples are followed by the definition and vice-versa. In the same way the order to introduce operational or structural definitions also varies.

Properties

The textbooks add different properties to the definition of the concepts or to relate different concepts, as described below:

P1. Least squares property. Most textbooks explain that the regression lines make the sum of residuals from the points to the line minimum. Usually the explanation is only visual (a formal deductive proof is avoided).

P2. Two different regression lines. Most of the books implicitly remark that there are two different regression lines and part of them warns the students of the danger of using an inadequate line to make a prediction. Two books ([H2] y [H8]) do not remark on this property. This omission may reinforce the deterministic conception of some students (Estepa, 1994), since in deterministic dependence there is only one algebraic expression (function) to express the dependence.

P3. Percentage of variance explained (r2). The determination coefficient measures the goodness of fit. Some textbooks also analyze its interpretation as the percentage of variance explained by the regression line: "*(r^2x100)% is the percentage of variance of Y explained by the value of X*"([H6], p.185).

P4. Estimation using the regression line. The regression line serves to predict the value of response (*Y*) given a value of the explanatory variable (*X*). The books implicitly indicate that these estimates are only approximations. They insist that, contrary to functional dependence, there are several values of *Y* for a given value of X, and the regression line provides the average of all these values: "*These estimates are approximations and involve a probability; it is probable that when $x = x_o$ the value of y is approximately $y(x_o)$.* ([H1], p.230).

P5. The regression line crosses the distribution centre of gravity, a property only included in half the books in the study by Sánchez Cobo (1999).

P6. Estimates are more accurate for values closer to the centre of gravity. However some books only judge the reliability of estimates by the value of the correlation coefficient.

Concepts	H1	H2	H3	H4	H5	H6	H7	H8
C1. Dependent and independent variable					O			O
C2. Model of fit			ES	SE				
C3. Line of best fit (linear models)	ESO	EOS	SO	SOE	SOE	SOE	SOE	SO
C4. Regression coefficients	O	SO		O				
C5. Goodness of fit.					SOE	OE		
C6.Non linear models					SOE	SOE		

E = Examples; O = Operational definition; S =Structural definition

Table 2: Concepts linked to regression and type of definition

P7. Reliability of estimates and sample size. It is included only in a few books: *"The estimate accuracy increases with the number of data; the regression line computed with few data has little reliability even if r is high"* ([H5], p. 260).

P8. Strength of correlation and angle of regression lines: This angle varies from perpendicular lines (independence) to only one line (perfect linear dependence).

P9. Regression line, covariance, correlation. Covariance and correlation are interpreted as regards the closeness of the points to the regression line. Their sign is related to the slope in the regression line: "*Depending on the position of* (x_i, y_i) *as regards* $(\overline{x}, \overline{y})$, *the product* $(x_i - \overline{x}) \cdot (y_i - \overline{y})$ *will be positive or negative. If many points are close to a line with a positive slope, most of these products are positive and the covariance and correlation are positive"* ([H1], p. 228). These properties were not found in the books analyzed by Sánchez Cobo (1999).

P10. Product of regression coefficients. Some books suggest that the product of regression coefficients is equal to the square of the correlation coefficient: r^2. This property was found in most books in Sánchez Cobo's research (1999) but is found in only two books in our study.

PP11. Correlation and reliability of estimates. Most textbooks relate both concepts: "*The higher the correlation coefficient r, the higher the reliability of estimates: when r is close to zero, there is not much sense in doing an estimation; as r approaches to 1 or -1, the real values will approach our estimates; when r = 1 or r = -1, real values and estimates coincide"* ([H4], p. 226).

In Table 3 we summarize the properties of regression included in the books. There are great differences between textbooks, because while some of them ([H4], [H8]) hardly describe any of the properties analyzed, others ([H3]) include almost all of them. The most frequent property is the least squares, the existence of two different regression lines, estimation with the line, centre of gravity crossing the line, and relationship of reliability in the estimate, centre of gravity and correlation coefficient. Globally the books introduce a rich set of properties of regression. We remark that some textbooks do not include the properties P8 and P9; this omission may reinforce the students' failures in interpreting the relationship between the correlation coefficient and the slope of the regression line described by Sánchez Cobo (1999).

DISCUSSION AND IMPLICATIONS FOR TEACHING

Our results suggest little changes in the presentation of regression in the high school textbooks, as regards the analysis by Sánchez Cobo (1999), although the books studied by this author were published between 1977 and 1990. Our analysis complement that research and that by Lavalle, Micheli, & Rubio (2006), because neither of these previous studies analyzed the properties linked to regression, in spite of the fact that Sfard (1991) considered that the properties are an essential part of the concepts. This study also complements our previous studies: (Gea et al., 2013), where we analyzed with more detail the problem-situations used to contextualize correlation and regression, and (Gea et al., 2014) where we described the symbolic, verbal and graphical language used in this theme.

	H1	H2	H3	H4	H5	H6	H7	H8
P1. Least squares property	x	x	x		x	x	x	x
P2.Two different regression lines	x		x	x	x	x	x	
P3. Percentage of variance explained (r2)					x	x		
P4. Estimation using the regression line	x	x	x	x	x	x	x	
P5. Regression line and centre of gravity	x	x	x		x	x	x	x
P6. Reliability of estimates and centre of gravity	x	x	x		x	x	x	x
P7. Reliability of estimates and sample size			x		x			
P8. Strength of correlation- angle of regression lines	x		x				x	x
P9. Regression line, correlation, covariance	x		x		x	x	x	
P10. Product of regression coefficients	x		x					
P11. Correlation coefficient – reliability of prediction	x	x	x	x	x	x	x	

Table 3: Properties of regression

Although all the textbooks introduce linear regression and propose methods to compute the line of best fit and make predictions with the same, only a few of them introduce procedures to compute the determination coefficient and its interpretation as a percentage of explained variance; however these properties are introduced theoretically with no practical applications or procedures related to the same. Similar to the study of Lavalle, Micheli, & Rubio (2006), only a few textbooks introduce examples of non linear regression, even when a few propose tasks where different models would be preferable. This coincides with Sánchez Cobo's research (1999) where some textbooks introduced examples of non linear regression without discussing these models.

We found few definitions of the concepts linked to regression, apart from the definition of the line of best fit. This fact could be explained because these textbooks use most of the available space for this theme in the study of correlation (computing correlation coefficients and interpreting its sign and strength), as we are shown in (Gea et al., 2013). Although correlation is no doubt an important concept, it doesn´t make much sense that the books devote so much space to its study if this study is not completed with the study of regression; the need to fit a model to the data is the reason to study correlation between variables; the isolated study of correlation is useless. We therefore recommend reinforcing the study of other concepts linked to regression, such as model, centre of gravity, regression coefficients, and parameters of the line of best fit (slope; coordinate at the origin).

In general, these textbooks cover many important properties of regression; the variety of concepts linked through these properties suggests the high semiotic complexity of the topic, due to the richness of the associated epistemic configuration. However these properties are mostly introduced at an operational level (Sfard, 1991), that is, present the property by a formula or procedure, with too excessive emphasis on computation and giving little relevance to the meaning and interpretations of these properties, which are scarcely introduced at a structural level. For example, the textbooks introduce the computation needed to determine the regression lines (formula); but there is no deep discussion of the meaning of the parameters in the lines (slope, ordinate in the origin). The relation of the regression line with the correlation coefficient is only established in an operational way to study the reliability of prediction, with no connection, for example of the sign of correlation and the slope of the regression line. In the same way there is no discussion of examples where a low correlation coefficient may be associated to a strong non linear dependence; for example a parabola. It is also important to emphasize explicitly the existence of two different regression lines; that may sometimes be very close when r is close to +1 or -1, but may be very different in the general case. Many times the difference is only implicit.

When comparing the different books, [H5] and [H6] are far more complete than the other books, as they present all the procedures for the linear model; they are the only books that define the goodness and non linear models (although they do not include the procedures for these models) and introduce the majority of properties analyzed.

Mathematics teachers' conceptions of how to promote decision-making while teaching statistics: The case of Japanese secondary school teachers

Orlando González

Hiroshima University, Graduate School for International Development and Cooperation, Hiroshima, Japan, ogonzalez@hiroshima-u.ac.jp

The role of informed decision-making in today's society is very important at personal, professional, societal, and even educational levels. Thus, mathematics teachers are required, now more than ever, to provide students with appropriate tasks having the potential to promote decision-making skills. This article reports on the features and competence demands of tasks that are thought to promote decision-making skills by a purposeful sample of twelve Japanese secondary school mathematics teachers. A qualitative analysis on the collected data revealed some commonalities between the answers, as well as correspondences and discrepancies between what the participants and statistics educators think a task with the potential to promote decision-making is.

Keywords: Decision-making, teachers' conceptions of decision-making, statistical tasks, Japanese secondary school mathematics teachers, statistics education.

INTRODUCTION

Statistics has become very important at all levels of citizenry in today's society, in which large amounts of data are available to almost everyone. Thus, to be part of modern society in a competent and critical way, citizens need to be able to interpret such data in a broad sense, and understand the variability, dispersion, and heterogeneity which cause uncertainty in interpreting information, in facing risks, and in making decisions. In the particular case of the latter, many statistics educators, curriculum developers and international agencies around the world agree on the increasing importance for students to gain competence in using, handling and interpreting data to inform decision-making at personal, professional, and societal levels (Garfield & Ben-Zvi, 2008).

The last reform to the Japanese Course of Study echoes these ideas. In fact, the "difficulty … in description-type problems that require thinking, decision-making, and representation", reported in the 2006 Programme for International Student Assessment (PISA) study report about Japanese students by the Organization for Economic Cooperation and Development (OECD), is the first motivation to that reform (MEXT, 2008, p. 1; MEXT, 2009, p. 1). As a result, in the particular case of secondary school level, the latest Japanese Course of Study emphasizes – in the mathematical domains "Practical Use of Data" at junior high school, and "Analysis of Data" at senior high school – nurturing the attitude and ability to purposely process daily-life data, capture its trends and features, and make decisions based on such analysis (MEXT, 2008, 2009). Thus, on account of the significant place held by fostering decision-making skills in the Japanese secondary school mathematics curricula, teachers must be able to carry out themselves data-based decision-making, as well as to design instruction aimed to develop students' decision-making skills.

Despite the attention given to students' development of decision-making skills and attitude in the latest Japanese Courses of Study, teaching guides, and even the 2007 amendment to the School Education Law, what decision-making is, and how to promote the skills related to it, are not explained in any of those official documents. Therefore, teachers are left to determine by themselves how decision-making could be promoted in their students, which raises particular concern, due to the reported need for appropriate training in statistics education in the preparation of mathematics teachers in Japan (Isoda & González, 2012; González, 2014).

Then, in order to shed light on how Japanese mathematics teachers conceptualize decision-making and its promotion, the following research questions are addressed:

(1) What kind of tasks do Japanese secondary school mathematics teachers regard as having the potential to promote decision-making?

(2) What knowledge and skills do Japanese secondary school mathematics teachers believe to be associated with the promotion of decision-making?

THEORETICAL BACKGROUND

Decision – What is it?

A decision is defined as "the broader process within which a choice among specific options will be made" (Brown, 2005, p. 1). Through this process, the decision-maker is ultimately able to determine what action to take, by identifying a choice – i.e., selecting among previously-identified options (Brown, 2005, pp. 1, 236–237).

Decision-making situations demand from the decision-maker to determine a course of action, typically while considering uncertainty and data variability (Gal, 2004). In fact, a decision-maker operates, at once, in all the four dimensions of statistical thinking identified by Wild and Pfannkuch (1999).

Before choosing a particular course of action, a decision-maker has to engage in the many phases of the decision-making process, which are identified below (Wild & Pfannkuch, 1999; Gal, 2004, p. 43; Arvai, Campbell, Baird, & Rivers, 2004; Edelson, Tarnoff, Schwille, Bruozas, & Switzer, 2006):

Definition: here decision-makers define the specific decision that has to be made, as well as a broad set of end objectives in the context of the impending decision. This phase is the equivalent to the "Problem" step of Wild and Pfannkuch's (1999) statistical investigative cycle, known as the PPDAC cycle.

Planning: during this phase, the identification, design, and choice of optimal ways to use resources – i.e., means to achieve end-objectives – are determined. The choices must be a set of appealing and purposeful alternatives from the objectives previously defined. Here, the identification of constraints and considerations as basic criteria for the decision is also fundamental, since some choices might be eliminated based on failure to meet constraints, while others may be ranked based on how they fare on considerations. This phase is not only connected to the "Plan" step of the PPDAC cycle, but also with strategic type of thinking, and the "Generate" step of Wild and Pfannkuch's (1999) statistical interrogative cycle.

Data: the "Planning" phase tends to be followed by a recalling and seeking of information, as well as by collecting statistical data relevant to the achievement of end-objectives. This phase is connected to the "Data" step of the PPDAC cycle, to the "Seek" step of the statistical interrogative cycle, and to the recognition of need for data (Wild & Pfannkuch, 1999).

Evaluation: here, decision-makers must assess the implications of different choices for the decision, as well as the impact on the different stakeholders involved in the decision on hand. This phase is connected to the "Criticize" step of the statistical interrogative cycle, as well as to the strategic type of thinking, and being logical.

Weighing impact: during this phase, decision-makers weigh the impacts of the different options on stakeholders based on their own values. Thus, in this phase decision-makers bring in their values and see how different values can lead to different decisions. This phase is connected to both the "Analysis" and "Criticize" steps of the PPDAC and statistical interrogative cycles, respectively.

Making and justifying a decision: during this phase, decision-makers finally select the course of action that better addresses their objectives, in the light of the decision-makers' constraints, considerations, assumptions, value systems, judgment of probabilities, stakeholder impact, etc., and provide an informed justification for such a decision. This phase is connected to both the "Conclusions" and "Judge" steps of the PPDAC and statistical interrogative cycles, respectively.

Decisions – What types are there?

In the present study, decisions will be classified in four types: three of them – i.e., personal, professional and civic – were identified by Brown (2005, pp. 5–7), while the last type – i.e., object-related – is proposed by the author.

Personal decisions: those that decision-makers make on their own behalf; for example, about a career path or going on a date.

Professional decisions: those that decision-makers, as professional individuals and specialist decision aiders, make on behalf of others in a work capacity, such as in business management or medical practice.

Civic decisions: these are decisions made on a public – i.e., not personal – issue, such as when decision-makers, as citizens, take a private position on someone else's – e.g., government's – choice, for which they have no direct responsibility.

Object-related decisions: those that decision-makers make about parameters or particular features of the statistical objects – i.e., decisions regarding language situations, concepts, propositions, procedures and arguments (Godino, Ortiz, Roa, & Wilhelmi, 2011, p. 277) – involved in a given statistical problem. An example could be a decision about what measure it would be appropriate to employ to decide what the best design for a paper plane is – e.g., decide whether to use the distance travelled, accuracy, or time spent airborne to determine which design is the best.

Decision-making while studying statistics – How to do it?

According to Godino and colleagues (2011, p. 274), a basic statistical problem concerning decision-making is contextualized in a real situation; is driven by uncertainty; involves specific statistical practices – such as randomization, collecting sample data, transnumeration, data reduction, and using statistical models – ; and leads to the emergence of specific representations, concepts, procedures, properties and arguments. Several statistics educators – e.g., Makar & Fielding-Wells, 2011 – recommend to engage students in decision-making through making them experience the complete statistical investigation cycle. This makes absolute sense, because it is possible to match every phase of the decision-making process to steps of the PPDAC cycle.

METHODOLOGY

Data-collection instrument and participants

In order to address the research questions of this empirical study, an assignment-like survey was designed, asking respondents the following open questions:

1) From a textbook, teacher's guide, student workbook, internet, academic journal, or other type of source, choose a task or activity that, in your opinion, would promote decision-making skills in your students in secondary school mathematics when you teach contents in the mathematical domains "Practical Use of Data" or "Analysis of Data". You may also develop a task or activity by yourself.

2) Attach a copied or printed version of the chosen task or activity, and write down its source.

3) Briefly explain why, in your opinion, the chosen task or activity has the potential to promote decision-making skills.

At the time of writing this article (September 2014), the data-collection process – which began in mid-July 2014 – was ongoing. Thus, in this paper it is reported a preliminary analysis of the data gathered from the first twelve teachers who voluntarily and anonymously responded and mailed back the survey booklets. The respondents are part of a purposeful sample of 25 Japanese secondary school mathematics teachers who participated in a national academic meeting on mathematics education in Japan. Five of the respondents were working at junior high school, while the remaining seven were working at senior high school. The respondents were between 24 and 63 years old, and they had between two and forty-one years of teaching experience – with seven of them with at least 13.

Data analysis

During the initial phase, all the questionnaire answers were translated from Japanese into English by the author of this paper. Also, they were read repeatedly in order to gain an overall impression, as well as to identify commonalities among the participants. A "bottom up" approach to coding was initially used to analyze the tasks' features and the participant's reasons for choosing such tasks. This grounded form of analysis ensures that the themes or categories extracted were, in fact, grounded in the data and hence reflected the participants' own knowledge base and conceptions regarding decision-making. The author reviewed all the given answers to the three questions and identified answers that occurred frequently in the data. Such answers appearing to contain similar content were initially given the same code, and each code was further analyzed to find true meanings within their text. A process of reduction and clustering of categories, which were refitted and refined, followed, resulting in summary groupings (or "clusters") of themes sharing common meaning.

RESULTS

Tasks' features – What kinds of tasks are thought to promote decision-making?

The participants used a variety of sources to select their tasks. The most commonly used source was the Internet, used by four teachers – i.e., by T2, T7, T11 and T12. Three teachers – i.e., T3, T5 and T6 – referred to research reports or academic journals; used activity books, mathematics textbooks or exercise books – i.e., T4, T7 and T11 – ; and developed the chosen task by themselves – i.e., T1, T9 and T11. Two teachers – i.e., T1 and T8 – chose problems from the National Assessment of Academic Ability and Learning Situation, conducted yearly by the National Institute for Educational Policy Research of Japan. Finally, one teacher – i.e., T10 – selected a task he learnt at the prefectural training program.

From the qualitative analysis performed on the collected data, several task features were identified, including the number of solution strategies, number and kind of representations displayed, or if the task was set in a real-life context. The result of sorting and clustering such task-based features is shown in Table 1.

From Table 1, it seems the all the participants agree that a task intended to promote decision-making should engage students in statistical investigations, connect different statistical concepts, be set in a re-

		TEACHER

Table 1: Features of a task with potential to promote decision-making, according to the information provided by the participants on the questionnaire

al-life context, and have multiple ways to be solved. This is in line with many previous studies on the instruction of decision-making at school level – e.g., Arvai et al., 2004; Edelson et al., 2006; Edwards & Chelst, 2007; Garfield & Ben-Zvi, 2008; Godino et al., 2011; Pfannkuch & Ben-Zvi, 2011.

Since 11 out of 12 teachers chose a task to be carried out completely inside the classroom, it seems that the majority of participants consider that promoting decision-making should be done within the limits of the mathematics classroom. By doing so, students might miss the opportunity to extend their knowledge beyond the limits of the classroom, into the real world, which is needed to be statistically literate – cf. Garfield & Ben-Zvi, 2008.

Nine participants shared the idea that a task with the potential to promote decision-making must explicitly ask students to provide arguments justifying their decisions. In fact, this feature is the ultimate phase of the decision-making process. Many researchers – e.g., Edelson et al., 2006; Edwards & Chelst, 2007 – recommend teachers to give substantial guidance when introducing the decision-making process to students, in order to provide scaffolding for them to learn how to do well-informed and justified decisions by themselves.

Half of the respondents seem to consider that a task intended to promote decision-making should be a multi-step problem, or should explicitly request finding multiple solving strategies. Thus, regarding these pair of task features, this sample of respondents did not lead toward a particular one. In relation to being a multi-step problem, some teachers added questions to the original tasks in order to assure students of considering multiple solving strategies. For example, after challenging students with a problem from the 2012 National Assessment of Academic Ability and Learning Situation for Grade 9, T1 added the following step: "Listen to your friends' ideas. At the end, whose idea do you agree with? (Do not mind if it is your own idea.) Please, also write down the reason." In this way, T1 is not only handling classroom communication, but also facilitating discussion and negotiation, which is fundamental in any statistical investigation (cf. Makar & Fielding-Wells, 2011).

Also, it is also noticeable from Table 1 the lack of an overwhelming consensus about which type of decisions should be requested in a problem intended to promote decision-making. Five teachers chose tasks requiring an object-related decision; personal decisions were required in the tasks selected by four teachers; and three respondents demanded civic decisions in their problems. In this regard, specialists say that, although decision-making skills are not specific to any particular type of decision, developing such skills has been done mainly in the context of personal and civic ones, to which students can most immediately relate (cf. Brown, 2005, p. 155; Edelson et al., 2006). Moreover, by just requesting object-related decisions, the completion of the task seems to depend more on students' statistical content knowledge, and hence it is missed an opportunity to create and strengthen a link between the learning of statistics and students' actions in real situations.

Reasons for choice – What competence aspects are associated to decision-making?

From a grounded analysis of the reasons given by teachers about why their chosen tasks have the potential to promote decision-making, six category clusters of competence aspects that participants seem to associate with decision-making were identified. Such results are shown in Table 2.

Many trends in teachers' answers were noted from the results in Table 2. For example, 10 out of 12 participants associated decision-making with skills related to mathematical and statistical literacy, by using expressions such as "mathematical grounds", "handling of information and data", "knowledge about statistical ideas", "ability to read data properly", "ability to grasp data trends", and "practical use of multiple statistical representations". This is in agreement with what many statistics educators have previously reported on this matter: that decision-making heavily depends on skills related to statistical literacy such as understanding, explaining and quantifying the variability in the data (e.g., Gal, 2004; Pfannkuch & Ben-Zvi, 2011).

Only 3 out of 12 participants expressed that decision-making requires the enactment of personal or societal values, such as social fairness. In this respect, it is important to highlight that two of these teachers – i.e., T5 and T9 – selected tasks requesting either a personal or a civic decision. This is in agreement with previous studies on decision-making – e.g., Arvai et al., 2004; Edelson et al., 2006 – , which point out that creating a set of appealing and purposeful alternatives, as well as making thoughtful and high-quality decisions, needs the application of decision-maker's values and technical information.

Just 3 out of 12 of the respondents highlighted that decision-making involves an opportunity for students to build their own criteria or rules for decision, which is emphasized in the literature as one of the main characteristics of the decision-making process (cf. Brown, 2005; Edelson et al., 2006; Garfield & Ben-Zvi, 2008, p. 277).

The fact that decision-making involves engagement with a familiar real problem was pointed out by only two teachers. This could be a likely reason for having five teachers selecting tasks requesting object-related questions to students. According to many authors (e.g., Brown, 2005, p. 155; Edelson et al., 2006), students relate more easily to realistic decision-making scenarios, particularly those in which they are asked for personal or civic decisions.

Nine out of the 12 participants pointed out that decision-making involves engagement with different steps of the open-ended approach. These teachers mentioned aspects such as "coming up with a diversity of ways of thinking", "generating alternative designs", "dealing with problems related to uncertain events", "opportunity to decide about parameters and methodologies", and "opportunity to determine what properties would be good to examine". The number of teachers falling into this category is not surprising at all, because in Japan the lessons usually involve mathematical activities using ill-defined questions, which are often solved by engaging with the open-ended approach method. In fact, "dealing with the openness" during the decision-making process is a main feature of it (cf. Edelson et al., 2006; Edwards & Chelst, 2007; Makar & Fielding-Wells, 2011).

Finally, only 2 out of the 12 respondents explicitly related the decision-making

process to social and inter-personal processes such as discussion, communication, argumentation, persuasion and negotiation to build consensus and common understanding. This result was quite unexpected, since a typical Japanese mathematics lesson has the "takuto" and "neriage" phases, in which students present their solutions or ideas to the whole class, and discuss the validity and pertinence of the proposed ideas, respectively. Many researchers (e.g., Arvai et al., 2004; Edwards & Chelst, 2007) are of the idea that the decision-making process is much stronger with discussion and feedback, and therefore recommend that students should at first brainstorm on their own a list of objectives related to the decision, and then convene to discuss them in groups and with the rest of their class, in order to overcome particular biases related to individual and group thinking, and then to

effectively undertake the decision-making process in the classroom.

CONCLUSIONS

In general, this study found how the surveyed Japanese mathematics teachers conceptualize decision-making and the tasks intended to promote it. A majority of the respondents selected tasks embedded in a real-life context, having multiple ways of solving, requiring the connection of different statistical and mathematical ideas, meant to be carried out entirely inside the classroom, involving a partial or complete engagement with the statistical investigation cycle, and requiring to communicate and justify procedures and solutions. All these features are, indeed, characteristics of tasks able to promote decision-making skills indicated by previous researches.

The information about how the participants conceptualize decision-making was obtained from the different cognitive aspects identified in teachers' explanations of why they chose their tasks. The majority of participants related to decision-making aspects such as engagement with steps of the open-ended approach, and practical use of mathematical and statistical literacy skills. These features of the decision-making process are in line with those identified in the specialized literature. However, other main characteristics of decision-making – e.g., engagement with a familiar real problem, formulation of personal decision criteria, and engagement with particular social processes – were not explicitly noted by most of the surveyed teachers. Also, just two teachers explicitly considered affective aspects of decision-making, such as the enactment of personal and societal values. Due to the relevant place promoting decision-making in students has in the Japanese mathematics curriculum, it seems that secondary school mathematics teachers need to improve their professional knowledge about what decision-making is and how to promote it, in order to make them appreciate decision-making as a statistical rather than a mathematical work.

Realization of the potential of any task to promote decision-making heavily depends on teachers' statistical knowledge for teaching (González, 2014). Thus, examining how teachers may implement their chosen tasks seems a natural next step for this study.

Secondary education students' understanding of sampling

Gilda Lisbôa Guimarães and Tâmara Marques da Silva Gomes

University Federal of Pernambuco, Recife, Brazil, gilda.lguimaraes@gmail.com, tamara_msg@hotmail.com

This study aims to identify what students in the 5th and 9th grades from Secondary Education (10 to 14) understand of sampling. Semi-structured, person-to-person audiotaped interviews were carried out with 40 students (20 from each grade), to whom questions were asked concerning some different skills related to sampling. It was noted that, besides the differences between the years of schooling, there was no significant difference in association with the students' performance. This study shows that, albeit all difficulties, students in the 5th grade are able to answer the sampling aspects.

Keywords: Sampling, sample, population, statistics education.

STATISTICS EDUCATION

Statistics data have been present in various different social situations, thus becoming increasingly essential to understand them so that we can consciously exert our role in society. Due to this fact, statistical literacy has been important to Basic Education, since it enables students to develop their critical, investigative, and reflexive attitude. This posture is greatly necessary for the current society characterized by data dissemination (Campos, Jacobini, Wodewotzki, & Ferreira, 2011).

In the Brazilian curriculum, the National Curriculum Parameters (NCP) have outscored that, in the early years (9 to 10 years old), statistical content should be looked upon in the classroom to enable students "to analyze relevant data regarding knowledge and establish the highest number of relation among them by using mathematical knowledge to interpret them and critically assess them". (Brasil, 1997, p. 48). By the 3rd cycle (11 and 12 years old), abilities will need to be developed by students to build sample space and show success possibility of an event by using reasoning (Brasil, 1998, p. 75).

After analyzing Probability and Statistics teaching in the Mathematical Curriculum for Secondary Education, Lopes (1998) took into account the importance of these themes for students' formation as they provide for interdisciplinary approach, experiments, and exploration of random events, which lead to a change of the deterministic model characterized in mathematics.

Among the several statistical concepts that must be worked with students, sampling should not be overlooked. It is part of the investigative cycle of a research and helps to elaborate teaching systematic situations.

For data collection, it is essential to figure out who and how many individuals should be investigated, and how to approach them and put the questions to them in such an efficient way as to gather the most possible representative data. At the moment of data analysis and interpretation in statistical research, researchers must take into consideration the way the data are selected, the methods are applied, the variables analyzed, so that they can understand what is being investigated in context and then compare them to other situations. Sampling is noted implicitly and explicitly through all of these steps. Therefore, an approach using these steps along with mathematical teaching may contribute to important reflections upon the use and the importance of this concept for statistical activities.

It's important to show that this article doesn't provide a discussion of the various types of samples, but investigates the importance of working the concept of sampling from the early years of schooling so that students understand the relationship between the variability of the sample and the generalizability of the data for the entire population.

SAMPLING

The sampling concept is one of several statistical concepts to be developed with students, as part of the investigative cycle research. According to Stevenson (1981), sampling is the part of the group being examined, and the entire group is called population or universe. To him, "the purpose of sampling is to make general assumptions about the whole group, without examining every and each of its elements" (Idem, p. 158).

Some authors as Rubin, Bruce and Tenny (1990), Garfield (2003) and Innabi (2006) have mentioned difficulties students and lay people alike face when tackling statistics to understand the basic concepts of sampling. Besides, when pondering on the rigor of the samples, these people may be neglecting the quintessential factors of their representativeness, namely, size and variability.

Ben-Zvi, Makar, Bakker and Aridor (2011) noticed that by using a sequence of activities with 11-year-old students, in which an increase of the size of the samples had been identified, they got stimulated to think about the relations population-sample. The analysis of the individuals' inferential reasoning showed a development in points of view on what may be concluded from a small sample (contradictory and full of uncertain inferences) and with large ones, which favor the use of informal inferences.

The same way, during a didactic sequence applied to 12-year-old children, Gil and Ben-Zvi (2010) noticed that the students' first explanations, after being questioned about the rigor of the information based on the sample, reflect a conflict between random sample perception and reliability in their inferences. However, along with the activities and discussions, Gil and Ben-Zvi undertook the development of conceptions about sample and sampling, as students tried to infer from a random sample on population. Ideas at random and random sampling were partially understood and used by students at that age group. They were able to understand the implications in sampling representativeness and their variability. However, they were not able to understand their relations.

Pfannkuch (2008) also noticed that, when carrying out a study aiming to identify conceptual growth on students from New Zealand about sampling variability, 14-year-old students started to build some relations about sample variability upon studying samples of different sizes. It was concluded that the comprehension of sampling concepts became even more complex due to limited knowledge of other concepts, such as distribution and variability. Nevertheless, by involving students in contexts composed of discussions over sampling, students were able to show development regarding ideas of sampling variability and to relate population and sample.

The study of Pfannkuch (2008) ratifies the idea that the aspects approach linked to sample and population concepts, such as representativeness, sampling variability, inference, and distribution, when carried out with interrelation, facilitates understanding and building of sampling.

Given the importance and the needs to develop skills related to statistical reasoning, a research realized by Gomes (2013) was carried out to verify what students in the 5th and 9th grades of schooling understood of sampling. This article show some questions about this study emphasizing the definition of the sampling concept, an example of sampling, selection, size, purpose and representativeness of the sample, and population definition.

METHODOLOGY

Our aim is what students of 5th and 9th grades understand about sampling? Forty students in the 5th grade (10 years old) and 9th grade (14 years old) of Secondary Education took part in this study, 20 of each group. These groups belong to the final grade of each level of the Brazilian curriculum. Semi-structured, person-to-person audiotaped interviews composed of 10 questions on sampling were carried out as follows by one of the research. Based on the answers given by the students categories were created observing and valorizing the diversity of responses on each question: not respond, incorrect, partially correct and correct. A comparison of these grades allows observing the teaching of these concepts in school has provided a meaningful learning.

RESULTS

Regarding sample concept, students were encouraged to answer two questions: "*What do you think sample means*?" and "*To find out which candidate running for* *mayor of Recife has a greater chance to win the elections, researchers interviewed a sample of one thousand voters. What does this sample mean in this case*?" Most of the students did not answer or answered incorrectly these two questions about sample definition (33 individuals). It was noticed that the word "sample" was mostly associated with the verb to show (they are homographic in Portuguese). This association shows the influence of regional linguistic characteristics in the formulation of concepts, provided that this word is many times applied as synonym of 'to show' by people that live in Pernambuco, as shown in the following example:

> Student 1: Amostrar alguma coisa, um objeto (*To show something, an object*.)
> Student 2: Quando a pessoa pode mostrar alguma coisa.(*When someone can show something.)*

A great number of appropriate answers for the first question from students in the 9th grade were observed. The difference in the years of schooling is really meaningful ($X^2 = 4.329$, gl 1, $p< 0.037$). It was also common among the appropriate answers examples to be given in lieu of defining the concept of sample, as seen in the following example:

> Student 37:Uma amostra de sangue que as pessoas tiram.(*A sample of blood people collect.)*
> Student 40: Eu acho que é uma pequena parte de tudo. *(I guess it is a small part of everything.)*

In the second question, the students who gave appropriate definition for sample were those who defined sample as a part of all voters in Recife.

> Student 34: Eu acho que essa tá significando uma parte dos eleitores pra saber o que eles preferem. *(I guess it means a part of the voters to know what they prefer.)*

At this question, although the 9th graders had shown a greater number of appropriate answers, unlike the previous question, there was no significant difference in the years of schooling (X^2 1.558, gl 1, $p < 0.212$). These data imply that the same concept has different ways of tackling its definition, that is, by approaching directly or by a context.

When students were once again asked to give an example of sample, most of them (30 individuals) did not exemplify nor presented incorrect examples. A great deal of the given examples did not show any association with statistics. In fact, they were linked to the concept of sample defined by the students at the first question.

> Student 01: Eu quero lhe amostrar (mostrar) meu caderno, aí eu amostro à senhora. *(I want to show you my notebook, then I show to you.)*
> Student 14: Eu pegar esse lápis e lhe amostrar (mostrar). *(I take this pencil and show you (to show).*

Students in the 9th grade gave significantly better answers than students in the 5th grade (X^2 4.800, gl 1, $p < 0.028$). In studies carried out by Rubin, Bruce and Tenny (1990), it was shown that several answers from the students had been grounded on their own personal experiences. Because of that, we believed this question would have been quite easy for them to respond. We found daily situations in which *sample* was used, such as: free sample of products, or else blood or saliva sample for DNA test. Yet, it was clear the participants did not relate these examples to the applied question.

Nevertheless, the appropriate answers presented by the students in the 5th grade show that it is possible for the students at this age to learn this concept. Those who defined this concept partially or totally correct proved to understand sample as part of a whole.

> Student 10: Por exemplo, um suco, uma amostra de suco. *(For instance, some juice, a sample of juice.)*
> Student 32: Aqueles vidrinhos de perfumes ou aqueles papeizinhos com perfume quando a gente passa e entregam pra gente. (*Those little bottles of perfume or those pieces of paper sprayed with perfume given to us when we pass by the stores.)*

Concerning the sample selection, two questions were asked chiefly to understand whether students were able to list important criteria in order to select a sample. During the first activity, students were encouraged to come up with a strategy to select a sample, as being the most possible representative of the studied population. Thus, the following situations were introduced: "*A researcher wanted to know the students' favorite snack in the public schools of Recife. As he could not interview all students, he decided to interview only two hundred of them. How should he choose these students in order to have a better scope on their preference*"?

The performance of most participants, once again, was below the expected. The number of appropriate answers was higher among participants in the 9th grade. However, there was again no significant difference in the years of schooling (X^2 0.476, gl 1, $p < 0.490$). By suggesting the way of sample selection, these students showed similar answers to those found in Rubin, Bruce and Tenny's (1990) studies, with students in High School (14 to 17 years old). The participants presented variable models in association with sample selection so that it could represent the expected population, as long as their answers were grounded on personal intuition.

Answers with at least one aspect referring to probability sample were taken as correct; in other words, those that may be used with the entire population. In this kind of answer, it was common for the participants to suggest that the sample be chosen by drawing the lots, characteristic of random sampling, as described below:

> Student 28: Ele dividia pelas escolas que tem no Recife e sorteava. *(He divided by schools in Recife and drew the lots.)*

The second question about the sample selection showed a hypothetical context: "*Five friends wanted to know approximately how many books the people who live in their neighborhood read a year. As the district had about 10.000 residents, they couldn't to interview every one*". Participants were asked to indicate the most appropriate sample among five options: 100 residents who frequent de local library (large and biased); 100 residents of the district (large and unbiased); 10 residents who frequent de local library (small and biased); 10 residents of the district (small and unbiased); men, women, boys and girls (without information about size and sample selection criterion). Thirty-one students gave inappropriate answers, supporting their answers without taking into account whether the sample had characteristics of the studied population or a bias of selection. Once again, there was no statistical difference between grades analyzed (X^2 1.290, gl 1, $p < 0.256$).

In the same question, answers were analyzed taking into consideration, this turn, size in association with sample selection. Although there has been a difference between grades, it was not shown to be significant (X^2 3.750, gl 3, $p < 0.053$). The results achieved revealed a more appropriate performance of the participants, since twenty-three participants had their answers classified as partially correct, and only one as correct.

Answers were considered partially correct when students took into account the larger number of residents, disassociating population with the number of individuals of the sample as well as one of the criteria for their representativeness.

> Student 1: Porque a opção um tem mais moradores. (*Because option one has more residents.)*
>
> Student 13: [...] A opção 2. Porque tem mais pessoas. [...] *(Option 2. Because it has more people.)*

The single participant with a correct answer was a student in the 9th grade, who emphasized the size of the sample as one of the important factors for its representativeness. Likewise, although a smaller sample could also represent the population of the mentioned example, a larger number of individuals would be more appropriate.

> Student 34: [...] porque o três pegou só 10. Vai dar, mas vai dar muito pouco para saber do bairro todo. *([...] because the number three had only 10. It will do, but it will not be sufficient to learn about the entire neighborhood.)*

Regarding the purpose of using samples, participants had to answer the following question: "*To find out which candidate running for mayor of Recife has a greater chance to win the elections, researchers interviewed a sample of one thousand voters. Why do you think they used a sample and not all voters in Recife*"?

It should be pointed out that, despite the fact that a large number of participants could not produce a definition, nor provide a correct exemplification, when led to a situation of research by using samples and asked to explain why using them, almost half of the students (16 individuals) answered appropriately. Among these participants, 8 (eight) were students of the 5th grade, who explained their answers based on the convenience of using samples, as well as declared to have skills to broaden their knowledge on the purpose of using samples, as answered the student 34:

> Student 34: Se tiver 2 milhões de habitantes no Recife e ele pegou mil já dá pra ter pelo menos uma ideia. (*If there are 2 million inhabitants in Recife and he got a thousand, it is enough, at least, to have an idea.)*

There was no significant difference between the levels of schooling (X^2 0.000, gl 1, $p < 1.000$). Results achieved by this question highlighted the importance of activities with different contexts, involving sample concept to enable learning.

Still, another aspect verified has to do with sample representativeness. It is important to remember that it had been assessed indirectly in other questions; however, being representativeness the main purpose of sampling, it had already been used directly in specific questions. A situation was presented to the students, in which a research would be carried out in a school assigned beforehand. They were asked whether to select individuals for a research in order to represent the school, it would be more appropriate to draw students of all years of schooling or rather only a class would be enough. More than half of participants responded incorrectly (22 individuals). When answers were classified as appropriate or inappropriate, it was clearly proved that the difference in the performance of 5th and 9th graders was not significant (X^2 2.558, gl 1, $p < 0.110$). Some students chose the sample without justifying the reason for the option; others presented justifications unrelated to the sample representativeness; and there were those who inappropriately used aspects associated with sampling, as Student 25 explains:

> Student 25: Melhor (só de uma turma). *(It is better (only one classromm).*
> Researcher: Por que melhor? *(Why is it better?)*
> Student 25: Porque vai ser mais rápido para entrevistar eles. *(Because it is going to be quicker to interview them.)*

Better posed answers indicate that, if encouraged, students of different ages would be able to develop the skills needed to list eligible criteria of a sample. For justifications partially correct or correct, the relevance of sample variability was implicit.

> Student 27: Pegar de uma sala só é pior, professora. Não é melhor escolher da escola toda que tem mais variedade?! Da mesma sala vai mostrar só daquela. *(Collecting from only one classroom is worse, teacher. Isn't it better to choose form the entire school that has more variability?! From the same classroom it will show only from that one.)*

This comes to show that, although students could elaborate a more formal and complete answer, they noted that, to validate a sample, it must have some specific features of the population.

To investigate the understanding of population, two questions were asked. The first question raised the idea of population as a group of people. Thus, it was included in the previous situation about the candidate running for mayor of Recife, the following question: "What would the analyzed population be?" More than half of participants (25 individuals) responded appropriately; however, more students in the 9th grade responded in an appropriate and significant fashion (X^2 5.227, gl 1, $p < 0.022$). The correct answers narrowed the population as to target variable, in other words, those who could vote.

> Student 29: Os eleitores. Do Recife. *(The voters. From Recife.)*

The second question took population as a group of objects: "If a research intending to find out how long computers of a specific brand last were carried out; what type of population would be analyzed in this research?" In this situation, most of them responded incorrectly (35individuals) without any significant statistical difference within the grades studied (X^2 5.227, gl 1, $p < 0.022$). Five students, three in the 5th grade, answered correctly, proving to understand that population not always are people, but the whole being researched, as it is clear in the answer of student 06:

> Student 06: Os computadores da marca. *(Computers of a brand.)*

This understanding shows that even more complex definitions could be more simply worked in the early years of schooling.

Thus, it is important that these students' performance differences be discussed during activities that involve the same definition. As Ben-Zvi, Makar, Bakker and Aridor (2011) state that a variety of situations encourage students to think about the population-sample relations.

CONSIDERATIONS

Investigating different skills with the same students enabled us to identify what skills are more easily understood by them. Similarly, when we verify partial understanding of these different skills, we have some suggestions to put into use during the teaching-learning process, starting with the situations understood by the students in order to build more structured and complex knowledge.

This research showed that despite the great difficulty of the students to understand concepts related to sampling, students from the 5th grade already show to understand concepts associated with sampling in some situations. The identification of this students' aptitude make us to ratify that it is necessary to rethink of what schools can and should offer to the students. The learning ability of these contents from the early years, as shown by the individuals of this research, outscores the idea that studies on sampling should not be limited to the last years of schooling; rather, it must seek strategies to improve these skills in order to find positive changes since the initials levels of education.

Rolling the dice – exploring different approaches to probability with primary school students

Markus A. Helmerich

Universität Siegen, Siegen, Germany, helmerich@mathematik.uni-siegen.de

This paper focuses on a probability project and shows how primary school students develop probabilistic thinking according to different approaches to probability. In the project students explore the rolling of "odd dice" and compare the winning chances of these dice. By experimenting with the odd dice and comparing their structure to achieve insight into winning strategies the students have to deal with different approaches to probability, especially the subjective and frequency interpretations. A specific work-flow for processing such projects is presented.

Keywords: Probability, frequentist approach, subjective approach, learning environment, classroom project.

INTRODUCTION

This study wants to make a contribution on how teaching of probability in primary school could be laid out, by introducing a mathematical project on "odd dice", which is open for an experimental approach and rich discoveries on probabilities beyond the standard material in stochastics. Furthermore a specific project work-flow for the design of the classroom interaction and for the analysis of the learning process as a diagnostic tool is presented.

THEORETICAL FRAMEWORK: APPROACHES TO PROBABILITY

There are mainly three different approaches to the concept of probability which are crucial for teaching probability at primary schools and aiming at a broad and reasonable understanding of probability for students. Since you only have limited access to an axiomatic interpretation of probability in school mathematics it is important to show alternative interpretations which connect to students' previous knowledge and everyday experiences, even appreciating subjective ideas and conceptions and relate them to mathematical views on probability.

Subjective approach

The subjective approach to probability is the one you will encounter first when teaching probability in school mathematics. "We identify probabilities with degrees of confidence, or credences, or 'partial' beliefs of suitable agents" (Hájek, 2012). Almost all children gathered experiences with statements on probability in the context of chances in games e.g. rolling six dots with dice in the game "Ludo". The subjective approach is fully loaded with individual experiences, naïve ideas and with personal preferences to the point of superstitious beliefs like lucky numbers (see Büchter et al., 2005). Children hold certain ideas and conceptions and that is what teachers have to deal with for successfully teaching stochastics. By setting up activating learning environments such pre-experiences of students could be made explicit for the learning process. The teaching problem is that some of the students' conceptions do not match with the mathematical concepts. To overcome this gap it is necessary to get students into a reflection on concepts.

Frequentist approach

The frequentist approach to probability will help to develop a broader understanding of probabilistic processes. It defines a probability of an event as the limit of its relative frequency in a large number of trials, according to the law of large numbers. In primary schools one often deals just with counting absolute frequency in relation to a fixed number of trials, e.g., rolling the dice 100 times and then counting the number of occurrences of the pips. This empirical approach suits well with activating learning environments in which students are able to determine probabilities by random experiments. Students will evaluate their experiments with tally tables.

Classic approach

At last the classic approach to probability will be considered as a mathematical sophisticated approach which has a profound theoretical meaning but is only accessible in a limited way in primary schools. The probability of an event is given by its ratio of the number of cases favorable to it, to the number of all cases possible. This requires that none of the cases occur more than any other i.e. all cases are equally possible. This approach goes back to a definition by Laplace from 1814 in his Philosophical Essay on Probabilities. Since fractions and rational numbers are only available in a very limited way in primary school it will not be possible to apply this approach in-depth. But the basic idea could be used to count the favorable cases and compare them to a fixed number of possible cases. A special case of the classic approach is the geometric interpretation of probability, e.g. looking at the faces of the dice and – assuming that all faces are the same size – the probability for each face will be the same.

"ODD DICE" – A PROBABILITY PROJECT

The teaching material "Spürnasen Mathematik" [mathematics sleuths] consists of a box with mathematical projects on arithmetic, geometry and stochastics aiming at an open, activity-oriented learning process, accompanied with working books for a systematical training and learning process. To ensure rich experiences with mathematics and linking-up with situations of everyday life the projects are starting always with a hands-on activity for children, followed up by a step by step systematization and formalization with mathematical tools and mathematical language. This specific approach is chosen to increase the motivation to deal with mathematical contents and tools, and to see the potential of mathematics to describe everyday life situations, to solve real life problems and to provide a language to communicate and compare information and data. The mathematical tasks and the project work are open according to Peschel (2007) in the classroom format and social form in which the children will work on the projects (e.g. most project tasks could be carried out individually, pair or group work), the organization of the learning process (e.g. the children can choose from different materials to work with), and the conceptual opening (e.g. the children are encouraged to solve the problems on their competence level and in their way of mathematical thinking). Therefore the projects have a high potential for differentiation in the learning process and the resulting products. This classroom research report will focus on the project named "Only by Chance" classified as a stochastics project. This projects aims for an exploration of dealing with chances and probabilities in different contexts.

One part of the project looks at "odd dice" and the odds to win by playing dice and the corresponding probabilities. The odd dice are given by their cube nets (see Figure 1). These four coloured dice are an adaption of the "Miwin dice" (Winkelmann, 2012) and do not show the usual dots of a dice and equally probable occurrence of each side of the dice, but a special arrangement of the numbers 0 to 6 as shown in Figure 1.

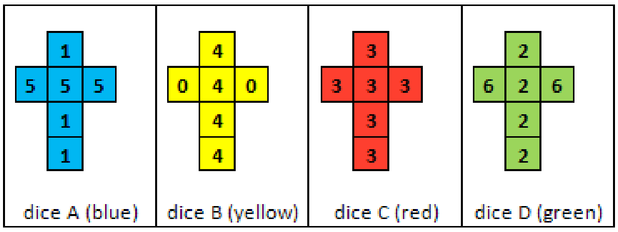

Figure 1: Cube nets of the odd dice for the probability project

In the following I will outline the project tasks for the students, some of the learning outcome objectives and possible solutions of the problems. (Remark: In the teaching material "Spürnasen Mathematik" all the tasks are gathered on a task instruction card. Since the material is in German the original card is not shown.)

Task 1

The first task of the project asks the students to explore with prepared odd dice, which numbers on the dice will occur most frequently. After making a guess, the students roll the dice and take track of the occurrences with a tally sheet (see Figure 2). This will help students to get started with the project and become more familiar with the odd dice, since they probably haven't been working with such dice beforehand. The students learn to estimate the possible outcomes of throwing the dice, and are encouraged to experiment and set up a series of dice rolling. By documenting their results in tally sheets they will learn a specific technique of data representation.

Figure 2: Suggestion for documenting the occurrences

Task 2

The second task is to roll the dice in a little game of dice for two students using the red and green dice. The student throwing the higher number will win and gets one point. The game will stop when one student has gained 10 points. Again the students should make an assumption first and then use a tally list to write down the gaming results, and observe which dice is winning the game. It is necessary to give the students enough time to explore the different dice and to analyze which dice is better. The game and a systematic representation of the game result will lead to a reasonable good assumption of the better dice.

Task 3

In the following task the students should play the dice game over and over again with two different dice in order to find "the best" dice, using one of the various suggested documentation styles for their assumptions and their results. With a systematic approach for testing all combinations of dice – this is encouraged by the proposed documentation forms – the students have to explore, communicate and argue to find the best dice of all. A demonstrative and helpful tool for comparing the dice are the tables showing for each pair of dice the possible events and marking the winning dice (see Figure 3).

These tables give insight into the winning probability of each pair of odd dice. For example have a look at the top left corner of Figure 3. There you can see dice C (red) and dice D (green) with all possible cases of rolling dice results. Each table cell states (by colour and letter) which dice is the winning dice for a certain case. You can clearly see, that the red dice will win in more cases than the green dice (to be precise in 24 out of 36 cases), thus making the red dice the better choice for the game. Evaluating all tables you will end up with a diagram shown in Figure 4. There is no dice with exclusively outgoing or incoming arrows in the diagram, therefore none of the dice could be considered 'the best', but you always find one dice which is – on the long run – better than (or at least as good as) a certain chosen dice. This will not imply you are winning in every turn of the game, but if you as second player in the game choose the "right" dice according to the diagram you will enlarge your winning odds and on the long run with many follow-ups of the game win the game more often.

Task 4

By using proposed forms of documentation the students will result in a good overview of the winning odds of the dice and be able to answer the last task. In the final task the students are requested to discuss a given statement of student Jonas (illustrated in the teaching material), that you will always win the game if you take the second turn to pick one dice, and to argue on the question, why these dice are called "odd". Here the students are trained to take a close look at

dice D (green) \ dice C (red)	3	3	3	3	3	3

Figure 3: Comparison of the odd dice

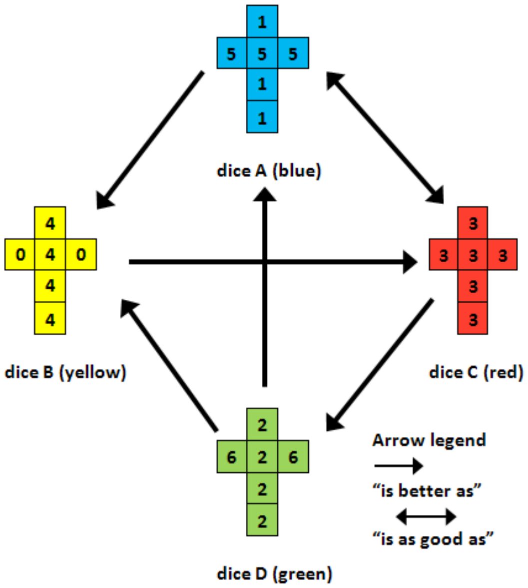

Figure 4: Diagram showing the relation between the odd dice

the situation: Jonas' remark just states that there will be a reasonable choice for a dice in response to a chosen dice in the first draw. But there is no "best" dice at all. This finding is an explanation for the naming of the odd dice and linking these odd dice to the widely known "rock, paper, scissors" game with an analogous relation between the three possible events (there is always one beating another, but no move to win in every case).

RESEARCH QUESTIONS AND DESIGN OF STUDY

The following empirical findings will describe which approaches to probability are used by students working on the project "odd dice" and how their understanding of probability could be developed to a broader approach by working on the tasks concerned with odd dice.

The probability project learning environment was applied in a primary school at Eitorf near Siegen (Germany) in a third grade class with 23 kids (11 girls, 12 boys, age ranging from 8 to 10 years old, 5 with special needs). The students were chosen because they were used to work on open projects since it is the usual learning environment in this school. This was an important criterion to observe if and to what extent it is possible to make students understand a specific mathematical content like probability in such a learning environment setting. The project "odd dice" was processed by two groups with each four students and a third group with two students in about 2 hours. The student's documents and observations of a trainee teacher (Nelia Kasemir who documented the students' results in her final thesis, see Kasemir, 2013), are the basis for an interpretative approach for the in-depth data analysis. The trainee teacher was very familiar with this class and basically played the role of managing the working and learning process according to the work flow presented below (see Figure 5). Only in the first plateau phase some examples for probabilities of events were presented and in the later plateau phases, students were encouraged to share their intermediate results.

For evaluating these project products and learning and teaching processes, a work flow for mathematical projects of the teaching material "Spürnasen Mathematik" (see Helmerich & Lengnink, 2013, and Lengnink, 2012) could be used, following the "Think,

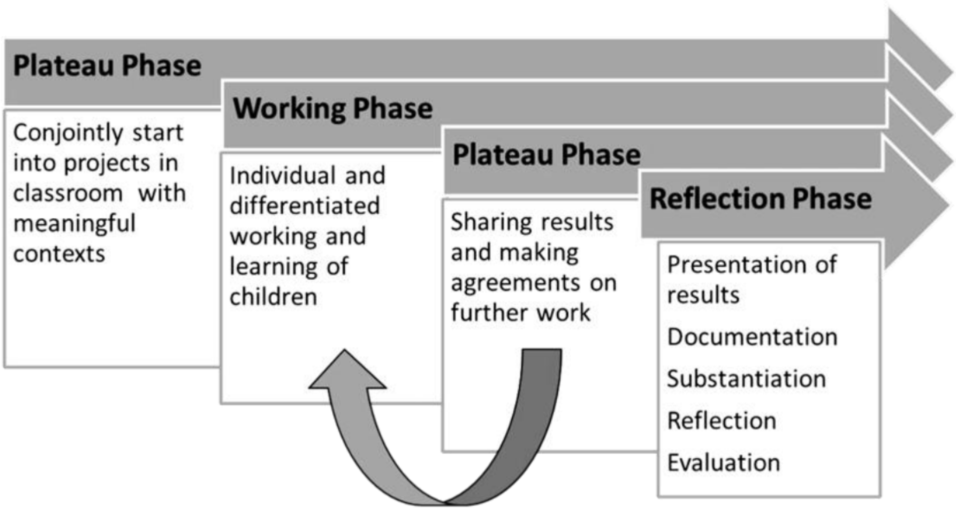

Figure 5: Work flow for mathematical projects in classroom interaction

Pair, Share" method (for example, presented in Barzel et al., 2007, p. 118).

The children are introduced to learning objectives and possible tasks in the project, before starting off with individual and group work. The students of third grade already acquired competence in dealing with probability in the sense of assigning several everyday-life situations to a probability continuum chart reaching from "impossible", over "unlikely" and "rather probable" to "certain". Before the odd dice project they worked on probabilities of usual, regular dice and the urn model and projects on probability of drawing a certain colour out of a package of chocolate beans, and the probability of letters in words and de-coding strategies in Caesar code applications. Within a sharing circle the pre-knowledge was re-activated. The recurrence of plateau phases, where children share their ideas and preliminarily results marks the important issue of reflecting the process and give teachers the opportunity to adjust the children's work for the next working phase.

ANALYSIS OF THE WORKING PROCESS AND RESULTS OF THE STUDENTS

This phase model will be used to analyze the learning process and to show different approaches to probability as seen in the students' documents. In the first phase the students' previous knowledge on and experiences with probabilities are activated by collecting situations in everyday life in which the term 'probability' appear. The students are asked to find a definition for probability and state some events which in their opinion are probable, impossible definite. The most common paraphrase for a "probable event" used, was something "that could happen, but doesn't have to." With this preparation the students start with their group work on different probability projects.

In the second phase the students started off with their work on the project tasks. The students mainly worked together in pairs of two, which were formed at random. With the first task of the "odd dice" project two approaches to probability are activated: the students are supposed to estimate the number of occurrences of the dice faces which activates subjective views. Some students decided to analyze the dice of their favorite colour or the dice with their lucky number on it. The only notion before starting the rolling experiment was on dice C (red) with exclusively threes on each face. It was obvious for the children that this dice will produce the event '3' all the time. Other estimations were not made. With rolling the dice the frequentist approach came into action. It seemed clear that rolling the dice several times will show, which results one can get with each dice. However, some students restricted their tally sheet only to some numbers on the dice, so the actual distribution of the events is not represented but could be extracted from the notes. For example Simon (see Figure 6) rolled all the dice ten times, so you can calculate the number of occurrences of the other dice rolling results. Final remarks on the probabilities or a location in the probability continuum were not made at this stage.

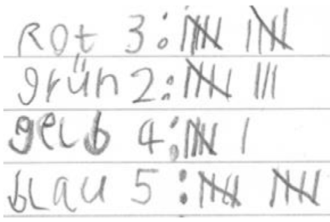

Figure 6: Simon's tally sheet on task 1 (marking the results for the red ("rot"), green ("green"), yellow ("gelb") and blue ("blau") dice)

The students stepped on to task 2 and the comparison of dice. Interestingly some students started the game using both the same coloured dice (see Figure 7). This could be explained by the need to become more familiar with these odd dice and to set up a situation ensuring a level playing field. In these cases the students achieved as expected narrow outcomes in their game.

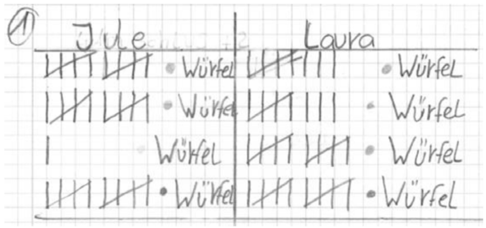

Figure 7: The table of Jule and Laura ("Würfel" means dice)

To overcome this strategy and to get to the actual task it was necessary to compare the first results in a plateau phase. Thereby Jule and Laura were encouraged to proceed with the comparison of dice. In Figure 8 the results of the comparison of the blue and the yellow as well as the red and green dice are shown in a conjoint table.

In this task the difficulty occurred that the results of the game did not represent the expected insight into the relation of the dice since the game stopped

Figure 8: Jule and Laura playing the dice game ("blau" = blue, "orange" = red, "gelb" = yellow, "grün" = green)

with one student gaining ten points. To get over this problem, it might have been helpful to have a systematic look at the dice and their faces and draw tables as shown in Figure 3. Due to the limited time for the project during class this was not worked out in detail. But the students nevertheless tried to figure out whether there is always a dice for winning the game like Jonas suggested. In this process it is interesting to state that the students did not carry out the systematic comparison according to the classic approach to probability but fall back on subjective views. Looking at Simon's documentation of task 4 (see Figure 9) reveals that Simon (in the table abbreviated to "Sim") plays the game with Saheb (short "Sah") by choosing a pair of dice, roll them, record the result and play again with a new pair of dice. This approach to focus on the single outcome of the game could be characterized as a uni-structural thinking (Shaughnessy, 2007; Watson & Kelly, 2004). Thinking in relations and an understanding enriched by relational conceptions was not achieved of Simon. This emphasizes the challenge of teaching probability, to master the mental step from a subjective approach to the more elaborated classic approach of probability.

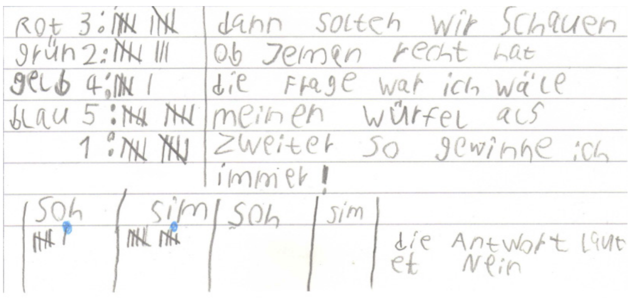

Figure 9: Simon's argumentation on task 4: "then we should have a look if someone is right: the question was: I choose my dice second, thus I will always win! The answer is no."

DISCUSSION AND CONCLUSION

Such mathematical projects like the one on odd dice make it possible to let students explore different approaches to probability in an activating, experimental way. The project even shows the potential not only to stick to the subjective and frequency interpretations of probability but to merge these aspects to the classic approach. The broader view on probability is especially inherent in the plateau phases when students have the opportunity to share their work achieved so far and could be enriched with some new ideas and strategies, also from the teacher, for further project work. In higher grades this project on odd dice could be unfold to a broader mathematical analysis of the odd dice using the classic approach to probability and calculating and comparing the probability for each number on the dice. This might be an approach to an extension of the probability concept to non-Laplacian experiments and the law of large numbers, since in the game situation with a limited number of dice rolls the experiment does not always lead to the theoretically expected outcomes. The project is a contribution to the fundamental mathematical idea of "data and chance" as it is stated in the national standards for mathematics teaching in Germany (e.g., KMK, 2004). It combines the idea of data collection by rolling the dice with the ides of chance by investigating the probabilities of the dice. This study was the starting point for a broader investigation of mathematical ideas in stochastics in primary school teaching. It just gives some insight on the thinking and reasoning of primary school students, but shows the potential of such projects for diagnostic approaches in research of learning processes.

Students' informal inference when exploring a statistical investigation

Ana Henriques and Hélia Oliveira

Universidade de Lisboa, Instituto de Educação, Lisboa, Portugal, achenriques@ie.ul.pt

This paper reports on preliminary results of a study aiming to identify informal inference aspects that emerge when grade 8 students explore a statistical investigation using the software TinkerPlots for data handling. Examples from students' work on one task in a sequence, designed to engage students in posing statistical questions about meaningful phenomena, in collecting and representing data and finally in making data-based inferences, illustrate how informal statistical inferences emerge. The results provide suggestions for further research and some educational implications are drawn.

Keywords: Informal statistical inference, statistical reasoning, statistical investigation, tasks, TinkerPlots.

INTRODUCTION

Students' ability to reason about data and to use them effective and critically for prediction and decision-making is now a priority in statistics education, meeting the call for having statistically literate and informed citizens in our data-driven society (Batanero, Burrill, & Reading, 2011). Informal statistical inference (ISI) is widely recognized as an important foundation for statistical reasoning, given its potential to deepen students' understanding of the purpose and utility of data in meaning making of the real-world, aspect that has been neglected in statistics education (Makar, Bakker, & Ben-Zvi, 2011; McPhee & Makar, 2014). Hence, it is important to rethink the nature of students' statistical school experiences in order to consider how to best develop their informal ideas of inference. Reflecting these concerns, this paper reports on preliminary results of a study that aims to identify informal inference aspects that emerge when grade 8 students explore a statistical investigation using the software *TinkerPlots* (Konold & Miller, 2005) for data handling.

INFORMAL STATISTICAL INFERENCE

Informal statistical inference is described as a reasoned but informal process of "making probabilistic generalizations from (evidenced with) data that extend beyond the data collected" (Makar & Rubin, 2009, p. 83). For these authors, three key principles are fundamental to ISI, wherein the first is particular to the process of inference and the latter two are specific to statistics: (i) generalization (predictions, parameter estimates, conclusions) that extends beyond describing the given data; (ii) the use of data as evidence for generalizations; and (iii) the use of probabilistic language for describing the generalization, including reference to levels of certainty about the drawn conclusions. Moreover, deriving conclusions that apply to a universe beyond the data leads naturally to the need of providing persuasive arguments based on data analysis. Accordingly, Ben-Zvi (2006) argues in favour of an integration of both informal inference and informal argumentation when aiming to develop students' statistical reasoning in rich learning contexts.

References to ISI appear in curriculum documents (e.g., Common Core State Standards Initiative, 2010; Franklin et al., 2005; National Council of Teachers of Mathematics [NCTM], 2000), as well as in recent research in statistics education. The research advocates the development of students' informal ideas of statistical inference from the earliest years of schooling as it is a known area of difficulty for older students when formal ideas are later introduced (Ben-Zvi, Makar, Bakker, & Aridor, 2012; Makar, Bakker, & Ben-Zvi, 2011). However, ISI should not be taught to students as an entity in itself but rather it would be preferable to focus the instruction on reasoning processes that lead to inference (Makar & Rubin, 2009). Thus, one possible approach to foster the emergence of students' inferential practices is to embed those processes in a data analysis cycle, like the PPDAC (Wild & Pfannkuch, 1999). Presenting statistics as an investigative process to solve real-world problems may be quite motivating for students. They can engage in posing their own statistical questions (hypothesis) about a meaningful phenomenon, designing and employing a plan to collect appropriate data, selecting adequate graphical or numerical methods to analyse the data, and finally drawing data-based conclusions and inferences that relate the results interpretation to the original questions (Franklin et al., 2005; McPhee & Makar, 2014). Due to their nature, statistical investigations often provide a distinctive context for observing students' conceptual ideas about statistical reasoning, namely fundamental processes like variation, transnumeration, evaluating statistical models and integrating contextual and statistical features of the problem (Wild & Pfannkuch, 1999). At the same time, they may involve students (even the younger ones) in fundamental components of informal inference, such as decision making and prediction (Makar & Rubin, 2009; Watson, 2008). For teachers, the use of investigations also provide knowledge that can be used in the design, implementation, and assessment of instruction in statistics and data exploration (Henriques & Oliveira, 2013), since they incorporate domain-specific knowledge of students' statistical reasoning. Accordingly, Pratt and Ainley (2008) argue that inferential reasoning and statistical investigations cannot be separated.

Additionally, the huge development of technology has provided teachers and students with new tools to explore the ISI in rich and meaningful contexts, including through the broader process of statistical investigation (Ben-Zvi et al., 2012). The educational community has been leading a number of studies on the affordances provided by dynamic statistics learning environments, such as the *TinkerPlots* (Konold & Miller, 2005), for making inferential reasoning accessible to (even young) students, with very encouraging results (Ben-Zvi et al., 2012). These studies illustrate how the use of such software, in combination with appropriate curricula and instructional settings introducing ISI, may help students to develop a strong conceptual base on which to build later a more formal teaching of inferential statistics.

RESEARCH QUESTION

While the referred perspectives and studies have begun to shed some light on important aspects of ISI, research results are still insufficient to guide an effective implementation of instructional settings that support students' informal notions of statistical inference. This paper addresses the following research question which has been used to structure the study and the analysis of the collected data: *What aspects of informal inference do grade 8 students reveal when exploring a statistical investigation using the dynamic statistics software TinkerPlots for data handling*?

THE STUDY

Background

This study arose in the context of a developmental research project (DRP), conducted by the two authors, aiming to provide opportunities for professional development in statistics for basic education mathematics teachers in Portugal. The DRP is part of a larger research project – *Developing statistical literacy: Student learning and teacher education* (Oliveira, Henriques, & Ponte, 2012) and strives to understand of how sequences of instructional activities, based on the use of the software *TinkerPlots*, promote students' statistical reasoning. In Portugal, formal statistical inference is reserved for high school courses and, traditionally, grade 8 (13–14 years old) students are not exposed to ISI methods. The eleven basic education mathematics teachers, who accepted the invitation to participate in the DRP, are effective and innovative teachers, in the sense of including inquiry in their mathematics classes and became interested in learning how to use an instructional approach aligned with the recent curricular trends in school statistics (Franklin et al., 2005; NCTM, 2000).

Participants and methods

Research studies involving teaching experiments are especially powerful because they enable researchers and teachers to trace students' individual and collective development in statistical reasoning during instruction. The study followed a teaching experiment design (Cobb, Confrey, diSessa, Lehrer, & Schauble, 2003) where a sequence of tasks and classroom implementation conditions are improved through iterative cycles. The results reported here come from the study's first cycle which was carried out during the second term of the school year of 2013/2014 in one class of thirty grade 8 students (20 boys and 10 girls, which are referenced by their first names' initial letter). The class teacher was one of the participants in the above referred DRP. Data collection included students' written work, screen records of their work with *TinkerPlots* (using *AutoScreenRecorder 3.1 Pro*) and audio and video records across the lessons. A qualitative and interpretative analysis of the data, using Makar and Rubin's framework (Makar & Rubin, 2009), provided insights about the characteristics of ISI that emerged in students' work on a statistical investigation.

Lessons context and tasks

A classroom culture which promotes inferential reasoning requires students addressing problems in an environment that encourages collaborative norms, statistical concepts (formal or informal) and one complex problem context where they face conflicts with their knowledge and beliefs about the world (Makar, Bakker, & Ben-Zvi, 2011). In all lessons, students worked both autonomously in pairs and participated in whole class discussions, in order to create a classroom culture that supported questioning and the use of evidence.

Participant teachers in DRP and the authors jointly selected and adapted or produced tasks and materials for a sequence of lessons aligned with the Statistics Reasoning Learning Environment principles defined by Garfield and Ben-Zvi (2008). Since in Portugal, inference is not included in mathematics syllabus for this age group, the sequence of tasks was not explicitly designed to focus on inference. However, these tasks, using meaningful contexts and real data, provided opportunities to engage and simultaneously support students in several aspects of informal inferential practice. *TinkerPlots* software (Konold & Miller, 2005) was used in all tasks, as a tool for data handling, since it is easy to use and provides a dynamic learning environment to support the development of students' statistical reasoning. Students can create and explore, in ways that they choose, the potential of different graphical representations and statistical measures, by using the drag-and-drop facility or a set of informal operators (e.g. separate, stack, and order). Taking advantage of the software's tools the students can also engage in goal-directed activities that may lead to further insights in their data examinations.

Two preliminary tasks (tasks 1 and 2) were applied to build students' skills that they would need for conducting a statistical investigation and for making inferences, since they were not familiar with this kind of activity. Tasks 1 and 2 engaged students in exploring real data using *TinkerPlots*, while developing key statistical concepts of syllabus as well as their reasoning. Since this was the students' first contact with the software, task 1 was structured and oriented by a set of questions leading them to interpreting contexts, exploring data (available from *TinkerPlots* database) in several ways and using various representations (which were discussed regarding their adequacy to give evidence). Finally they used their knowledge of the data to answer one initial question and to make predictions. Task 2 involved students in comparison of distributions using simulations provided by the *TinkerPlots* tools.

This study focus on task 3 – *The human body: a study in school*. Following the previous activity, this task engaged students in a statistical investigation (Wild & Pfannkuch, 1999) to discover more about the students in their school. Students were required to use their previous knowledge about the context and statistical concepts and processes (e.g., understanding the need of data, graphical representations, distribution, variability and sampling) to make informal judgments and predictions about the school population, based on data collected in their class. Finally, students were asked to explain their reasoning, integrating persuasive data-based arguments in their conclusions.

RESULTS: THE EMERGENCE OF STUDENTS' INFORMAL INFERENCE

In this section, a description of students' work in the context of a statistical investigation provides an opportunity to envision the role of this activity in the emergence of students' informal inferential practices.

Making generalizations beyond the data

This component of informal inferential reasoning emerged in students' work in different moments of the task. The teacher introduced the task in the whole class with an initial question aimed at having students collecting data and using them to make predictions and draw conclusions about a population beyond the collected data: "How would you characterize middle school students [grades 7, 8 and 9] of your school regarding some of Vitruvius' measures such as height, foot size and arm span?". In the subsequent whole class discussion, it was clear that students understood the utility of the samples in the inferential process, to draw conclusions, because they showed no intention to survey the entire school population to get the information they needed to answer the question. They said: "It is best to conduct a survey" (E) and "To randomly select [students] from grade 7 to grade 9" (R). Although they were not unanimous about how the sample could be collected and used to find out the characteristics of all school students, they stressed randomness as an important condition to ensure the representativeness of the sample. Due to time limitations, students agreed to collect data from their own class, although recognizing the lack of representativeness of the sample.

After data collection, the teacher also asked them to formulate possible interesting questions (hypothesis) about the phenomena in study and to predict how their questions might be answered, first without providing them with data. This was proposed to later confront students' anecdotal answers with data-based evidences, pushing them to understand the need of data. Some students reveal inability to think about the data as an aggregate and to full make sense of the questions' intention to help them to answer the initial question in the task. Some of the emerging questions/hypothesis such as "What is the biggest value for the arm span?" (W&F), "What is the percentage of students with more than 160 cm?" (B&R) or "Does the highest student has the bigger shoe?" (B&R) reveal a deterministic nature and did not prompt students to think beyond their data. As expected, some of these students justified their predictions based on guessing and simple observation: "Based on [the observation of] my colleagues, I think that the average height of the students [boys] is 165cm" (M&S). Although these findings were consistent with the difficulties observed in other studies (e.g., Meletiou-Mavrotheris & Paparistodemou, 2014), students had just collected their own data and this activity might have diverted their attention from using inferentially the data. However, the majority of students seemed to accept the existence of variability and formulated general questions/hypothesis such as "Boys tend to be bigger than girls" (T&D), "Do boys and girls have similar arm spans?" (D&B) or "I think that maybe the arm span has a higher value for boys" (B&B). These statements show students' attempts to find one global description that accounts for variability between the groups. These claims could be considered a progress if compared to the ones in the previous questions, which are mostly local. However, they still focus on describing the class. These predictions also contained elements of uncertainty, which reveal that students were beginning to adopt a statistical perspective of trend.

After the exploration of the collected data (from the class), using the *TinkerPlots*, each group wrote a report predicting what they might find about the height, foot and arm span, more generally, for the whole school, and explaining what evidences they had to support their conclusions. These reports aimed at pushing further the students to see their own data as evidence for making inferences about whole school, building their ability to think "beyond the data". As occurred with young students (Watson, 2008), their initial focus on describing their own class data did not restrict them from creating more global interpretations of data. In fact, students' responses suggest that many of them did see the data collected in their class as useful evidence for their predictions. The excerpts below show that some students assumed that data collected in the class would have very similar properties to the data from the whole school, and generalized the results: "Considering the whole school students, the boys' height and arm span are bigger when compared with the girls, based on our class" (A&E) and "Boys tend to be bigger than girls, based on our class data" (A&N). It is interesting to notice that in their predictions students used probabilistic language and were attentive to the distribution and not to specific measures as they were in the formulation of the initial questions. This finding may suggest that students associated the generalization to uncertainty and that previous work in organizing and describing their own data supported them to go further in the inferential reasoning by helping them to improve their thinking of the data as an aggregate and to consider variability. Even though they have found the average height for their class, their predictions went beyond that to include uncertainty, adopting the statistical perspective of trends that are generally true but still have exceptions: "On average, boys are higher. But we also observe boys with 1,4 [m] who are shorter than girls (...)" (W&F). On contrary, a noteworthy number of students predicted that there would be some differences, as observed in the following claims: "The average height of the school students probably will increase due to students' natural growth" (M&S), "Boys will be higher than girls, so the average will move towards the boys' value because, probably, there are more boys than girls in school" (T&D) or "Although some differences in the height may occur, the average height will be higher, depending on the grade" (J&D).

Using data as evidence for generalizations

Making predictions about the whole school from their data was evident across the groups of students. Initially, students explored the data collected in their class, based on graphical displays created as they use the *TinkerPlots*. Given that students have not been oriented toward a specific graph, it was interesting to observe that they created a variety of graphical displays and adequately used them to represent and interpret their own data to get evidence for their claims, which shows their meta-representational competence (English, 2014). Dot plots were the most popular representations to gather evidence for answering deterministic questions focused on individual features, but most students also created boxplots to compare the two genres regarding the variables in study, as the ones shown in figure 1. These students' graphical displays were accompanied, respectively, by claims such "Students' average height is 162,7" (S&P), "The percentage of students with more than 160 cm is 55%" (B&R) and "Boys are higher than girls. Boys' average is 163 and girls' average is 160 cm" (E&S).

Students started comparing groups by noticing special values within distributions (such as the average or the maximum) and then moved to think about between-group variability. The comparison activity, based on their representations, also supported their claims about the whole school, as they said: "Boys tend to be bigger than girls, based on our class data" (A&N) or "We have based on our class which has more boys than girls and they are higher" (D&B). Moreover, their claims are not based only on data but also on their knowledge about the context which is familiar to them. For example, one group states "I think that for the whole school we will find something similar because our class is the 8th grade and that is the "median" of the middle school [it includes grades 7, 8 and 9]" (R&R). The exploration of a sample (data collected in the class), guided by the initial questions and facilitated by the visualization provided by graphical representations created in *TinkerPlots*, supported the students' involvement in the subsequent generalization of the observed characteristics and the use of such data as evidence.

Using probabilistic language to describe generalizations

Students' responses, presented in previous sections, suggest that they recognized that their predictions were tentative since they included, in their claims, several elements of uncertainty expressed by the terms "probably", "maybe" or "something similar" instead of equal. They also used the term "tend to be" showing that they started to adopt a statistical perspective of trend. In all these cases, the uncertainty was expressed qualitatively, without confidence levels or margins of error (Dierdorp, Bakker, van Maanen, & Eijkelhof, 2012), as expected taking into account the students' statistical experience. Nevertheless, this component of ISI was the less evident in students' work, suggesting the need of specific work regarding probabilistic language.

DISCUSSION

In this paper, we described some examples of students' ISI that emerged through an informal data-based approach, rooted in the statistical investigation cycle (Wild & Pfannkuch, 1999). Despite the reported findings are limited to one task in one class, those examples give us some insight into the students' capabili-

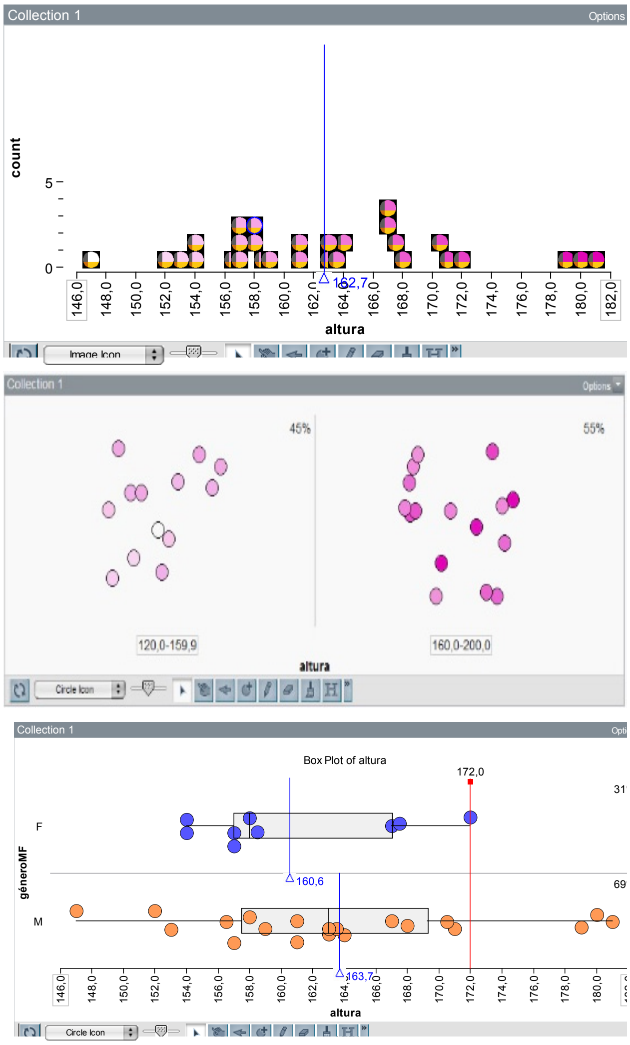

Figure 1: Students' graphical displays

ties and the challenges they faced in making informal statistical inferences when experiencing statistics as an investigative process.

All students, even in the less successful groups, were able to demonstrate some aspect of informal statistical inference during the lessons. Students drew their conclusions based on the data they had collected from their class and often used the data to make inferences about an unknown population (whole school). Few students used probabilistic language for describing their generalizations but even those who made it had difficulties in including references to levels of uncertainty. These results highlight the need of working on probabilistic language issues, helping students to evolve from a deterministic perspective of inference to include uncertainty in their statements.

There are also some evidences from the study that the software *TinkerPlots* was used by the students as a reasoning tool (Ben-Zvi, 2006) providing opportunities for structuring and displaying data in ways they choose and understand. However, this was not the focus of this study, and although students' interaction with the software in the previous tasks seems to have contributed to their meta-representational competence (English, 2014) the complex role of technology in supporting ISI deserves further discussion. These encouraging findings do suggest that the adoption of a statistical investigation approach in a technological environment has the potential to make ISI accessible to students, as observed in other studies (Ben-Zvi et al, 2012).

Finally, many studies show that several skills are required for the emergence of students' practices of ISI, such as: articulating or predicting from observations, recording and organizing data using invented methods and working with aggregates and variability (e.g., McPhee & Makar, 2014). The proposed sequence of tasks in this DRP appeared to have supported students' development of such skills but they still need to be re-examined before they are used in a new teaching experiment. Further analysis of students' interaction within the groups, which were not considered in this study due to time and space limitations, may convey new and deeper insights on their reasoning, as well as to contribute for the reformulation of the tasks and their implementation conditions.

AKNOWLEDGMENTS

Study supported by national funds through FCT – Fundação para a Ciência e Tecnologia, Project Developing statistical literacy: student learning and teacher training (contract PTDC/CPE-CED/117933/2010). We thank Ana Isabel Mota who assumed the role of research assistant for her extensive work in data collection.

Improving teachers' reasoning about sampling variability: A cross institutional effort

Bridgette L. Jacob[1], Hollylynne S. Lee[2], Dung Tran[2] and Helen M. Doerr[3]

3 Syracuse University, Syracuse, United States

The research reported here uses common items to assess statistical reasoning of teachers enrolled in a graduate-level education course to evaluate their reasoning about sampling variability. In particular, we discuss key aspects of a purposeful course design aimed at improving teachers' learning and teaching of statistics, and the resulting different ways of reasoning about sampling variability that teachers exhibited before and after the course.

Keywords: Statistics, sampling, variability, reasoning, assessment.

Given the strong attention to statistics in the secondary curriculum in many countries (e.g., England Department of Education, 2014; CCSSI, 2010), many teacher professional development efforts and graduate courses include more opportunities for secondary teachers to develop their statistical reasoning and to learn pedagogical strategies for teaching statistics. Researchers have investigated the statistical knowledge needed for teaching using various frameworks (e.g., Burgess, 2011; Noll, 2011). Each of these frameworks has identified teachers' own statistical reasoning as a foundational aspect of their ability to teach statistics.

Our research is situated within the collaborative design and implementation of a graduate course across two institutions focused on teaching and learning statistics. Our design work is largely influenced by Pfannkuch and Ben-Zvi's (2011) recommendations for designing experiences to develop teachers' statistical reasoning. Though our courses aim to develop teachers' understanding for *teaching* statistics, in this paper we report on teachers' reasoning related to sampling variability, without regard to their understanding of how to teach others about sampling variability. To help assess the impact of the experiences we designed in our courses, we used both qualitative and quantitative data sources. The focus in this paper is to examine how teachers' reasoning about sampling variability changed.

Understanding sampling variability has been established as difficult, but key, in one's overall statistical reasoning (e.g., Shaughnessy, 2007). Two aspects of sampling variability are reported in this paper: representations of sampling variability and the effect of sample size on variability. Researchers have found that the understanding of variability from expected values among samples improves with experience and age (e.g., Watson & Kelly, 2004). The role of sample size in variation from expected values has also been the focus of much research. Concerning the effects of sample size, researchers have reported that students, and teachers, use equiprobable reasoning in determining the likelihood of two events without considering differences in the sample size of the two events. (e.g., Watson & Callingham, 2013). In a meta-analysis, Noll and Sharma (2014) discussed the Hospital Task, one of the four items reported here, which has been used to assess reasoning about the effect of sample size on parameter estimation. Since the original version presented by Kahneman and Tversky (1972), it has been revised and implemented with students from approximately 10 years of age through college with the predominant response being the equiprobable response. In 2013, Lee, Doerr, Arleback, and Pulis reported that after experiencing an earlier version of our graduate course, teachers still exhibited difficulties with sampling variability, including a tendency to apply equiprobable reasoning by ignoring the effect of sample size on variability. Our reflections on those findings led to the current work.

COURSE AND PARTICIPANTS

Following from the results of Lee and colleagues (2013), a team of four instructors from two institutions began conceptualizing ways to improve a graduate course focused on teaching and learning statistics. Related to sampling variability, suggested improvements included readings and discussions targeted to draw attention to students' tendency for equiprobable reasoning. These suggestions also included purposeful task design using technology tools for data exploration. The team met weekly via videoconference for an academic year (2013–14) to design a 15-week course, and to discuss issues and alter plans as the course was taught in Spring 2014. The course consisted of opportunities for teachers to engage in statistical investigations with real data and tasks designed to develop their understandings of distribution, samples and sampling distributions, and inferential statistics, especially using randomization approaches. The course used the dynamic software *Fathom* (Finzer, 2005) and *TinkerPlots* (Konold & Miller, 2011), as well as online applets and resources such as StatKey (lock5stat.com/statkey). The course included readings and discussions about (a) the nature of statistical reasoning, and (b) students' learning and reasoning related to the aforementioned topics. Software tools were used to support teachers' learning by allowing them to flexibly explore graphical representations, easily compare data sets, and make changes to data in displays to explore conjectures. The software provided the simulation tools necessary to create representations of a population, a sample, and an empirical sampling distribution. Given the research on students' struggle to understand sampling distributions (e.g., Saldanha & Thompson, 2014), we saw these representations as critical for developing teachers' knowledge of sampling variability.

Across institutions, the course served a variety of graduate students (n = 27, 8 in Course1 and 19 in Course2). Participants consisted of one pre-service teacher (5th year senior), six pre-service and 11 in-service teachers in masters programs, one full-time masters student in mathematics education, seven doctoral students in Mathematics or Mathematics Education (three currently teaching in post-secondary contexts), and one doctoral student with interests in statistics education. Twenty-one participants were female and six were male, with six participants for whom English was a second language. Most participants had completed the equivalent of an undergraduate major in mathematics, with all but two having had at least one course in statistics. Henceforth we refer to course participants as teachers.

DATA SOURCES AND ANALYSIS

One source of data was participants' responses to a statistical concept inventory constructed to align with our course goals, content, and experiences. On the first day of class and during the final week of the course, all participants completed a 20-item multiple choice test with items in five categories: distributions (5 items), comparing distributions (3 items), probability (2 items), sampling variability (7 items), and formal inference (3 items). Eleven items were drawn from validated instruments (delMas, et al., 2007; Garfield, 2003), with seven selected from the ARTIST database (apps3.cehd.umn.edu/artist), and two items adapted from research (e.g., Watson & Kelly, 2004; Zieffler et al., 2008). The 20-item test was agreed upon by instructors during the planning phase to ensure items had content validity to measure concepts to be addressed in the course. For two of the four sampling variability items we highlight in this paper, teachers were asked to justify their choices.

After the course, semi-structured interviews were conducted with selected teachers (n = 14) across institutions to understand changes in their reasoning and perceptions of what might have influenced those changes. Interviews (45–90 minutes) were audio or video taped. Interviewees were purposely selected because of trends in their responses to items on the test. For example, some were selected because they had improved from an incorrect response to a correct response on several items, while maintaining incorrect responses on other items. During the interview, participants were shown an item, given time to reread, told which choice (A, B, C, etc.) they had selected on the pre and post-test, and then asked about their reasoning. Based on responses, the interviewer asked questions prompting them to elaborate about their reasoning.

Descriptive statistics and t-tests were used for the 20-item assessment to document the change in teachers' performance on the pre and post-test, both overall and on individual subscales. Teachers' responses to the two open-ended items and responses of the 14 teachers interviewed were open coded to identify emerging themes to gain insight into the teachers' reasoning about the changes in their responses.

RESULTS

Analysis of the pre and post-test showed significant improvement in teachers' overall scores (out of 20), with a mean increase of 1.84 points (s.d.=1.98). Strong gains were found in the items related to sampling variability, with a mean increase in scores (out of 7) of 1.3055 (s.d.=1.19). In this paper, we report on changes in teachers' reasoning for two key categories: (1) the effect of sample size on the likelihood of outcomes, and (2) representations of sampling variability.

Two items, Brown Candies and Two Hospitals, pertained to the effects of sample size on the likelihood of outcomes from a sample. At the beginning of the course, about half of the teachers correctly answered each of these items. Two additional items, Sample Means and Sample Proportions, asked teachers to reason about expected variability in a distribution of sample statistics when sampling from a given population distribution. For both of these items, a larger proportion of teachers were able to correctly respond at the beginning of the course, 78% and 70% respectively.

Effect of sample size on the likelihood of outcomes

Table 1 illustrates the distribution of responses for the Brown Candies item. There was a major shift to 83.2% responding correctly on the post-test. Most notable was the decrease in the number of teachers choosing the equiprobable response (E).

By the end of the course, the teachers gained a clearer understanding that smaller sample sizes have greater variability than larger sample sizes, thus resulting in small samples being *more likely* to have larger deviations from the expected percentage of 50% brown candies. The following is representative of teachers' responses when asked to explain their reasoning about the Brown Candies item.

> The large [bag] is more like 50%, the small [bag] is more unlikely because of smaller sample size. For example you flip a coin, you have more chance to have 8 and 2 whereas you flip 200, you are more likely to get 50%. (Teacher 27)

The single teacher to choose 'B', the larger bag having more variability, on the post-test, chose the equiprobable response 'E' on the pre-test. However, during the interview, she realized she had chosen in error and stated her reasoning:

> Maybe at first when I answered it, at first I think I didn't have any idea about sample size. But after we learned something about sample size in class and how it will affect, you know, like the variability... [reading the problem] So Sam is the one having a larger, a large family sized bag? So that implies that large family sized bag will have a large sample size? And that implies that we should have less variability? I think I was wrong. So it should be 'C'. (Teacher 1)

This teacher appeared to have difficulty with the complex terminology in the item rather than a misunderstanding of the underlying concept. Three teachers

Brown Candies: A certain manufacturer claims that they produce 50% brown candies. Sam plans to buy a large family size bag of these candies and Kerry plans to buy a small fun size bag. Which bag is more likely to have more than 70% brown candies?		
	Pre-Test	Post-Test
Sam, because there are more candies, so his bag can have more brown candies.	0.0% (0)	0.0% (0)
Sam, because there is more variability in the proportion of browns among large samples.	3.7% (1)	3.7% (1)
Kerry, because there is more variability in the proportion of browns among smaller samples.	**51.9% (14)**	**83.2% (23)**
Kerry, because most small bags will have more than 50% brown candies.	3.7% (1)	0.0% (0)
Both have the same chance because they are both random samples.	40.7% (11)	11.1% (3)

Table 1: Results of the Brown Candies Item

chose 'E', the equiprobable response, on both the pre and post-test. One teacher explains:

> I was thinking about this idea of flipping a coin... flipping it head, the next time you flip, it is 1 over 2. So ... making an analogy to this it says that a certain manufacturer claims that they produce 50% brown candies... So it doesn't really matter whether the bag has ten candies or a thousand candies... there is 50% chance I mean 50% of them... would be brown. So long as the bag contains candies from this manufacturer. (Teacher 7)

This teacher is equating samples in the large and small bags of candies to tossing a single coin rather than a series of coin flips in the long or short run.

For the related Two Hospitals item, teachers needed to reverse their thinking by choosing the hospital that was *less likely* to record a high percentage of female births. Teachers were also asked to write about their reasoning for this item on the test. Table 2 shows results for the Two Hospitals item in which gains were made in teachers' correct responses. Again, we saw a decrease in the number of teachers choosing the equiprobable response (C) and an increase in the correct choice (A).

Of the 22 teachers answering this correctly on the post-test, the responses below are representative of their thoughts about sample size and variability.

> So Hospital B is more likely to have 80% or more. And then I also thought about the numbers, if you're doing 50 births a day, 40 girls out of 50 seems like a lot compared to 8 out of 10. (Teacher 3)

> The larger hospital will have less variability from the expected value of 50% boys and 50% girls. (Teacher 17)

These teachers illustrated an understanding of the relationship between sample size and variability. In the open-ended responses, four teachers also referred to the actual number of births, stating 8 out of 10 female births was a likely outcome for the smaller hospital but 40 out of 50 female births was unlikely for the larger hospital. During interviews, six teachers noted the conceptual similarity between the Brown Candies and Two Hospitals items and that they had to "reverse" their thinking for the latter.

Of the five teachers choosing incorrectly on the post-test, three of them indicated the smaller hospital was less likely to record a high percentage of female births (B). During interviews with two of these teachers, they indicated they had misread the problem on the post-test. "Yeah 'A', the big one. The reason is because there is more variability... [laughs]. The answer is wrong but my explanation is correct. There is more variability in the small sample." (Teacher 6) Both teachers had responded instead to which hospital would be *more likely* to record 80% female births.

The remaining two teachers responding incorrectly on the post-test chose the equiprobable response. One of them chose the equiprobable response on the pre and post-test, as he had done for the Brown Candies problem. His open-ended response on the post-test revealed his reasoning, "Each birth is independent of the other births and there is a 0.5 probability that each birth (independent) of others would result in a boy or a girl." (Teacher 7) Both teachers demonstrated the difficulty of dispelling the notion of equiprobability of events with small and large samples.

Representations of sampling variability

The Sample Means and Sample Proportions items assess teachers' understanding about sampling distribution by asking teachers to predict variability from expected outcomes, using different representations.

Two Hospitals: Suppose about half of all newborns are girls and half are boys. Hospital A, a large city hospital, records an average of 50 births a day. Hospital B, a small, rural hospital, records an average of 10 births a day. On a particular day, which hospital is less likely to record 80% or more female births?

	Pre-Test	Post-Test
Hospital A (with 50 births a day)	**51.9% (14)**	**81.5% (22)**
Hospital B (with 10 births a day)	14.8% (4)	11.1% (3)
The two hospitals are equally likely to record such an event	18.5% (5)	7.4% (2)
Not able to determine based on given information.	14.8% (4)	0% (0)

Table 2: Results of the Two Hospitals Item

The Sample Means item provides a graphical display of the population distribution with the mean and standard deviation, and asks teachers to choose the most likely dotplot of five sample means of size 10. The Sample Proportions item gives the population proportion numerically and asks which set of five proportions from random samples of size 20 is most likely.

Table 3 shows the distribution of teachers' responses on the pre and post-test for the Sample Means item. Initially 78% of the teachers were able to identify reasonable variation from expected. This number increased by 11% after the course. Further examining the open responses and interviews gave insight into their reasoning.

Seven of the 14 teachers interviewed were able to eliminate too little variation (response a), and too much variation (response b), indicating a strong sense for reasonable expectations in variation. For example, Teacher 15 stated, "Here with only five samples, I think 'a' would be too perfect. I would throw out 'b' because the chance you have 10 values with the mean of 8.5 would be very slim, if even ever [pointing to dot above 8.5 on dotplot]". Four of the teachers were able to distinguish between the population, samples and sample means, and the sampling distribution. "I try to grasp my head around five students with 10 values, so that this dot represents the mean of 10 values, not just one value I picked out" (Teacher 15). In addition, they could incorporate the sample size into the expected variability of the sampling distribution. As an example, Teacher 11 replied:

> Sample 10 seems to me not a large sample size set of data so I am certainly expecting... if I take 1000 values, I am convinced that the sample mean should be put together. With 10 values I am suspicious. That's possible but less probable. And by exactly the opposite reasoning, 10 seems big enough that I see so much variation that I see. No way I can quantify... that is too much variation of sample 10. That dot [pointing to right dot in 'b'] I should have many values over here [pointing to right tail of the population distribution] that's simply outrageous; I believe if it is 1 sample [pointing to 'b'].

When reasoning about the population, samples, and the distribution of sample means, the teachers either went back to the graph of the population to estimate the means, or used the numerical statistics given to evaluate the possibility of the sample means.

Sample Means: The distribution for a population of measurements is presented at the right. The mean is 3.2 and the standard deviation is 2. Suppose that five students each take a sample of ten values from the population and each student calculates the sample mean for his or her ten data values. The students draw a dotplot of their five sample means on the classroom board so that they can compare them. Which of the following dotplots do you think is the most plausible for the one they drew on the board?

	Pre-Test	Post-Test
	14.8% (4)	3.7% (1)
	7.4% (2)	7.4% (2)
	77.8% (21)	88.9% (24)

Table 3: Results of the Sample Means Item

> I think the new SD should be between 1/2 and 1. I don't know if 10 is large enough, but with large number of sample, the sampling distribution is approximate a normal distribution so I think if the mean is here [point to about 3.2 in 'c'] so other will be 1/2 SD from the mean and other is about 1 SD within the mean. (Teacher 18)

> It is about 76%, then 2SD of 95%... I am looking for most of the things within that. This is like 8.5, it is way out of range. This [pointing to 'a'] does not have enough of deviation within 1 SD, they cramp together. 'C' seems more within the 2SD. (Teacher 30)

These responses reveal teachers' reasoning about sample means using the sampling distribution and the Central Limit Theorem.

Three teachers who got this item wrong on the post-test did not show a robust understanding of population, sample, and sampling distribution. For example, one teacher seemed to believe the distribution of sample means should resemble the population distribution "I think 'b' is making the most sense because I can see the skewness to the right." The sampling distribution remained complicated for her even though the course focused extensively on that construct.

Table 4 shows the distribution of teachers' responses on the Sample Proportions item. While teachers (70.4%) began our course with a good intuition about variation from expected, almost all correctly responded to this item after taking the course.

Teachers' interview comments indicated they were able to eliminate wrong options based on their sense of variability from expected. For example:

> I eliminate 'C' because of the 5% and 95%. If I know 35% of the candies are yellow, I know it is not impossible but, I just don't see someone picks 20 candies all but one being yellow and I know there are enough candies in there just 35% of 1000, it could happen. I just, 20 candies is not enough to see the perfect 35% every time. One kid might see it; not every kid might see it. (Teacher 13)

For the teachers who chose an incorrect response, they seemed to be using either equiprobable reasoning or the thinking that anything can happen.

Reasoning across Items

At the beginning of the course, only 10 of 27 teachers (37%) answered both the Brown Candies and Two Hospitals items correctly. Of the 13 teachers choosing incorrectly on the Brown Candies item, the predominant response chosen by 11 of them was 'E', the equiprobable response (Both have same chance because both are random samples). Of these 11, only four teachers chose the equiprobable response for the Hospital item as well. Another common misconception that larger sample sizes have greater variability was demonstrated by one teacher for the Brown Candies item and four teachers for the Hospital Problem.

After the course, 20 out of 27 teachers (74%) correctly responded to both items; a marked increase from the pre-test. Of the remaining seven teachers, three chose an equiprobable response to one of the items, repeating their error from the pre-test. There was only one teacher who exhibited an equiprobable misconception for both items on the pre-test and the post-test.

For the Sample Mean and Sample Proportion items, before the course 16 out of 27 (59%) teachers correctly answered both items. By item, 21 judged the variation

Sample Proportions: Imagine you have a barrel that contains thousands of candies with several different colors. We know that the manufacturer produces 35% yellow candies. Five students each take a random sample of 20 candies, one at a time, and record the percentage of yellow candies in their sample. Which sequence below is the most plausible for the percent of yellow candies obtained in these five samples?		
	Pre-Test	**Post-Test**
30%, 35%, 15%, 40%, 50%.	**70.4% (19)**	**92.6% (25)**
35%, 35%, 35%, 35%, 35%.	14.8% (4)	3.7% (1)
5%, 60%, 10%, 50%, 95%.	3.7% (1)	0% (0)
Any of the above.	11.1% (3)	3.7% (1)

Table 4: Results of the Sample Proportions Item

in a graphical format correctly whereas 19 selected a correct response for the question concerning variation in a numerical format. By the end of the course, almost all teachers correctly answered both items (24/27, 88.8%).

DISCUSSION AND CONCLUSIONS

Overall, the teachers improved their understanding about sampling variability, in particular the relationship between sample size and variability, and variability from expected. This could be attributed to the extensive focus on statistical investigation and many experiences with simulations in which attention was drawn to expectations from a population distribution, collecting samples and sample measures, and discussing the distribution of sample measures. A few teachers still had difficulty on these items, corroborating prior findings that sampling distribution and sampling variability is complicated to understand (e.g., Saldanha & Thompson, 2014).

The results of this study also confirm that equiprobable reasoning can be misapplied in reasoning about samples of different sizes, and that this reasoning may become more stable for some teachers (e.g., Watson & Callingham, 2013). We observed that for two of the teachers, even with intensive experiences with variability, they still held a deterministic understanding of probability. This might be rooted in their early exposure to theoretical probability that they need to revisit and re-evaluate in order to build up a robust understanding.

We also observed that teachers could develop a sound understanding about sampling variability and reason correctly about an item, yet still choose a wrong answer. This resulted from a misreading of a problem or a misunderstanding of a particular word. Also, for the Sample Means item, teachers could give a correct answer, reasoning with a sense of variability from expected without necessarily understanding the relationship between a population, samples, and the sampling distribution. Thus, we are concerned that this item may be more useful for measuring understanding of variation from expected values rather than sampling distributions.

This study adds to the sparse literature related to teachers' reasoning about statistics, focusing on their understanding of sampling variability. It illustrates how a carefully designed graduate-level course in teaching and learning statistics improves teachers' understanding of important statistical concepts. In particular, the focus on statistical investigation and reasoning experiences, and the emphasis on a simulation approach for inference, seems to improve teachers' knowledge about sampling variability.

A Bayesian inspired approach to reasoning about uncertainty: 'How confident are you?'

Sibel Kazak

Pamukkale University, Denizli, Turkey, skazak@pau.edu.tr

This paper focuses on a task design that is aimed at eliciting young students' reasoning about uncertainty as it relates to their personal degree of confidence through a Bayesian inspired informal inferential reasoning about chance games. This Bayesian inspired approach is described and discussed based on preliminary analyses of data from a teaching experiment in a designed-based research study. With this approach, beginning by a hypothesis (or prediction) about the fairness of a game and revising it based on new information appear to come natural to the students. The change in strength of their personal level of confidence seems to vary by the conflicting results obtained by playing the game, the size of the data collected, and the multiple computer simulations conducted using TinkerPlots software.

Keywords: Uncertainty, probability, inferential reasoning, task design.

INTRODUCTION

Making decisions and inferences based on data is part of everyday life. In statistics, statistical inference deals with "drawing conclusions about populations or processes based on sample data" (Zieffler, Garfield, delMas, & Reading, 2008, p. 40) by means of certain techniques, such as confidence intervals and hypothesis testing. As argued by Engel and Erickson (2013) it is yet hard to grasp the logic behind statistical inference for students. In order to develop the foundation for the formal ideas involved in statistical inference early on, informal statistical inference has become the focus of the statistics education research (Rubin, Hammerman, & Konold, 2006; Makar & Rubin, 2009). As a relatively recent concept, informal statistical inference refers to a way of making conclusions about a population or process from which the data come by using statistical processes (Pfannkuch, 2006). In addition, the underlying reasoning process leading to informal statistical inference is called informal inferential reasoning (Makar, Bakker, & Ben-Zvi, 2011).

In recent research studies, there has been a great emphasis particularly on informal inferential reasoning to help students develop deeper understanding of statistical concepts, ideas, and processes (Ben-Zvi, Aridor, Makar, & Bakker, 2012; Jacob & Doerr, 2013; Makar, 2014; Paparistodemou & Meletiou-Mavrotheris, 2008). One of these ideas at the heart of informal statistical inference is uncertainty because drawing conclusions beyond the data about a wider population requires an articulation of uncertainty (Makar & Rubin, 2009) and probabilistic justifications (Rossman, 2008). When it comes to teaching probability as part of statistics, a current debated topic is to introduce Bayesian thinking at school level because of its applications in realistic situations and its closeness to how people actually reason about uncertainty (Chernoff, 2014; Nilsson, Blomberg, & Ärlebäck, 2014; Martignon & Erickson, 2014). Therefore more research into supporting young students' development of Bayesian thinking is needed.

The aim of this paper is to describe a Bayesian inspired approach in a task design for eliciting students' reasoning about uncertainty as it relates to personal degree of confidence. First, I outline the ideas behind this approach for task design, which is followed by a brief description of the study and the task. Then I focus on how these ideas are explored during the task as a way to articulate students' reasoning about uncertainty with some preliminary analyses of students' reasoning.

THEORETICAL BACKGROUND

Informal statistical inference and inferential reasoning

In an informal statistical inference, a common underlying reasoning process involves "assessing the strength of evidence against a claim" (Rossman, 2008, p. 7) based on observed data. This type of informal inferential reasoning known as Fisherian approach can be described as follows (Rossman, 2008): formulating an initial hypothesis (or null hypothesis); evaluating that if the hypothesis were true, observed data would have been very unlikely (i.e., intuitively computing a p-value); and rejecting the initial hypothesis based on the very small p-value. According to Rossman, students yet do not appear to use this common reasoning naturally when making statistical inference.

Alternatively, another approach to statistical inference involves a Bayesian perspective based on the subjectivist interpretation of probability. A main distinction between Bayesian inference and Fisherian approach is drawing conclusions based on a subjective or personal assessment of uncertainty. So the reasoning process from a Bayesian approach includes starting with a priori probabilities associated with a hypothesis based on a personal belief and updating these probabilities in the light of new information or data (Rossman, 2008). Albert (2002) argues that the Bayesian reasoning is more intuitive than the Fisherian perspective in statistical inference and better reflects the commonsense thinking about uncertainty in everyday life.

Reasoning about uncertainty

Both in school mathematics curricula and research on students' understandings of uncertain events, games and experiments involving chance devices, such as coin, dice, and spinners, are quite widely used. Games of chance provide a rich context for children to explore random situations, to notice the unpredictability of outcomes and to see the need for probability (Cañizares, Batanero, Serrano, & Ortiz, 2003) while making decisions under uncertainty. The notion of fairness in game situations has also been recognized as a motivating and productive area of inquiry for students investigating probability and uncertainty (Pratt, 2000; Watson & Moritz, 2003; Stohl & Tarr, 2002). For example students can build on their intuitive ideas of fairness to evaluate whether each player has an equal chance of winning or whether each possible outcome is equally likely in different games involving coins and dice.

These studies on fairness in chance games mainly focus on the concept of probability from classical and frequentist approaches. There is a lack of research on young students' conceptions of subjective probability, which is closely related to the Bayesian reasoning mentioned above. One of the earlier studies both relevant to games of chance and subjective perspective to probability (Huber & Huber, 1987) suggests that young children are able to use personal knowledge or beliefs when comparing the likelihoods of chance events in the contexts of sports and gambling. It is also noted that children's subjective probability evaluations tend to be more stable in the gambling context because the objective probabilities could be assessed also through the sections in the spinner device used in the task (Huber & Huber, 1987).

OVERVIEW OF TASK DESIGN

The purpose of the task design was to elicit students' reasoning about uncertainty in the context of informal statistical inference about the fairness of chance games. A previous study using an earlier version of this task suggested that students' reasoning about uncertainty was inherent both in the chance games and in personal degree of confidence (Kazak, Fujita, & Wegerif, 2013). The task then was revised to closely look at students' reasoning about uncertainty as it relates to personal degree of confidence, which is the focus of this paper. To build on students' intuitive and informal inferential reasoning, a Bayesian inspired approach was adopted to design the Matching Tokens Game task in which students were asked to make probability assessments and state their level of confidence in judging the fairness of a game. This approach enabled students to articulate uncertainty while evaluating the fairness of different chance games by making an initial hypothesis and expressing their confidence in the likelihood of a particular game actually being fair or not, and then by revising both their hypothesis and level of confidence with new information obtained from the data through physical experiments and computer simulations. The underlying process is usually viewed consistent with people's way of developing intuitions based on learning from their experiences and revising their beliefs as new information is acquired (Falk & Konold, 1992).

Study background

The task design is part of a design-based research study. As described by Cobb, Confrey, diSessa, Lehrer, and Shauble (2002), this study involved an iterative design through planning, testing, and revising conjectures about students' learning and ways of supporting their learning of domain specific content, i.e. probability and statistics. The research cycle involved designing instructional materials and a learning environment that supports the desired learning goals, conducting teaching sessions, and retrospective analysis. Three iterations in local schools in Exeter, UK were conducted as part of the larger research study. In these teaching experiments, students worked in groups of two or three on a joint activity. Each group was given worksheets and videotaped while working around a computer. The task described here was tested and revised based on the earlier iterations. The empirical data used to explain a Bayesian inspired approach in this paper are from the last iteration with eleven 10–11-year-old students: group A (Justin, Owen, Matt), group B (Taylor and Sam), group C (Meg, Julie, and Jailyn), and group D (Maya, Eleanor, and Jena).

Task and tools

The Matching Tokens Games involve randomly drawing a token from each bag shown in Figure 1. For example, in Game 1 one bag has 3 red tokens and 1 blue token and the other has 1 red token and 3 blue tokens. To play the game, a token will be randomly drawn from each bag. If both tokens are the same color, students win. If they are different (mixed) color, teacher wins. The question posed to students before playing the game is whether the game is fair or not. These four games were chosen and sequenced based on the students' responses on the previous two iterations of the task. Students investigated each game one after another in the given order.

Through adapting a Bayesian inspired approach this game context was introduced to students in a specific structure involving three phases and ten questions. As seen in Figure 2, in the prediction phase students began by formulating a hypothesis about the fairness of Game 1 based on their personal knowledge/belief. Then on a scale (0–10) they evaluated how confident they were about the un/fairness of the game initially based on the explanation they were asked to give in question 1. In the game-playing phase, students working in groups collected as many data as they wanted by playing the game with the given bags and recording their results and used the results to update their initial hypothesis as well as their level of confidence if needed. In the modeling phase, they built a computer model to simulate the game results and to collect more data, and again revised their previous hypothesis and level of confidence in the light of new information.

TinkerPlots software (Konold & Miller, 2011) was used as a modeling tool in this study. The Sampler tool in *TinkerPlots* allowed students to build their own chance models using a variety of devices (i.e., mixer, spinner, bars, stacks, curve, counter) that can be filled with different elements to sample from. It also enabled students to collect outcomes and carry out a large number of trials quite quickly. For instance, to build a model of Game 1 in *TinkerPlots* (see Figure 3) group B used two connected mixer devices, one with

<u>Game 1</u> Bag one: 3 red tokens, 1 blue token Bag two: 1 red token, 3 blue tokens	<u>Game 2</u> Bag one: 2 red tokens, 2 blue tokens Bag two: 2 red tokens, 2 blue tokens	<u>Game 3</u> Bag one: 4 red tokens Bag two: 2 red tokens, 2 blue tokens	<u>Game 4</u> Bag one: 3 red tokens, 1 blue token Bag two: 2 red tokens, 2 blue tokens	
Figure 1: Games given on each worksheet

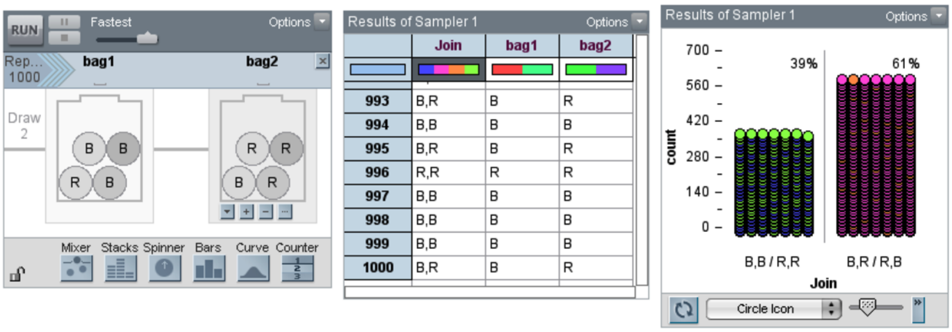

Figure 3: Computer model of Game 1

three red (R) and one blue (B) balls and the other with one red and three blue balls, representing the number of red and blue tokens in each bag. Repeat number is set to 1000. After randomly being selected from each mixer, the outcomes of each trial are displayed in the results table for 1000 repetitions. In the graph, the individual outcomes, 'B,B' and 'R,R' then 'B,R' and 'R,B', are combined into a bin by dragging one into the other to display the percentage of "the same color" and "the mixed color" outcomes respectively.

CHARACTERISTICS OF A BAYESIAN INSPIRED APPROACH TO REASONING ABOUT UNCERTAINY

In order to develop students' reasoning about uncertainty through informal inferential reasoning, the task design involved a Bayesian inspired approach to informal inference in the context of chance games. Each game investigation starts by having students state their initial hypothesis about the fairness of the game with an explanation and then rate their level of confidence about the un/fairness of the game on a scale from 0 to 10. In order to test their initial predictions students play the game to collect some data and record their results on the worksheet (questions 3 and 4 in Figure 2). Judging the fairness of these games, except Game 2, were found to be highly counter-intuitive based on the students' initial responses in the previous iterations of the task (Kazak, Wegerif, & Fujita, 2014). So, students are expected to update their initial hypothesis and level of confidence based on new evidence from the game results. Subsequently students build a model of the game in *TinkerPlots* to collect more data to reevaluate their previous hypothesis and confidence level through computer simulations. Next I describe the phases of the student investigations characterized by the adopted Bayesian inspired approach with some analyses of students' responses on the worksheets.

Forming a hypothesis with a level of confidence

Based on their current understanding of probability students began by stating their initial hypothesis about fairness of each game and explanation for it. These students had previous experience with simple events, but the ones described in the games required an understanding of combined outcomes. Thus they relied primarily on their intuitive ideas, which generally led them to an incorrect judgement. The explanations given for their predictions indicated that they seemed to focus either on the symmetry in the total number of red and blue tokens in the bags with an additive reasoning in Game 1 or on the likelihood of simple events in each bag, i.e., the chance of getting a red token from a bag in Game 3 and Game 4. Unlike these counter-intuitive games (1, 3 and 4), Game 2 was consistent with the students' intuitions. Although their predictions about Game 2 were correct, their reasoning was problematic. They expected that the symmetry in the combined bags (equal number of red and blue tokens) would generalize to the combined outcomes.

Starting with students' initial predictions about the fairness of the games was an essential part of the Bayesian inspired approach used in the task. When dealing with uncertainty, we often draw upon a variety of evidence, but particularly personal knowledge or belief or past experience in the absence of empirical results or theoretical knowledge. From the Bayesian perspective this is the basis for subjective probability. Since these beliefs can change based on new evidence, it is important to assess personal degree of confidence in the initial hypothesis or prediction and look at how it changes over the course of gathering new relevant information. Each group's responses on the worksheets showed that students were likely to be more confident about their initial hypothesis in Game 2 that was more intuitive. The initial confidence level in Game 2 was on average 9.4 (out of 10) for all groups while the average level of confidence in Game 1, Game 3, and Game 4 was 8.9, 8.4, 8.8 respectively. These values can be argued as indications for how much students are willing to rely on their personal beliefs or knowledge without additional evidence. Since the fairness judgment for the games 1, 3, and 4 were less intuitive to them, none of the groups correctly identified whether the game was fair or not initially.

Using information based on experiment data to update level of confidence

To test their initial predictions, each group played the game as many times as they wanted. The number of times that the games were played, i.e. the number of trials, tended to be small and varied among groups, from 5 to 30. Students mostly did not incline to revise their initial beliefs based on the game results unless they believed that they had contradicting results. For example, group A changed their first predictions in Game 1 (based on "same wins=11", "mixed wins=19") and Game 3 (based on "same wins=2", "mixed wins=3"), and group B modified theirs in Game 1 (based on "same wins=5", "mixed wins=15") and Game 4 (based on "same wins=5", "mixed wins=5") after playing the game. These changes in predictions involved switching to 'unfair' in Game 1 and to 'fair' in Game 3 and Game 4. The changes in the level of confidence seemed to vary depending on how much they were convinced by the actual game results. While the level of confidence dropped for Game 3 and Game 4 by -4.5 and -1 points respectively, there was no adjustment for Game 1 in both groups.

Using information based on simulated data to update level of confidence

To further test their initial or current updated hypotheses, each group built a model of the games using *TinkerPlots* to quickly collect more data. Naturally the number of trials in computer simulations became higher, ranging from 100 to 100000. However, students mostly seemed to find 100 trials large enough to base their decisions. The simulated data results generally seemed to help students update their current hypotheses. When asked what would make them more certain in questions 6 and 10 (Figure 2), some groups tended to suggest conducting 'more tests', i.e., running the simulation again with the same number of trial. Indeed group A and group C carried out a few more simulations with the same number of trials using *TinkerPlots* and recorded the results. At the end of the task, the groups arrived at the correct judgment about the fairness in the majority of the games after running multiple tests using computer simulations. Moreover, there was a positive increase in the level of confidence overall during the simulations. While the average change in confidence level in the case of switching to a right judgment was +0.6, this was doubled (i.e., +1.2) when students already had the right judgment from the game results. This result can be an indication of the effectiveness of additional evidence to support current hypothesis and personal belief.

CONCLUSIONS

The main premise of a Bayesian inspired approach to reasoning about uncertainty is that students' informal inferential reasoning about the fairness of the chance games is closely associated with their personal degree of confidence. Starting with a hypothesis about whether the game is fair or not and revising it based on new information come natural to students. The task design described in this paper is intended to help this process be more systematic by scaffolding students' reasoning step by step in each of the three phases (Figure 2). This way students do not only change their predictions about the fairness of the game based on data they collect but also update the level of their confidence which is linked to their certainty level.

The preliminary analysis offered in this paper suggested that students' first 'intuition-based' hypotheses about the fairness of the games mainly led them to wrong judgments initially particularly in the counter-intuitive games. However, both their conjectures and level of confidence on them tended to improve as they collected more data. More specifically, conducting a large number of trials and multiple tests using *TinkerPlots* modeling tool allowed students to change their beliefs about the fairness of the games and the strength of their confidence. Moreover, obtaining 'surprising' results in the game playing phase generally helped students revise their initial predictions while their level of confidence seemed to decrease to some extend. Students however tended to show more confidence in their personal belief about the fairness of the game when it was confirmed by 100 or more data collected during the modeling and simulation phase of the task.

Overall, the study shows the importance of integrating the personal beliefs, level of confidence, and empirical results from experiments and simulations in reasoning about uncertainty when making inferences about the fairness of chance games. The approached used in this task suggests a way to bring Bayesian thinking to the school level and makes it accessible to young students as well. Further research on this approach using clinical interviews with more individual groups might be useful to deepen our understanding of how students' experiences based on game results and simulation results affect their beliefs about the fairness of the games, personal degree of confidence, and strategies in the long run.

Simulation approaches to inference have gained prominence in statistics education. In this paper we combine a theoretical analysis of the ways researchers and curriculum developers have represented models of simulation processes with an empirical analysis of the ways teachers represent models of the process they believe would be helpful to students. Our results cumulate in suggestions for a more explicit framework for using a simulation approach to inference.

Keywords: Teachers, modelling, technology, informal inference.

INTRODUCTION

The meat of doing statistics is making inferences about data. Researchers suggest introducing inference informally first and then transitioning to the procedures of formal inference (e.g., Zieffler et al., 2008). In building up informal inferential reasoning, a simulation approach can be an important tool to help students build a deep understanding of the abstract statistical concepts involved (Burrill, 2002; Maxara & Biehler, 2006). Indeed, Cobb (2007) suggests that educators can help students develop an understanding of inference through the "three R's: randomize data, repeat by simulation, and reject any model that puts your data in its tail" (p.12). Incorporating hands on experiences and dynamic statistical software can allow students to visualize the statistical process in order to develop an understanding of the inference process (Budgett, Pfannkuch, Regan, & Wild, 2013). Simulation approaches have been used in several curricula efforts in the US at the collegiate level, and new national standards in the US suggest such an approach for high school students. Researchers have reported modest results in improvement of students' understandings of inference through collegiate curriculum that use a simulation approach (e.g., Garfield, delMas, & Zieffler, 2012; Tintle et al., 2012).

A simulation approach seems to be an appropriate way to help students develop statistical inference conceptually. However, while the "three R's" process may seem simple, understanding all parts of a simulation is conceptually complicated. In fact, even students who know *how* to conduct a simulation, may not have a robust understanding of why they are conducting a simulation, what is being simulated, and how to make appropriate conclusions based on a simulation. Thus, *our research aims to consider, from a theoretical and empirical perspective, how teachers could and should represent the processes involved in using a simulation approach that could assist students in better understanding the general usefulness of such an approach in inference contexts.*

Our work is situated in a models and modelling perspective on teaching and learning mathematics as articulated by Lesh and Doerr (2003). In this perspective, models are systems of elements, relationships, operations, and rules that can be used to describe, explain or predict the behaviour of some other familiar system. Thus, we are very interested in how models (and modelling) can be used to improve teachers and students' understanding of a simulation approach to inference.

MODELS USED BY OTHERS

Many have engaged in research and curriculum development over the past 15 years, focused particularly on understanding inference and simulation approaches. For the purposes of our paper, we will highlight the work of several researchers whose models seem to build from one another. In 2002, Saldanha and Thompson reported that, when students can visualize a simulation process through a three-tier scheme, they develop a deeper understanding of the process and logic of inference. This scheme is centered around "the images of repeatedly sampling from a population, recording a statistic, and tracking the accumulation of statistics as they distribute themselves along a range of possibilities" (p. 261). The diagram in Figure 1 is meant to explicitly draw attention to the multiplicative relationship between a population, sample(s), and a distribution of sample statistics. Thus, the diagram can serve as a model for the process of repeated sampling. Their work also had students experience and attend to three levels in the sampling process: 1) randomly draw items to form a sample of a given size and record a statistic of interest, 2) repeat Level 1 process a large number of times and accumulate a collection of statistics, and 3) partition the collection of statistics to determine what proportion lies beyond a given value.

Several researchers have built from Saldanha and Thompson's multi-tier scheme and the models and modelling work of Lesh and Doerr (2003) for creating models that can assist students when using simulation approaches, or resampling techniques, for inference (Garfield et al., 2012; Lane-Getaz, 2006). Lane-Getaz (2006) offered the Simulation Process Model (SPM). This process includes three tiers: population parameters, random samples, and distribution of sample statistics. The SPM resembles Saldanha and Thompson's (2002) model and verbal description of three levels, but uses more explicit language in the diagram itself. The first tier is to describe the population distribution as the beginning of the simulation process, then, random samples are drawn from the population, and a sample statistic is selected related to the simulation process for Tier 2. In the last and third tier, the distribution of the sample statistics is formulated, and used to evaluate the likelihood of the event happened in the original problem (Figure 2). Lane-Getaz described how she used the SPM as an organizer to help students understand the general process of inference. She then adapted the SPM to specific examples used in her course so that students can see how the model frames the simulation process used in different contexts.

In line with Lane-Getaz's suggestion, Garfield and colleagues (2012) used a models and modeling approach in the design and research of the CATALYST curriculum (Catalyst for Change, 2012). Figure 3 shows their three-level framework including specifying a model, samples and numerical summary measures, and distribution of the numerical summary measures applied to one task (Cereal Boxes). They, too, advocated using a general structured diagram with students to organize their thinking about the general simulation process and for specific problems.

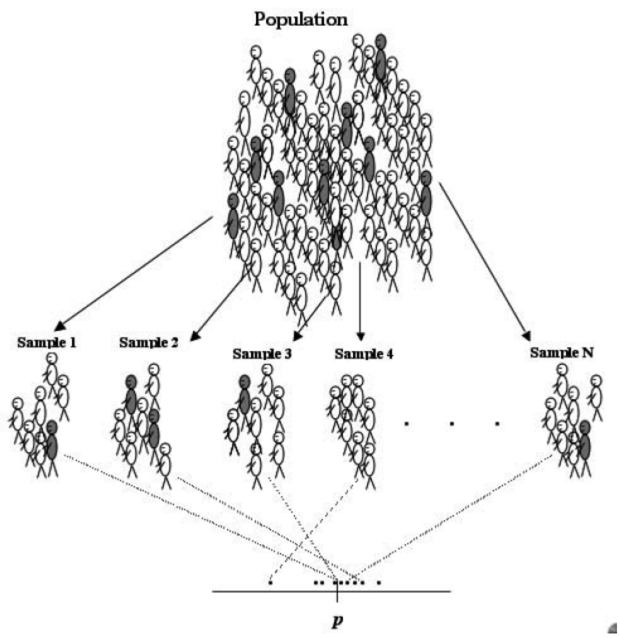

Figure 1: Model for sampling conception (Saldanha &Thompson, 2002, p. 267)

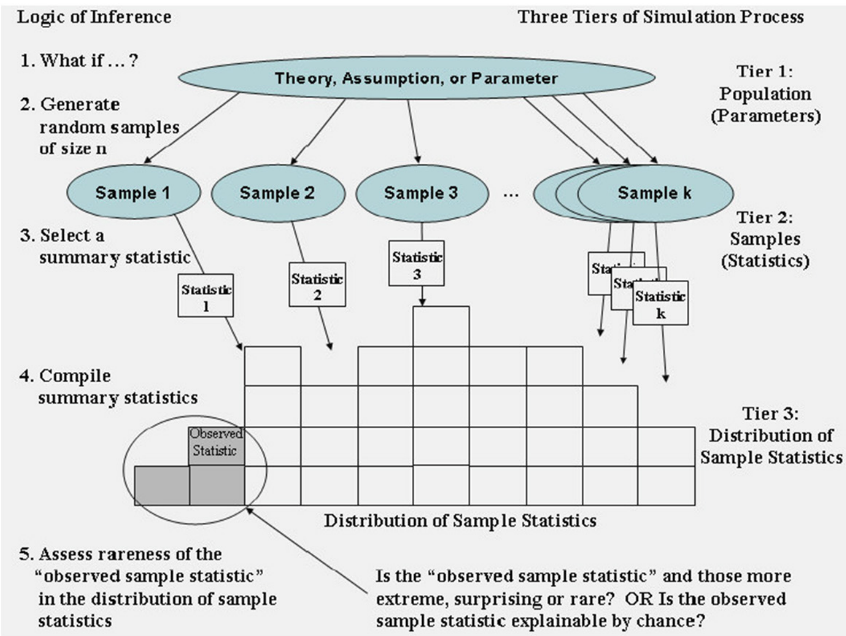

Figure 2: Simulation Process Model (Lane-Getaz, 2006, p. 280)

All the models shown in Figures 1, 2, and 3 include three tiers/levels for the simulation process, including population, samples, and sampling distribution, even though these terms are either implicitly or explicitly used. However, there are some differences. For example, Saldanha and Thompson (2002) implicitly allude to a statistic of interest in their diagram but explicitly refer to it in their verbal description of the three-level process. The statistic of interest is explicitly referred to in the other two diagrams (Figures 2 and 3).

Our understandings of the literature on simulation approaches to inference and the representations used by others, informed our design of tasks to use with teachers in a graduate course on teaching and learning statistics. What follows is a description of the course, participants, and several tasks that took a simulation approach to inference. The set of tasks served as a model development sequence (Lesh et al., 2003) that enabled us to support the development of teachers' understanding of a simulation approach to inference while also revealing and eliciting their thinking. As teachers (and students) are learning about simulation techniques, we cannot assume that they fully understand the computer representations of that process and the underlying randomization and sampling that is occurring. Hence, this paper focuses on a task presented to teachers to elicit how they would help students understand the simulation process. Specifically, we wondered: *What can we learn from teachers' visualizations of the components of a simulation process for drawing an inference to suggest a general framework (model) that could assist learners?*

COURSE AND DATA COLLECTION

A team of four instructors from two institutions met weekly via videoconference for an academic year to design a 15-week course offered at each institution, and to discuss issues and alter plans as the course was taught. The course consisted of opportunities for teachers to engage in statistical investigations with real data and tasks designed to develop understandings of distribution, samples and sampling distributions, and inferential statistics, especially using randomization approaches. The course used the software *TinkerPlots* (Konold & Miller, 2011) and applets (e.g., http://lock5stat.com/statkey). The software provided simulation tools needed to represent a population, a sample, and a distribution of sample statistics.

The simulation tasks used in the course were adapted from typical ones used by popular introductory statistics materials that use modeling and randomization approaches (e.g., *Paul the Octopus task*, Lock et

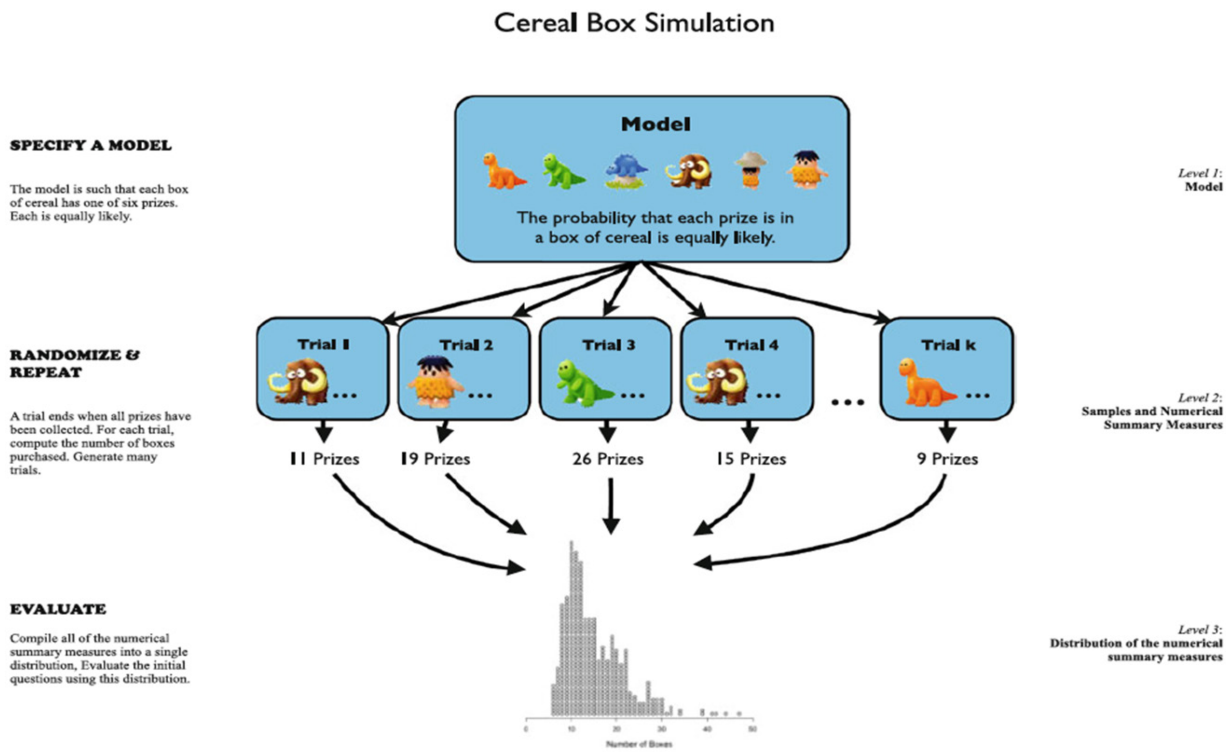

Figure 3: CATALYST modeling and simulation process (Garfield et al., 2012, p. 890)

al., 2013; *Dolphin Therapy task*, Catalysts for Change, 2012). Teachers had also been assigned two articles (Lane-Getaz, 2006; Lee, Starling, & Gonzalez, 2014) to read in which authors used diagrams (Figure 2, and another similar to Figure 1) to illustrate the simulation approach used in the tasks discussed in the articles.

After two simulation tasks (*Paul the Octopus* and *Dolphin Therapy*), the instructor summarized the models that were designed and the resulting simulation process used. The intent of this summary was to help make connections across the two simulation tasks and generalize the processes used to develop an overall conception of the modeling and simulation process. After this summary, and before the assigned readings had been discussed, the instructor used the following task to allow teachers an opportunity to express their developing conceptions of the simulation process in terms of how they would help their students to understand the process. Teachers formed nine groups of 2–3 to create diagrams on a large poster. The exact wording of the task posed to teachers was:

Suppose you were going to use a randomization approach with your students to help them use a simulation (with physical objects or computer models) to investigate if an observed statistic is likely to occur, or not unlikely to occur. Draw a diagram you could use to help students understand the general process used for applying randomization techniques for solving these types of tasks.

Across institutions, the course served a variety of graduate students. This paper focuses on the 19 participants from one institution, since this diagramming task was not completed at the other institution. The 19 participants consisted of one advanced standing preservice teacher (5th year senior), three preservice teachers enrolled in an M.A.T. program; 10 teachers in a masters program while currently teaching students in secondary or tertiary contexts; and five PhD students in Mathematics or Mathematics Education, three of whom were currently teaching in tertiary contexts. Fifteen teachers were female and four were male, with two teachers for whom English was a second language. All but one teacher had completed at least a first level course in statistics. Henceforth we refer to course participants as teachers.

ANALYSIS OF TEACHERS' DIAGRAMS

Five of the nine diagrams, created by teachers in our course are shown in Figure 4 (4a, 4b, 4c, 4d, 4e). These diagrams are representative of the collection of diagrams and were selected to illustrate points made in this section. Though we began our open coding informed by literature and the ways others had represented sampling and simulation approaches (Figures 1, 2, 3), we will explicate how our analysis of teachers' self-created diagrams led us to identify aspects that may be more or less salient for teachers, and perhaps other learners. What follows is a description of the major themes we identified in the representations/descriptions in the diagrams that indicated to us that teachers' had a strong (or incomplete) understanding of the simulation process. It is these themes that are shaping our vision for ways to be more explicit in our modeling processes when using a simulation approach to inference.

Representations in Level/Tier 1 (Population/Problem)

Lane-Getaz (2006) presented the process of using simulation to develop the logic of inference starting with a question in mind, "what if", to investigate a problem (see Figure 2). In this step, students need to specify a "theory, assumption, or parameter" for further sampling. In the Model level of Garfield and colleagues (2012, Figure 3), there are more explicit unpacking of the real world cereal box into statistical terms (six equally likely prizes). We consider this step as crucial in creating a model of the real-world problem. The purpose in the modeling process is to express the problem of interest in mathematical/statistical terms that include a set of assumptions (e.g., likelihood of an event occurring). Six teachers make this aspect of the modeling explicit in their diagrams. For example, the top row of "steps" in Figures 4a and 4e rudimentarily addresses the importance of creating a model of the real world problem. Figure 4c shows that the group of teachers decides to use a coin flip as a model of mom's reaction (yes or no) to whether we can have a party. Implicitly, this coin flip model makes the assumption that probability of a head/tail (likely assumed to be 0.5) is congruent to the probability of mom's response of yes/no. In Figure 4d, teachers also elaborate steps needed to model a real world problem by stating, "determine parameter of interest, determine assumptions for proportion(s), and simulation model (based on assumptions)".

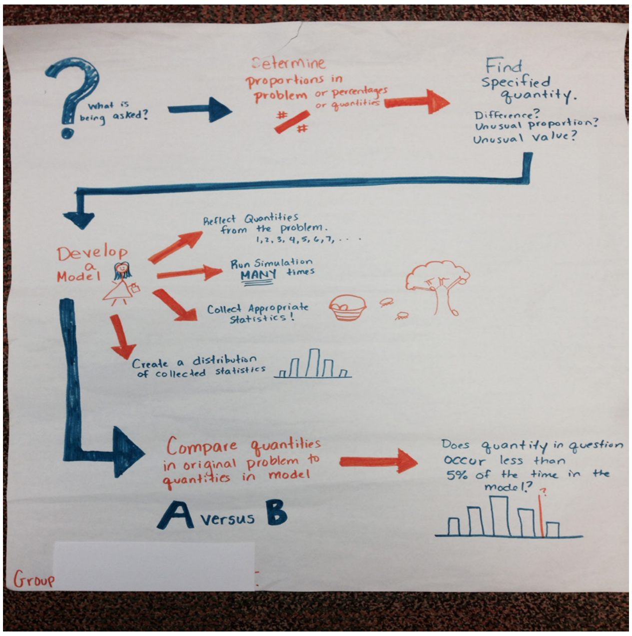

Figure 4a

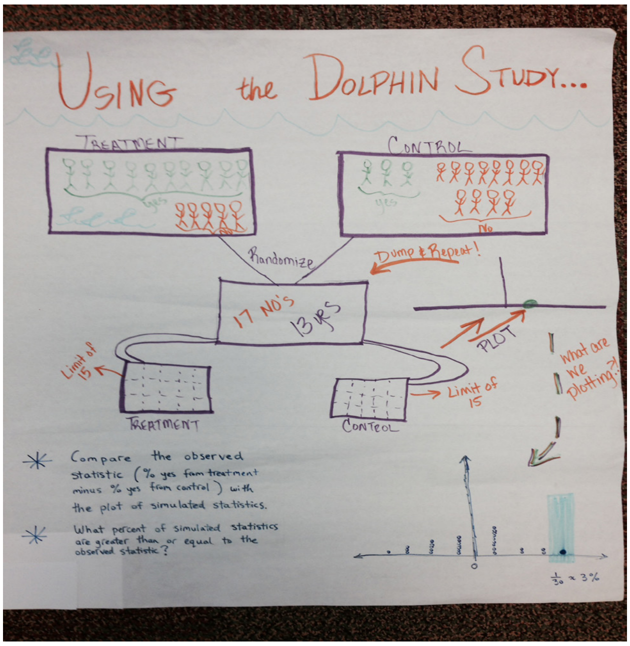

Figure 4b

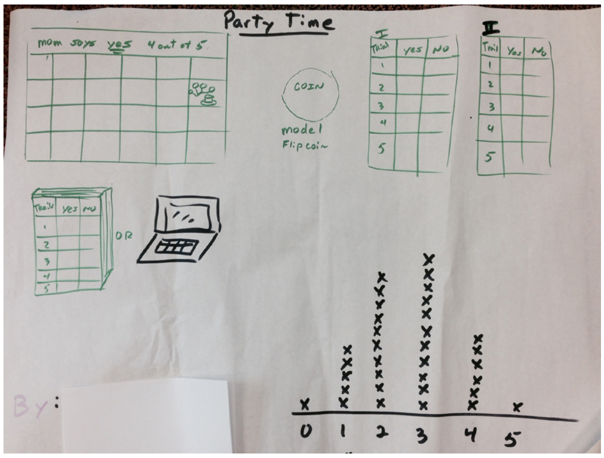

Figure 4c

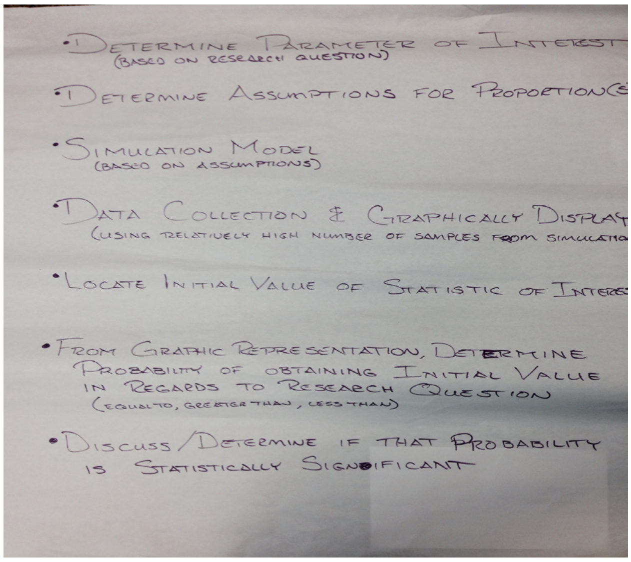

Figure 4d

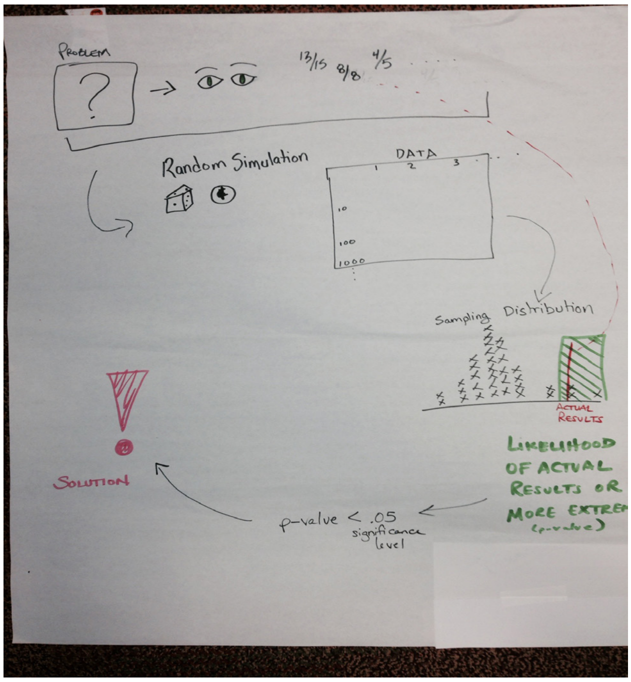

Figure 4e

Figure 4: Five diagrams created by teachers

Emerging from our teachers' diagrams, we noticed that they often attended to identifying the statistic of interest in the original problem that would be later used in the simulation process and for decision making. For example, the posters in Figures 4a, 4b, and 4e explicitly mark or indicate a quantity of interest form the original problem and refer to it later in the simulation process as the statistics to collect and that one needs to locate that statistics in the distribution of sample statistics for decision making. Thus, we found that six diagrams emphasized the process of creating a model for the real world problem and attended to the importance of the original statistics of interest in the problem. This level of detail does not appear explicitly in the models shown in Figures 1, 2, and 3.

After the model *of* the real-world problem is formulated, one needs to develop a model *for* the simulation process. In this modeling step, one decides which types of random-generating devices (physical or technological tools) can be used to accurately represent the random selection or assignment in the problem. When conducting the simulation, it is important to consider the assumptions behind the use of the tools to align with those made in the questions of interest. For example, when using a coin to model the chance of success in Mom saying yes to a party (Figure 4c), an assumption inherently made is that the coin is fair or the probabilities of a head and a tail are equal and equal to 0.5. Similarly, if one decides to use a simulator tool, it is important to specify the probability distribution and how it matches the assumptions in the problem (See Figure 4d "Simulation Model"). We also see in Figure 4b that teachers represented the process of combining all participants together and reassigning to groups for the *Dolphin Therapy* example.

Representations in Level/Tier 2 (Randomize and Repeat)

Teachers had very different ways of representing the process of generating a random sample of size n and computing a statistic, repeating this process k times, and collecting and displaying statistics from all k samples. To begin with, the notion of a random sample (or randomization process) was not always explicit. While posters in Figures 4b and 4e indicated random sampling, the poster in Figure 4c may have implied the random process by noting the "coin flip". The notion of a single sample of size n, repeated k times was also not always well represented. For the posters using a specific example (Figures 4b and 4c), the n that was noted in the pictures matched the problem context (n=15 in each group, and n= 5 responses from Mom). However, the teachers that drew or described a general process did not explicitly state the need for k samples of size n, though phrases such as "many samples" "high number" and the pictorial diagrams in Figures 4c and 4d implied a repeated process. As deliberately pointed out in the Lane-Getaz's (2006) diagram (Figure 2), "the samples of size n" are important to distinguish from k samples (often many) in sampling. Both n and k are critical parameters in designing and running a simulation, especially since they are often inputs required in software such as *TinkerPlots*.

All teachers explicitly or implicitly indicated that the simulation process including recording, collecting, and graphing a statistic of interest from each sample. However, the level of detail or pictorial representation of this process varied greatly. Since these diagram were meant for teacher to express a representation they could use to help their students understand this process, we were certainly left wondering whether they really understood the randomize, repeat and collect phase.

Representations from Level/Tier 3 (Empirical Sampling Distribution)

Seven diagrams included an image of an empirical sampling distribution in their diagram, with an exception shown in Figure 4d. Many also explicitly drew or indicated that the original statistic from the problem context should be located in the distribution (Figures 4a, 4d, 4e) and used to assess likelihood that the original statistics would occur under the assumed model of random selection or assignment. Only six diagrams explicitly indicated where to look in the empirical sampling distribution and how to estimate a probability (proportion) of the actual observed event by examining the tail(s) of the distribution (Figures 4a, 4b, 4e).

SUMMARY AND SUGGESTIONS

As we reflected on the diagrams constructed by our teachers and compared these with the diagrams for simulation processes discussed in research literature, we saw the need to propose aspects of a simulation approach that should be made much more explicit for learners and teachers. One major distinction we suggest is that more attention needs to be given to the modelling process. We feel that there is a two part modelling process that should be made explicit. This modelling process is similar to the emergent models that Gravemeijer (1999) purports can assist in transitioning from a real context to formal mathematics. The first is to create a local specific *model of* the real world context in statistical terms. The second is creating a *model for* the simulation process that can be used to generate random samples. The second model for the simulation process is more general because it can be applied to many problems. Most previous works have combined these two aspects into a single "model" or population level. We also suggest being more explicit concerning building a distribution of sample statistics, using the distribution to reason about the observed statistic, and making a claim about the chance of that observed statistic occurring. We encourage others to consider making explicit the following aspects:

Level 1. Population: Create a MODEL OF the real-world problem

- *Make assumptions to build a mathematical/ statistical model of the problem – determine a null hypothesis*
- *Specify the observed statistic and the statistic of interest*

Level 2: Simulation Model: Create a MODEL FOR simulation process

- *Choose appropriate tool(s) (physical/technological) for the problem that aligns with the assumptions made in creating the model of the real problem*

Level 3. Samples and Statistics: Randomize and repeat

- *Draw a random sample of same size n and record relevant statistic*
- *Repeat random sample k times (large number) and collect statistics from each sample*

Level 4. Empirical Sampling Distribution: Examine how statistics vary

- *Build a distribution for the recorded statistics*
- *Locate the original observed statistic in the sampling distribution*

Level 5. Final Decision: Making inferences from models

- *Use proportional reasoning to evaluate the likelihood of the event happened.*
- *Decide if the observed statistic and those more extreme are explainable by chance.*

We maintain that a simulation approach framework could help support scaffolding, and eventually abstraction, for how a simulation approach can be used for inference. It is also important for students to experience various models in specific situations. Such pedagogical approaches have been advocated for by many, and used successfully in work such as Garfield and colleagues (2012) and Podworny and Biehler (2014).

Analysing teachers' knowledge about sampling using TinkerPlots 2.0

Maria Niedja Martins[1], *Carlos Monteiro*[2] *and Carolina Carvalho*[1]

1 University of Lisbon, Lisboa, Portugal, marianiedjamartins@campus.ul.pt, cfcarvalho@ie.ul.pt

The conceptualization of sampling is crucial to understand statistical data. However, the teaching about sampling is not generally emphasised in school curriculum. This study investigated how teachers understand about size and representativeness of samples using TinkerPlots 2.0 software. The study was comprised of two sessions. A semi-structured interview and a familiarization about the basic use of TinkerPlots were developed during the first session, and participants engaged in three tasks on sampling using TinkerPlots during the second session. As a result, the teachers began to consider aspects of the variation of data to determine when representative samples were involved in TinkerPlots. The ability to select samples and analyse them seemed to contribute to improve their understanding about sample size and representativeness.

Keywords: Statistics education, primary school teachers, TinkerPlots.

INTRODUTION

The recognition of the influence of statistical data in the current society demanded the inclusion of this topic in national curriculum of many countries (Monteiro & Ainley, 2004). Several studies suggested that statistics education can provide bases to students develop abilities to argue and counter-argue information, understand the generation of statistical data and make informed decisions based on their analysis (Gal, 2002). Therefore, statistical knowledge is essential for critical reflective and participatory citizenship (Carvalho & Solomon, 2012).

An important knowledge that enables citizens to understand critically statistical data is related to conceptualization of sample and sampling. Bolfarine and Bussab (2005) conceptualize sample as any subset of a given population, and sampling as a technique of selection of such subsets. Innabi (2006) argues that in order to analyse the representativeness of a sample is necessary to know whether the sample is large enough and has the variety present in the population. It is recommended to increase the sample to ensure the variety of the population can be better visualized. However, sample sizes from a homogeneous population tend to be smaller, because such samples will have less variability.

To understand the conceptualization of sampling is crucial consider how the data were chosen, what methods are employed for the selection of these cases, what features and prioritized variables, so we can understand other contexts in which the information can be applied (Saldanha & Thompson, 2002; 2007). Therefore, the understanding about sampling seems to be essential as curriculum school content, therefore it is very relevant for teachers who teach statistics.

Although, the teaching about samples and sampling is fundamental to base the practices of statistics, it needs to be more emphasised in school curriculum (Watson, 2004). Recently, several studies investigated the conceptualization of sample and sampling among students from different levels. However, it is also important to investigate such situations among teachers who are going to approach such curriculum content (Martins, Monteiro, & Queiroz, 2013).

Several studies investigated the developing of understanding about sample and sampling using computer based tasks. For example, Manor, Ben-Zvi, & Aridor (2013) conducted a study that engaged students in designed instructional activities using computer modelling and simulations of drawing many samples. According to those authors, the research tasks enabled the students to think about sampling as a process when analyses are associated with samples.

Baker, Derry and Konold (2006) involved young students in two experiments about center and variation. In one of situations they used *TinkerPlots* (Konold & Miller, 2011) to develop a task in which students can get engaged in an inferential game. According to these authors "the inferential approach acknowledges that students with their teachers have to take part in the social practice of reasoning (p. 2)". When the students were comparing two distributions, they should realize that they needed of certain concepts to reach a conclusion on the distributions were different or not. The students could come to the conclusion that the concept of average was important to identify these differences. Therefore, the uses of certain concepts involved in a game of give and ask for explanations.

These studies suggest that it seems to be important the selection of several samples. The *TinkerPlots* offers the possibility to explore the relationships between data and chance (Konold & Kazak, 2008), since it is possible to perform simulations of samples and populations.

Delmas and colleagues (1999) used a computer environment in which the students could simulate several samples of different sizes and visualize the distribution of the values of a statistic. The results suggested that students indicated that larger samples should produce a statistical distribution similar to their population of origin. According to those authors it is possible that the students had the intuition that the average is a point within the population, and that gather more averages it will have a distribution very similar to the population.

In this paper we discuss some aspects of a study that investigated teachers' knowledge about sample size and representativeness. The aim of this study was to explore possible computer based tasks which can help teachers to understand those important aspects about the sample and sampling.

METHODOLOGY

This was a qualitative exploratory study that followed an interpretative approach. The research was conducted in a rural public school located of a municipality of Metropolitan Region of Recife (RMR), Brazil. The choice for this school was based on a survey conducted by GPEME - Research Group on Mathematics and Statistics Education (Carvalho & Monteiro, 2012), which identified 85 public schools in the RMR which had computer labs, and investigated how those labs were used.

There were two research sessions to collect the data. The first session was comprised of an individual semi-structured interview in order to have information about teaching experiences, as well as to identify their levels of understanding about the concept of sampling. The interview questions were based on a sample questionnaire used in the studies of Watson, Collis and Moritz (1995), Watson and Moritz (2000) and Watson (2004). These studies developed tasks associated with questions about sample, representativeness of small and large samples, sampling, and media news about sample surveys with inadequate statistical basis.

At the first research session, we also develop a familiarization with the *TinkerPlots2.0*. The researcher presented different functions of *TinkerPlots* to the teachers, including those to handle the database and produce graphs. This familiarization was carried out because the participants did not know about the software, and it was expected that they had certain autonomy to use the *TinkerPlots* during other research sessions.

The second session was comprised of three tasks using *TinkerPlots*. These tasks were about representativeness, size and type of sample. Therefore, in this paper due lack of space, we report examples taken only from analysis of task 1 and 2.

The study was developed with four female teachers. Due to lack of space in this paper, we report aspects of research data from one participant. For this report, her name was changed. Suzy was 30 years old, and she had 5 years of experience as a teacher. She uses the computer every day to search contents related to her teaching activities and to access emails. Suzy has university degree in Education. However, she said that never had any specific learning on sampling, and she did not know about *TinkerPlots* or other educational software for teaching Statistics. In this paper we do not discuss the data collected from the semi-structured interview.

Task 1

The aim of this task was to know if the participants understood that increasing a sample, could have better accuracy of inferences about the population, since the variability of the population would be better visualized.

Figure 1 shows a copy of screen with 625 cases (fish) of a *TinkerPlots* database called Fish Population. Each case had a numerical code, and information about the type and size of fish.

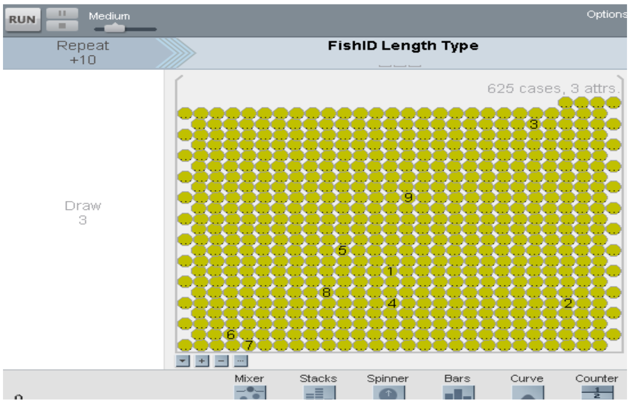

Figure 1: TinkerPlots Screen with 625 cases of Fish Population database

We asked the participant to read the following situation, which was based on the *TinkerPlots* resources:

> A certain fish farmer bought some genetically modified fish of a company with the promise that they would grow more than the non GM fish. In order to check whether GM fish grow more, the fish farmer joined GM fish with other fish that he used to have in a tank in which totalized 625 fish. After the total growth time of fish, the fish farmer gradually withdrew each fish from tank, and measured each one. From the data analysis in TinkerPlots, indicate which type of fish had greater length. Did the fish farmer make good deal?

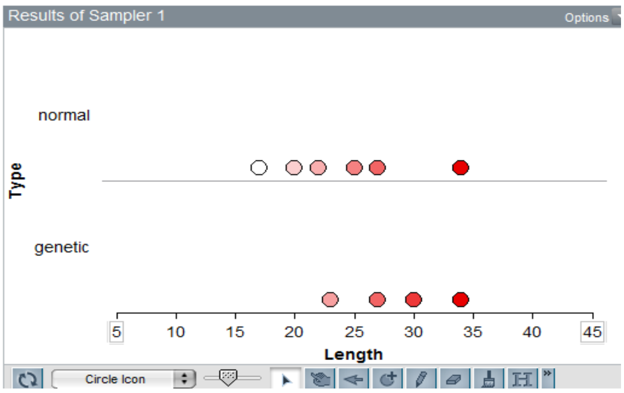

Figure 2: TinkerPlots Screen with fish population database, n = 10

During participants' analyses of task 1, we took initially samples from 10 cases, and then it was increased based on their indications. The participants should infer which population had bigger fish interpreting a graph similar to the Figure 2.

For each new inclusion of cases in the sample, we asked the participant to informally rate her confidence level in a scale from 0 to 10. Therefore, rate 10 should be teacher's maximum confidence. This procedure aimed to make explicit their understanding about changes on their own analyses (Prodromou, 2011).

Task 2

The second task was based two TinkerPlots databases: MysteryMixer1 and MyisteryMixer2, which were comprised of only one variable that is *number*. The Figure 3 presents a database used in this task.

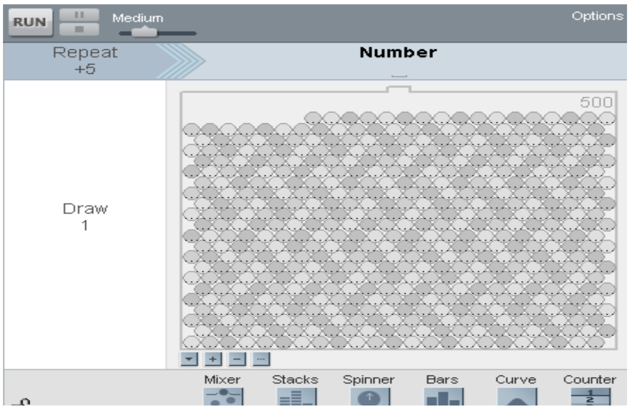

Figure 3: TinkerPlots Screen with MysteryMixer1 database N = 500

The database had 500 cases disposed in the simulator ranging from 0 to 100. This second task aimed to identify whether the teachers could reach a conclusion on a small sample. Therefore, the participants should identify clusters of samples and infer them to the population, using the smallest possible sample. To ensure this, we engaged the participants in a fictional situation about costs of sample survey:

> You have a limited amount of money to conduct survey on numbers. Each selection of five cases of this survey you should pay R$1,00. Your task is to identify a range in which all numerical values are repeated. You need to spend the least amount

of money possible, but you need to be quite sure about your answer.

In each task, the first author, acted as researcher asking questions to make more explicit the teachers' considerations about the data, and assisting them in the selection and manipulation of *TinkerPlots* tools.

The *Camtasia Studio 7.1* software was used to record on video the participants' speeches, their gestures and manipulations developed in the computer screen while solved Tasks 1 and 2. The transcriptions of audio records generated protocols which were base to the data analysis.

RESULTS

The analyses of participants' response suggested aspects of their understandings about the relationship between size and representativeness of samples.

Task 1

During the development of task 1, when we increased sample size the participants informally rated their level of confidence about their inferences. Table 1 shows the Suzy´s rates during this task.

Suzy gave a low confidence rate in their conclusions about small samples at the beginning of this task. The following extracts exemplify their arguments, when interpreting a graph similar to Figure 4.

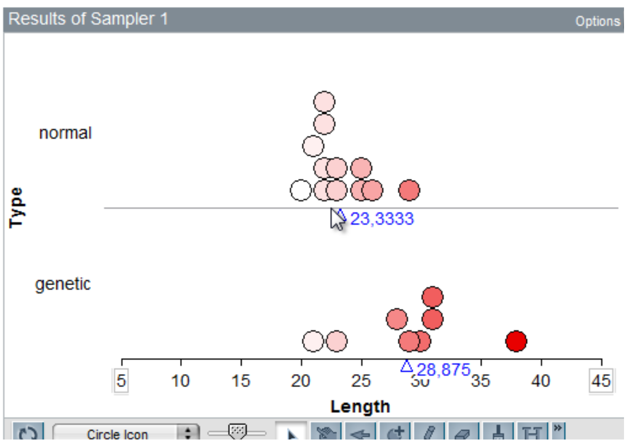

Figure 4: TinkerPlots Screen with fish population database, n = 20

Suzy: For me, this amount is not significant. It's because... well, the first time we had (a sample with) just over 2% (of the population) and now we have just over 3% (of the population). I think 3% is not significant value to buy something to put in a bowl and make a test. If so .. I would find significant 6% ... 10% ... just great! But to do a test ... to say ... (3%) I think very little.

Researcher: Right. But then, you see ... looking over here, can you observe who is showing a larger size?

Suzy: The GM.

Researcher: But, you are saying that perhaps this may not be significant for the rest?

Suzy: Exactly!

This fragment of Suzy's speech suggests that the teacher relates sample size to population size, and expressing that she considered the sample too small to make an inference. Suzy was unsure to make an inference, although that she identified a trend of genetically modified fish were larger.

Another extract from Suzy's protocol indicates that she was analysing the sample, and questioning the data variation in the samples, because she did not know the exact amount of fish for each population, since task 1 does not give this information.

Suzy: Does it [TinkerPlots] say the amount that it puts [in the sample]?

Researcher: No. It does not say the amount of one and another... whether it has more GM fish or normal ones. But, do you are absolutely sure that these here [GM] will continue growing?!

Suzy: It´s because, look... 12 and 8 [amount of fish for each type]. We do not know the amount per type of fish that he put here [in the population].

Researcher: What does that mean?

Suzy: That these results may change here because these data can be very different from there [population].

Teacher	S1	Confidence	S2	Confidence	S3	Confidence	S4	Confidence
Suzy	10	0	20	0	100	8	150	10

Table 1: Informal levels of confidence about the increasing of sample sizes

Suzy seemed to be concerned about possible errors due to small samples. We can infer that she was concerned about the variation, because only taking cases at random from the population would not ensure that the values of sample were identical to those of the population of origin.

In addition, Suzy developed the strategy of seeking patterns by analyzing the distribution of data and trends in the samples. This was reflected in her assigned increasing levels of confidence to her inferences, since Suzy could confirm in each sample a tendency on genetically modified fish to be larger. The need to use the concept of average also emerged, according to view in Figure 5. Suzy's response seemed to be influenced by the average value in the different samples:

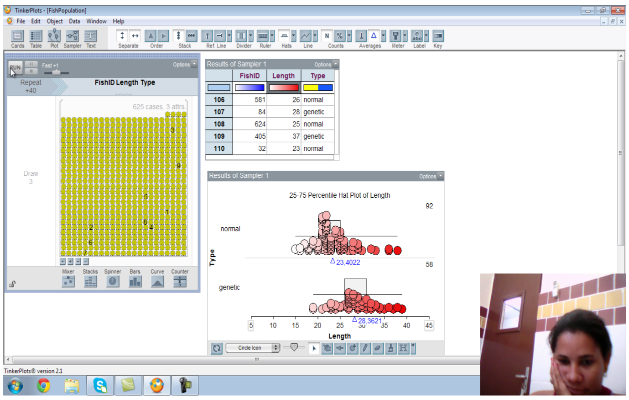

Figure 5: TinkerPlots Screen with fish population database, n = 150

Researcher: The average showed something to you?

Suzy: It shows that I'm correct! Because like this, it did not have changes. If the average had very fluctuated, there would be worrying. However, it remained constant to the extent that we have been getting more information.

Researcher: So it helped?

Suzy: It is. Now I have a 100% certainty.

Task 2

Suzy reached her answer with a smaller sample, and justify the response based on the idea of homogeneity of sample.

Researcher: Why did you find easy to say a response with lower number of cases?

Suzy: I think was because that issue of the group that I told you... because it was concentred in the group ... and ... don't know more.

Researcher: Concentred in the group? What do you mean?

Suzy: So... lets I say... don't know. I thought so... to the extent that we were taking... I thought, should not have 50%, then I was dropping, 25%. And with this there, I did far less than the percentage that I thought at first. And, to the extent that I was taking (cases from the simulator), and that I was doing, the concentration kept constant. Then, I did not need to take all this data, I had focused on to analyze a bigger percentage... I believe this happens because the information is contained like that, in that group. It is not one thing mixed. I think that's it. I just do not know to explain, but I understand.

Suzy's strategy to be able to generalize the results of the sample to the population focused on the analysis of the trend of data in successive samples. She quickly realized that the curve where was concentrated most of the data remained constant even when the sample grew and relied on it to provide a final inference.

Another strategy that also seemed important for Suzy to choose a representative sample was associated with hypothetical costs of sample. The following extract from Suzy's interview exemplifies how this aspect was relevant to her analyses.

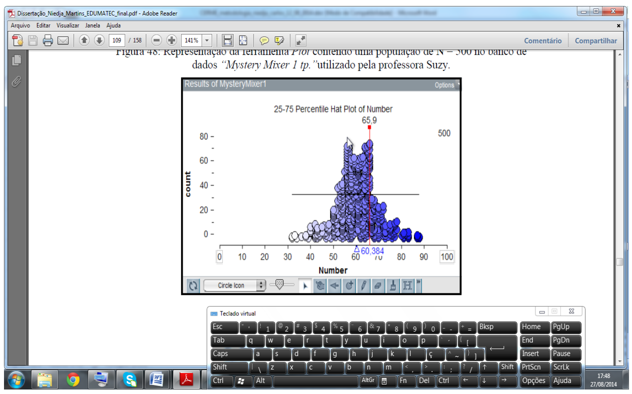

Figure 6: Graph produced by Suzy using MysteryMixer1 database

Researcher: [after show the graph with all cases according to Figure 6] Was close to what you said?

Suzy: I said 50 and 63. It was close!

Researcher: Were you pleased with your survey? With the amount you spent to give this approximate answer?

Suzy: Bargain, right?! [Laughing] So... Do you know one thing that I am worry about? In taking the part [sample], the bigger amount possible. And then, with the result, I can see that perhaps with smaller percentage, I could already tell you the answer. I could have been spending less because the sample was already confirming where it was [the cluster].

Suzy made inferences from 15 cases sample when she was interpreting the MysteryMixer2 database. The analyses of interview protocols suggested that this reduction was due to the fact that the teachers identify that the data of the samples were homogeneous.

CONCLUSIONS

The results of this study suggested that the teachers presented different ideas about sample when they analysed heterogeneous samples. This result corroborates the idea that the sampling involves different statistical concepts and ideas, and that inconsistencies of these notions can influence how a person perceives the representative samples.

In task 1, the analysis of variance of cases of homogeneous samples and the hypothetical cost to the sampling seemed to be the main influences on determining the appropriate sample size to make a final inference. One explanation for this result is the possibility that the teachers had to see the increasing of the samples and to compare the trends showed in *TinkerPlots* representations.

Therefore, the situations in which teachers can compare distributions may be potentially important to understand the tasks with the sampling; as seen in the study (Ben-Zvi et al., 2011) who found that the use of increasing samples can easily identify and recognize patterns representative established through comparison.

From the results of this study, further research is necessary to explore the autonomy of teachers to use software like *TinkerPlots* in order to build understandings of statistical concepts and also because teacher education in statistics software seems to have a gearing effect on eventual student learning of statistical ideas (Pratt, Davies, & Connor, 2011). In addition, it is crucial to investigate how this knowledge constructed from their interaction with software can motivate reflective situations to explore new ways to teach statistics.

Intuition about concept of chance in elementary school children

Jasmina Milinković

University of Belgrade, Teacher Education Faculty, Beograd, Serbia, milinkovic.jasmina@yahoo.com

The paper deals with initial development of stochastic reasoning in children. After short overview of the theories of development of stochastic reasoning, we focus our attention on intuition about probability. In the second part of the paper we report results of an empirical research on intuition about the concept of chance across grades 4th to 7th. The analysis of findings provides evidence of preconceptions about probability of undetermined events. These preconceptions are in conflict with formal theory but support Siegler's rule based model. We argue that we should take into account pupils' intuition about the concept of chance as well as other prerequisite mathematics concepts (fractions, proportions, etc.).

Keywords: Chance, intuition, Siegler's rules, stochastic reasoning, misconceptions.

INTRODUCTION

Probability is an area of mathematics contrary to math logic, paradoxical and counterintuitive (Kapadia & Borovcnik, 1991). How do we gain our initial understanding of events with uncertain result? How do we transform our initial conception of chance? Can we expect development of concept of chance despite of lacking opportunities to learn? We endeavoured to address these questions in order to find when the right moment is to introduce these topics in school curriculum. The early years of schooling in Serbian school system are considered as preliminary for empirical introduction of fundamental (and essentially abstract) concepts in mathematics such as relations, functions, equivalence, probability, and the like. The decision when we start to deal with a new class of concepts is associated with the decision on how we want to deal with them.

Our knowledge begins with experience. Experience provides basis for intuitive knowledge. Generally, intuition is expected to support (formal) learning. Kant notices that "... even our empirical knowledge is made up of what we receive through impressions and what our faculty of knowledge...supplies for itself (1929, pp. 41–42). Fishbein (1975) defines intuition as an autonomous cognitive activity based on individual experience. Intuition is general and immediate, which allows direct impact on the reasoning about situation. We can speak about two natures of intuitive reasoning in mathematics learning: the intuitive acceptability and intuitive anticipation. Intuition eligibility gives a sense of the sufficiency of the evidence of an assertion or obvious truth of certain facts.

The main aspects of intuitive knowledge about the probability of events are belief in the regularity of occurrence in the environment and (consequently) their predictability. Intuition is developed naturally as a consequence of experiencing the stochastic nature of the environment. Fischbein (1975) points out that humans need to rationalize and to predict leads us to search for regularities in phenomena. He noted that acceptance of intuition as a subjective conviction carries the conviction of self-proved (obviousness) and inner coherency. Chernoff (2008) discusses the dual classification of probabilities "belief-type" and "frequency-type". We may say that probability estimates are an expression of intuition about the relative frequency. In the case of intuition about the frequency of events, people tend to make judgments on the basis of time-limited past experience, which they estimate to be adequate.

Key theories about development of stochastic reasoning give us clues about appropriate time to start dealing with the concept of uncertainty. To begin with, Piaget and Inhelder (1951) claimed that at the operational level child finally becomes able to detect causal relationships that lead to the differentiation of unpredictable events. They recognize two sources of reasoning about probability: previous experience and mathematical constructions. Fischbein, on the other hand, believed that without formal education children cannot reach the operating concept of probability. He believed that intuition about probability is formed by the age of 14 or 15. Fischbein and his associates' study (Fischbein, Pampa, & Manzato, 1970) indicated a developmental leap of sixth grade pupils, but also the possibility of achieving a similar level of skills in younger trained pupils. Finally, Shaughnessy (1992) identifies four levels of conceptual development of stochastic reasoning linked to levels of formal mathematics education: (1) non-statistical level, (2) naive statistical level, (3) "on the horizon" statistical reasoning, and (4) pragmatic level. On the first level, reasoning is based on beliefs, deterministic understanding of phenomena, on causal inference or generalizations based of one case. The second level is characterized by conclusions using various heuristics such as representativeness, availability as well as by shifts in thinking about randomness and chance. The next level of reasoning is achieved when person has ability to apply normative models on simple problems, identify differences between reasoning based on intuition and on the basis of a mathematical model as well as knowledge of different mathematical representations of the concept of chance. Finally, the pragmatic level implies deep understanding of the mathematical model, the possibility of comparing different representations, the ability to apply a normative model and knowledge of the limitations of individual stochastic models.

Along the line of Piaget's theory comes Siegler's "rule-assessment approach" to cognitive development. His research encompasses the development of stochastic reasoning. (Yet, unlike Piaget, he does not advocate across domains cognitive developmental levels.) Siegler claims that cognitive development may be described as "acquisition of increasingly powerful rules for solving problems" (Siegler, 1981, p. 3). According to him, children first generate a series of alternative rules based on rational task analysis, previous empirical work and similar activities. Next, a set of problem types yields to patterns of correct answers and errors for children following each of the rules. Finally, if there is a theoretical prediction for a certain type of comparable problems, the asynchrony may be identified and cause changes in reasoning. Scholz (1996, pp. 301–302) reflects on Siegler's study which included variants of card games and drawing an object from the urn. He reports on Siegler's description of the pathway of cognitive development through process of decision making primarily based on implementation of (new) rules. There were four rules: 1) always choose urn with a larger number of favourable outcomes, 2) if the number of favourable and unfavourable outcomes are the same, elect the urn with fewer unfavourable outcomes, 3) the difference between the number of favourable and unfavourable outcome is calculated for each urn and the one with the greater difference is selected, and 4) the ratio of favourable and unfavourable outcomes is the election criteria (Scholz, 1991, p. 246). The rules were determined in relation to the dominant dimension of a favourable outcome and subordinate dimension of adverse outcomes. The researchers noticed that pre-schoolers only applied the first rule while the children in the lower grades applied the fourth rule and less the third rule while completely ignoring the second rule. Generally, the predictions of the respondents from 3 to 20 years, agreed with the first and fourth rule.

Initial research in the area of development of probabilistic reasoning dealt mainly with intuition, including misconceptions that we have about uncertain events as a result of growing up (not education). Here, we mention the research of Piaget and Inhalder (1951), Tversky and Kahneman (1982), Fishbein (1983), Green (1982), Hawkins and Kapadia (1984), and Nisbet and Williams (2009). Unlike, Kazak and Confrey (2006) for example, who claim that the results of their study conducted among 9 year old children supports the idea that confronted with various tasks with "chance settings" children could develop a quantitative perception of probability. In recent review of the research in probabilistic reasoning Schlottmann and Wilkening conclude that the contemporary research move boundaries for understanding concept of probability for earlier ages prior to instruction but does not provide understanding of the implications of these preconceptions (Schlottmann & Wilkening, 2011). Our paper offers a small contribution in this matter.

METHODOLOGY AND RESEARCH FINDINGS

The study was conducted among pupils in Serbia, where no probability and statistics topics has been a part of the state curriculum for elementary schools. Our research sample consisted of 392 children, Grade 4 to 7 (11 to 14 year old). We have observed lessons in 16 classes in 3 different school. All three schools are located in the centre of a large city (with about 2 million inhabitants) and a short distance away. Schools were selected based on the principle of similarity of children population, to eliminate factors of education or lifestyle that may have an effect on the intuitive understanding of statistical concepts of interest to us. The fact is that this population may be described as prone to reading the daily newspapers or watching shows on TV (which often use statistical data). The study was performed in regular classes and respected regular composition of classes. The teachers used lesson plans developed by researcher. The researcher made field notes during the lessons. The researcher and the teacher had meetings to discuss what was happening in the classroom.

Students observed and analysed through class discussion different situations that might provoke thinking about the concept of chance. Here, children were prompted to express their beliefs about simple game like situation with undetermined result. In the activity which is in focus of this paper, pupils discussed how likely is to get a red cube out of the boxes containing red and white cubes.

The teachers were expected to probe pupils' intuitive reasoning about chance. Their role were of a moderator. The teachers were not supposed to provide theoretical background, give correct answers or leading clues. They asked pupils either to conduct an experiment and analyse the data or to study a scenario describing results of this experiment.

There were three boxes with different numbers of white and red cubes. In the first one, there was 1 white and 1 red cube. In the second box, there were 9 white and 1 red cubes, and in the third, 2 white and 2 red cubes (Fig 1).

Box	Content
First box	□■
Second box	□□□□□□□□□■
Third box	□□■■

Figure 1: Three boxes

We quote and analyse pupils' logic during class discussion. The discussion started with the experiment of pulling a cube from the first box containing 1 red and 1 white cube.

Teacher: What do you think, which colour you are going to get out of the first box?
Milos: I'll get red because that colour is in charge.
Olga: I'll get red because I have to get it.
Angela: Red, it's a beautiful colour.
Goran: I think I'll randomly draw a white.
Jovan: We're sure to a draw some.
Zoran: I think I'll pull the red one, although the chances are fifty-fifty.

Milos, Olga and Angela considered that red was supposed to happen because of their desire to get a red cube. It could be discerned that those children believed that they somehow could affect the result of the pull. We could identify non-statistical level of reasoning among substantial number of children. Zoran and Goran apparently were aware of concepts such as "randomness" and "(equal) chance" but it did not prevent them from having "non-statistical" judgments. Significantly, we could observe confusion between what they believed and what they thought they were supposed to say. Successively, the same question was posed regarding the second and the third boxes. Children's judgments about the second box with 9 white and 1 red cube showed more sophisticated statistical views of children.

Ksenia: White, because there are more whites.
Luka: I'll get white. There are many more (white cubes), and they are more likely.
Obrad: I will pull both colours. Maybe I'll draw some more, but you never know that.
Danko: If we pull a cube for fifty times from the first box we could get, for example, 3 red and 47 white cubes, because anything is possible.

Ksenia and Luke ground their expectations in the principle of "the more favourable outcomes, the better chance." (Siegler's Rule 1). Unlike them, Obrad reasoned that the result of next drawing could not be predicted. Even more, he stretched his conclusion as he stated that "we cannot talk about any predictions what so ever." He was not the only one who believed in that. Danko, had similar thoughts about impossibility to predict results. Pupils who conducted the experiment, by the time of dealing with the third box, have already begun to change their opinion about the predictability of the outcomes on the basis of their experience with two prior cases. Some pupils simply concluded that they could not predict what they were going to get in the next trial.

Finally, teacher asked pupils to compare the chances to draw a white cube out of different boxes. Most children thought that the chance to get out red cube from the first box is bigger than from the second box (as if using Siegler's rule 2, comparing the number of unfavourable outcomes). But, then came the challenge of comparing chances to pull a red cube from the first box and the third boxes.

Marina: It's the same thing.
Mitar: Fifty, fifty. (No explanation what this means).
Goca: It is the same as 1 to 1 and 2 to 2.
Janko: Similar.
Jovan: They are approximate (numbers).
Milan: It is more likely if there is two plus two cubes.
Uros: The number of cubes in the box is important.

Note that pupils learned about equivalent fractions and about proportions in the 5th Grade, prior to this study. Goca was a 7th grade pupil (age 14). Similarly to Marina and Mitar, half of 7th grade class agreed with Goca that 1:1 and 2:2 are the same. But, the rest of children have not been convinced that the chances were the same. Milan's and Uros's answers prompted us to continue discussion. Younger pupils, from the 4th grade, were prone to offer incorrect answers. The teacher was provoked by these answers to test pupils' belief.

Teacher: Suppose you are offered a reward if you pull a red cube. Which box would you like to be given, the first one or the third one?
Janko: It is easier to draw a red cube from the third box because it had two cubes. And to me it would be easier.
Igor: I would like (to pull out of) the third one. Chances are bigger in the third. Because, there are twice more.
Dragana: The chance to win as well to lose are doubled when pulling from the third box.
Janko: It is easier to pull out a red cube from the first box because there are only two cubes in the box.

Only a small number of pupils thought that it does not matter whether it is drawn from the first box or from the third box. In the process of making judgment, the most common way of reasoning was similar to Igor's response, favouring the box with more favourable outcomes which is in accordance with Siegler's rule 1. But Janko used modified Siegler's rule 2 to pick a case with smaller number of unfavorable outcomes. We should mention that the teacher extended discussion to better understand pupils' perception. Somewhat surprisingly, pupils did not change initially opinion after prolonged discussion. For example, after Igor's response, the teacher inquired delicate questions.

Teacher: But there are also two white cubes in the third box. Does it matter to you?
Igor: No.
Teacher: Ok. If you are promised to get a reward if you pull a white cube, would you like to pull a cube from the first or from the third box?
Igor: From the third one. There are more whites in it, too.

When comparing the first and third case, most pupils agreed with Igor. Again, they followed up the Siegler's rule 1, comparing the number of favourable outcomes.

CONCLUSION

We have acknowledged in this study the existence of intuition about concept of chance in elementary school children. The episodes we have chosen to present demonstrated that pupils from age 11 to 14, have had formed certain preconceptions (and misconceptions) about chance, prior to any instruction. We remarked that pupil's answers indicated different levels of primary intuition of phenomena with an uncertain outcome. Our study provides evidence that such intuition develops regardless of lacking content matter in formal learning. The preconceptions about chance are in conflict with formal theory but partially support the Siegler's model of intuitive reasoning about chance. Our analysis unveiled that most of the time children displayed non-statistical level of reasoning or tended to rely only on Siegler's rules 1 and 2. Their preconceptions led them toward the simplest and naïve analysis of the "chance situations". The findings allow us to conjecture that grasping other mathematics concepts (such as fractions, proportions, etc.) are considerably important for understanding probability. The mastery of these concepts could influence children's advancements in formal stochastic reasoning and therefore should happen before learning about stochastic reasoning. The design of our study did not provide conditions for deeper analysis of pupil's preconceptions (as would e.g. one-to-one interview with a particular child). But we believe that pupils' preconceptions should be accounted for when planning initial formal learning of the concept of chance. Our proposal should be examined further.

Making sense of statistical and probabilistic information in the media texts: Pre-service teachers' critical thinking processes

Mehtap Ozen and Erdinc Cakiroglu

Middle East Technical University, Faculty of Education, Ankara, Turkey, ozmehtap@metu.edu.tr

This study aimed to investigate the critical thinking processes that pre-service middle school mathematics teachers utilize when they intensely engaged with the media text based on statistical and probabilistic information. Data were collected through in-depth interviews with four pre-service middle school mathematics teachers in a public university. The findings of the study pointed out that pre-service middle school mathematics teachers progressed through different critical thinking processes, including comprehending, making connections, inferring ideas, critiquing, and self-reflecting about the information given in the newspaper article.

Keywords: Critical thinking, statistical literacy, media texts.

INTRODUCTION

Probability and statistics are regarded as the domains interrelated with critical thinking, which has a crucial role in scientific and social contexts, especially in newspaper articles. Newspaper articles present statistical results about various social and scientific issues such as health, finance, education, and culture and address these results by using numbers, probabilistic statements, or representing them with graphs or tables. Journalists or researchers, however, may release misleading information or use vague language of probability and statistics. To cope with such misleading information, people should make sense of probability and statistics in these contexts and think critically about them (Gal, 2004; Watson, 2006).

In the school context, most of the students do not have enough knowledge of statistical concepts to interpret media texts and blindly adopt one's one-sided ideas or information without questioning, which could prevent them to make efficient decisions about their life (Watson, 2006). To help students in this sense, teachers themselves need be able to think critically about such information. However, teachers' lack of knowledge, as well as lack of critical perspectives could be an obstacle in providing such a help to students (Watson, Callingham, & Nathan, 2009). In mathematics teacher education programs, pre-service teachers complete statistics and probability courses. However, such courses do not usually stress critical use of statistical and probabilistic information in the contexts beyond the school. In this sense, this paper reports an investigation of pre-service mathematics teachers' uses of critical thinking processes to make sense of statistical and probabilistic information when they intensely engaged with a media text.

Critical thinking was conceptualized by various researchers (Ennis, 1985; Facione, 1990). Ennis (1985) defined critical thinking as "reflective and reasonable thinking that is focused on deciding what to believe or do" (p. 45) and conceptualized as a combination of certain cognitive skills (e.g., judging the credibility, analyzing arguments, drawing conclusions, or clarifying ideas) and dispositions toward critical thinking (e.g., being disposed to open different alternatives, to be informed, or to search for alternatives). In a further study, Facione (1990) worked on the conceptualization of critical thinking by forty experts in this subject. These experts had a consensus on two dimensions of critical thinking; cognitive skills (interpretation, analysis, evaluation, self-regulation, inference, and explanation) and affective dispositions (truth-seeking, open-minded, analytical, systematic, confident in reasoning, inquisitive, judicious). In the project of Jones and colleagues (1995), the framework proposed by Facione (1990) was reviewed by faculty, employers and policy makers to decide which aspects of critical thinking are more important for college students. The conceptual frameworks of critical thinking proposed by Facione (1990) and Jones and colleagues (1995) could be applicable to various subject matter domains and contexts (Ten Dam & Volman, 2004). In the current study we made use of their frameworks as a starting point and a baseline in order to identify indicators of critical thinking processes in the data obtained from in-depth interviews through which the participants were intensely working on a media text that involve statistical and probabilistic information. It is important to note that we focused on the cognitive dimension of critical thinking rather than affective dimension in this study. Previous studies pointed out that critical thinking is transferable to different subject matters or contexts. On the other hand, it is a challenge for teachers to enable their students to transfer such critical thinking processes to the contexts beyond school. To provide transferability of critical thinking, newspapers or other media texts could be used in teacher education programs (Halpern, 1998). In the context of statistics, recent research suggested to use tasks that require thinking about complicated educational issues (Osana & Seymour, 2004), newspaper articles (Watson, 2011); tasks that require statistical literacy based on infusion approach (Aizikovitsh-Udi & Kuntze, 2014). In line with these studies, the current study investigated pre-service mathematics teachers' uses of critical thinking processes while intensely working on a media text that involved statistical and probabilistic information.

METHOD

Participants

The study was conducted with four pre-service middle school mathematics teachers in the fourth year of Elementary Mathematics Education Program (EME) of a public university in Ankara, Turkey. The EME program is a four year undergraduate program in which the enrolled students are trained to be mathematics teachers of grade levels 5 to 8 in middle schools. In this program, courses named "Introduction to Probability and Statistics" and "Research Methods" are required for all students. Participants were selected among 38 pre-service middle school mathematics teachers in the fourth year. Participants were selected on the basis of their potential to provide rich data. To select the participants, all of the fourth year students were given a newspaper article that was not used in the main study and were asked to write down a critical reflection about the statistical information in it. The participants were selected randomly among the ones who could produce significant reflections, had tendency to use valid quantitative procedures and mathematical language, as well as could detect points to criticize in the article.

Data collection

The major data source of the study was in-depth interviews. Participants were asked to read the newspaper article about cheating partners, claiming men are better at detecting a cheating partner than females. It was published in the Mercury newspaper in Tasmania ("Cheat radar better tuned in men, study finds", 2008) and proposed by Watson (2011) to be used in educational settings. The newspaper article includes some probabilistic and statistical statements that participants may pay attention while trying to make sense of the given results (Table 1). During the interviews participants were asked to think and reflect about the following main questions: What is the main idea of the newspaper article? What conclusions did researchers reach? What conclusions could you draw from the text? How could the researcher conduct the study reported in the newspaper article? (e. g. how to select sample, how to collect and analyze the data, how

Statement 1:	The results, published in New Scientist, show 29 per cent of men admitted they had cheated compared with 18.5 per cent of women.
Statement 2:	Researcher Paul Andrews said men were better at judging fidelity than women. 'Eighty per cent of women's inferences about fidelity or infidelity were correct, but men were even better, accurate 94 percent of the time' Dr. Andrews said.
Statement 3:	Men were more likely to catch out a cheating partner, picking up on 75 per cent of the reported infidelities compared with 41 per cent discovered by women.
Statement 4:	Men are better at detecting a cheating partner than females, and they are more likely to suspect infidelities that do not exist.

Table 1: Some of the probabilistic and statistical statements in the newspaper article

to reach reported findings) How would you evaluate reported findings? What do you think about generalizability of the reported statistics in the newspaper article? In addition, they were asked what they understand from four probabilistic statements in the newspaper article (Table 1). The duration of each interview was approximately forty five minutes and interviews were audio and video-recorded. Data were collected in the 2011–2012 spring semester.

Data analysis

The data were coded in order to identify expressions of the participants that indicate their critical thinking process. To determine possible indicators of critical thinking, we made use of the frameworks of Facione (1990) and Jones and colleagues (1995) as a starting point and a baseline in order to identify indicators of critical thinking processes in the interview data. To be precise, data were analyzed and searched for instances and processes in their thinking by making use of the frameworks suggested by Facione and Jones et al. as a base line. In some cases, certain dimensions of these frameworks could not be completely matched with any part of the data in this study. Thus, to make the dimensions of these frameworks more suitable with our data, we adapted and restated them as the data codes and categories of the current study, without making major alterations in their conceptual meaning. For example, the critical dimension of "explanation" in the original framework of Facione was excluded in the current study, since it was not observed in the data. On the other hand, other dimensions of critical thinking such as interpretation, analysis, evaluation, and self-regulation were included, but revised and their explanations were restated to make them more suitable with our context. As a result of data analysis, five interrelated processes of critical thinking were identified (Table 2).

FINDINGS

Critical thinking about the bases of reported findings in the newspaper article

Bases of reported findings refer to the background of the study in the newspaper article, some of which are not explicitly given in the article such as selection of sample, data collection, data analysis, or reporting of the findings. Such information about the article was one of the dimensions that the participants reflected critically. They mostly attempted to use critical thinking processes of comprehending, critiquing, and self-reflecting. Regarding sampling, one participant (Ali) recognized the essential role of the sample and the need for sample to be representative in critiquing credibility of the study. He interrogated the extent to which sample size of the study is enough to make accu-

Comprehending
Identification of the main idea of the text (e.g. identifying extraneous ideas in the text)
Organization of the contextual information (e.g. making use of graph, diagram, or table to organize the contextual information)
Clarification of the information (e.g. defining the ambiguous or vague terms)
Making Connections
Examining link between ideas (e.g. identifying closely related statements)
Identification of claims or arguments in the newspaper article (e.g. determining whether author states reason for supporting his claim)
Inferring
Examining evidence (e.g. seeking the background information or issue that needs to be addressed)
Proposing alternatives (e.g. suggesting plans with the consideration of their pros and cons)
Drawing conclusions (e.g. figuring out new meaning by making use of clues)
Critiquing
Detecting misleading information (e.g. detecting inconsistencies or author's exaggerated generalization)
Recognizing factors of credibility (e.g. appreciating sufficiency of information such as sample, data collection, or analysis processes)
Self-Reflecting
Expressing one's own strengths and weaknesses of own thinking process (e.g. rereading sources to make sure that one has not overlooked important information; ask themselves questions about their beliefs or attitudes)
Making corrections or revisions when they realized their mistakes or misunderstandings

Table 2: Indicators used to code critical thinking processes of the participants

rate inferences about the study. He tried to support his evaluation by considering possible effect of extreme values in the data of a study with small sample size on drawing accurate conclusions from the data. On the other hand, the other participants just restated sample size of the reported study.

Regarding data collection, all participants focused on the issue of what was measured and how it was measured by clarifying the questions that were asked to the subjects of reported study. Meltem, for example, attempted to clarify question of "whether they [subjects in the study] had ever strayed" reported in the newspaper article, stating "...I mean, thinking of cheating in the past, [I thought that it was] a question such as 'Have you ever cheated?' The article could have just said like this: the young couple could have been informed that this study was about their current relationship." She stipulated the condition of "current relationship", which makes the meaning of question narrower and removing the ambiguity of the question that might lead readers to think about subjects' current relationship or relationships in the past. It was only Ali, who reflected a different critical thinking process by critiquing misleading statement in the newspaper article, stating "Are men better confessors or do men deceive [their partners] more, it is unclear, some might deceive [their partners] and say they didn't; that's why, I think this may not give an idea about who deceives more." He thought about the validity of the argument of "29 per cent of men admitted that they had cheated compared with 18.5 per cent of women" in the newspaper article with the consideration of the possible bias in measurement in which subjects might give misleading information about cheating of their partners.

Another finding was that all participants were in the process of comprehending by rethinking the categories in the article while considering about data analysis procedure of the study in the newspaper article. İrem was thinking about one of the statements in the newspaper article; that is "Eighty per cent of women's inferences about fidelity or infidelity were correct, but men were even better, accurate 94 per cent of the time."(Figure 1). By this table she analyzed women's incorrect inferences about their partners' fidelity. In this process, she organized the possible conditions to comprehend how the researchers could reach to the conclusions reported in the newspaper article and related raw data to percentages as a summary statistics.

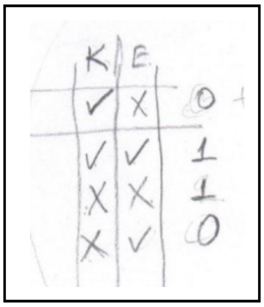

Figure 1: İrem's organization process regarding data analysis

Another finding was related to participants' thoughts about results or conclusions reported in the newspaper article. While thinking about the main idea of article, they did not raised any concern about the results in the article that presents only correct inferences of men and women. They restated the statements in the newspaper article as the main idea of the text and did not consider men or women's wrong inferences about their partners, which do not exist in the article. Moreover, while thinking about the results of the article, all of the participants attempted to critique the results in the article. However, their judgments were mostly subjective. Melek, for example, recognized the difference between the results given in the newspaper article to determine the reliability of the results or conclusions:

> If numerical data are compared, it was found that 80 of women's inferences were correct but 94% of men were right in these inferences. There is 14% difference; below [pointing the last paragraph of the article] there is much higher difference. It can have a difference of 75%; in the other one it can detect 41%, so that's why I thought the test is really reliable.

She assumed observed differences in the results are large enough, especially in the case of numerical values of 75% and 41%, which are given in the statement of "Men were more likely to catch out a cheating partner, picking up on 75 per cent of the reported infidelities compared with 41 per cent discovered by women." in the newspaper article. However, her judgment was subjective, indicating she might not be aware of statistical and practical significance of the results reported in the article. Supportively, in the process of critiquing of results and conclusions, two of the participants made self-reflection by reflecting their own thinking processes. Melek, for example, explained her subjective assessment in deciding if the study is reliable or not in the following:

> [...]when assessing the test, I think I'm adding my own opinions a little too; but, for instance, when considering its reliability, I'm looking at the claims made at the beginning and the numbers below, I'm comparing them. So even if I am not doing calculations, may be because it fits my line of thought a little, I mean I believe in it more.

In summary, regarding the background of the study in the newspaper article, participants were mostly in the processes of comprehending, critiquing, and self-reflecting. During these processes, they mostly focused on the existing information (e.g. sample size and questions asked to subjects in the study) in the article. Only few of them attempted to interrogate information about the background of the study, which does not exist in the newspaper article.

Critical thinking about the reported statistics

This part includes participants' critical thinking processes about descriptive or summary statistics (percentages and probabilistic statements), which already exist in the newspaper article. Participants reflected different critical thinking processes such as comprehending, making connections, inferring, and self-reflecting. One of the main findings was that participants dealt with clarifying the meanings of Statement 2 and Statement 3 (see in the data collection part of this study). For example, İrem had confusion with the meaning of "fidelity" concept and tried to define the terms of fidelity and infidelity:

> I think I don't know the meaning of the concept 'fidelity'. I can't distinguish these two conditions [Statement 2 and Statement 3]. I think predicting [fidelity] correctly means when they say that they don't think their partner cheated on them and actually they [their partner] hadn't; and predicting infidelity correctly means when they say that their partner definitely must have cheated on them and their partner had done so.

After developing an idea about these terms, she reasoned through proportionality and calculated the number of female and male who made correct inferences about her/his partner's fidelity or infidelity, stating "162 women predicted correctly whether or not their partner cheated on them. And I understood that 190 men accurately predicted whether their partner cheated on them." Although she expressed her difficulty understanding the difference between Statement 2 and Statement 3, she did not make clear the difference between them. When asked what she understood from the Statement 3, she stated "41 per cent of 203 couples; so, 83 women detected that their partner cheated on them.", which can be considered as an evidence that she did not recognise the condition of cheating immediately. After that, she realized Statement 1 in the newspaper article, which gives information about the number of people cheating their partners. She made connections between two related statements (Statement 1 and Statement 3). In this process, she overviewed the newspaper article and read statements again if she overlooked anything, which can show us her self-monitoring process. Then, he corrected her mistake, stating "men noticed 75% of the cheatings done by their partner. I mean, it seems that 75% of cheating partners were noticed". Surprisingly, Ali and Melek have such a recursive process of thinking in a similar way.In addition, during this process Ali and İrem constructed a table or diagram to organize the findings of the study reported in the newspaper, which also shows their making connections among reported statistics in the newspaper article. On the other hand, Melek and Meltem could not go further, which could be due to the fact that they could not make explicit the differences between the statements in the newspaper article, especially Statement 2 and Statement 3 whereas Ali and İrem advanced their categorization of the reported findings by examining closely related statements and drawing new conclusions from the newspaper article (see Figure 2).

Another finding of the study was that they had difficulty in detecting misleading statements in the newspaper article, especially regarding Statement 4, which require understanding of the conditional probability. For example, İrem tried to critique the Statement 4, which is "Men are better at detecting a cheating partner than females, and they are more likely to suspect infidelities that do not exist". In this critiquing process, İrem dealt with the clarification of the Statement 4. She proposed two alternative meanings for the concept of "being suspicious": Male/Female says that his/her partner is cheating, Male/Female says that his/her partner is cheating when his/her partner is not cheating in real world. The ambiguity about the meaning of this concept and having difficulty in conditional probability might have prevented her to draw an improper conclusion about Statement 4 and partially critiquing it, stating as "I think it [Statement 4] is wrong...1.4% [3/203] and for women, 2.8% [6/203].

I think this is the opposite of [Statement 4]. If we consider the first meaning [Male/Female says that his/her partner is cheating], it becomes true…it depends on the meaning of "being suspicious". If we think the second meaning that I believe in, women are more suspicious, that is, anyway women are suspicious unnecessarily."

Critical thinking about the generalizability of the reported findings

During interviewing, participants were encouraged to think about the generalizability of the reported findings. While thinking about this issue, all participants attempted to critique the arguments reported in the newspaper article with recognition of relevant factors to determine if it was generalizable to population or other similar contexts. In this process, they differ from each other by focusing on different factors such as sample size, sampling method, and cultural factors. Two participants (Ali and İrem) also reflected the process of inferring (examining evidence) regarding what background information about sample characteristics needs to be addressed to critique generalizability of the reported findings. For example, İrem discussed generalizability as following:

> Well, I don't know if 203 couples are enough. I don't think it can be generalized. My usual opinion, you can't imagine something big from a small sample. If I ask each of the 203 men or if I get 58 men, in this case, will only 23 of 58 of all their wives predict correctly? It seems that this will not be correct all the time…You know, different results will be obtained from different samples; well, here the 203 couples don't have any characteristic features anyway. I mean, where do they live, in which country, I don't know how long they have been married; maybe there are many influential factors. It has only mentioned that they are young couples […]

İrem was not sure about to what extent sample size is sufficient for generalizability from deterministic point of view, stating "you can't imagine something big from a small sample." Conversely, Meltem made somewhat immediate comments regarding generalizability and did not provide enough evidence to support his evaluation. She considered factor of the sample size of the study enough to generalize the conclusions and tended to relate the generalizability of the study to the clear presentation of the findings in the newspaper in the following quote:

> 203 is actually a good number; in statistics when we, for example, carry out a study, we say it's a good result when it is over 30, or 100, for instance. Well, 203, compared with that, is good, that's why…it can be generalized because everything is clear […]

In summary, all participants attempted to critique findings in the article when they were asked to think about the generalizability. However, they did not reflect comprehensible reasoning to make sound assessment about the generalizability.

FINAL REMARKS

One of the main conclusions arising from this study is that pre-service mathematics teachers mostly focused on the existing information rather than on the missing or misleading information in the newspaper

İrem	Melek	Ali

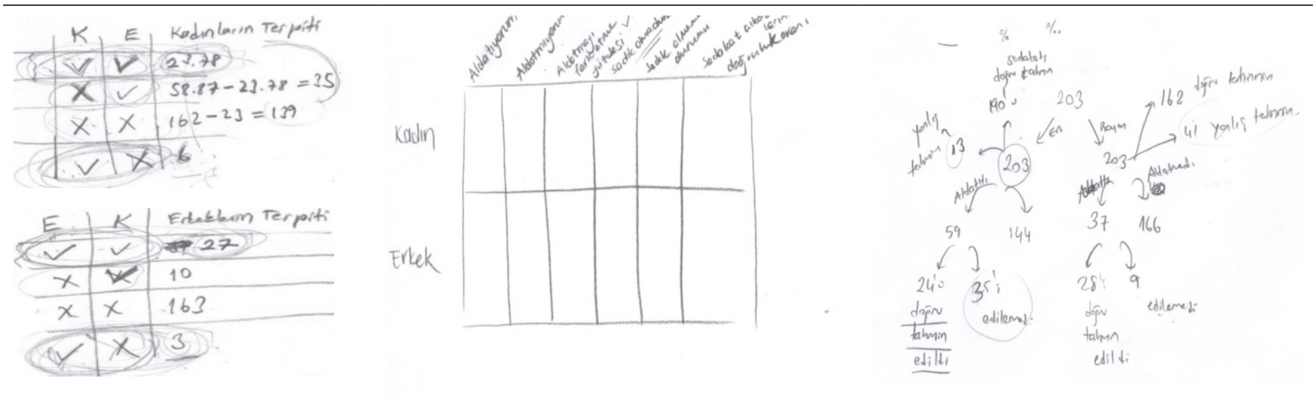

Figure 2: Three participants' thinking processes about the reported findings

article, which might have prevented them to detect one-sided arguments (Watson, 2006). Moreover, they mostly attempted to comprehend the statements in the newspaper article by clarifying their meanings and make immediate comments or overgeneralizations like "it is good" or "the results of the study is generalizable" without enough evidence to support their ideas, which contradicts with the nature of critical thinking that requires skeptical thinking, and inquiry on the basis of evidence (Facione, 1990). Another important conclusion is that they had difficulty in comprehending conditional probability statements, which might prevented them to make appropriate inferences and critique the reported findings in the newspaper article. These results are consistent with the findings of Ozen and Cakiroglu (2013). This indicates their lack uses of critical thinking processes regarding conditional probability in the media texts even though they have already studied about this concept in their statistics courses. This study contributes to our understanding pre-service mathematics teachers' engagement in the media contexts, which might lead us to reconsider the content of statistics courses in the teacher education programs regarding how these courses really address the issue of uses of critical thinking processes regarding the statistical and probabilistic information in real life contexts. Media texts could be used as a mediator to contribute their critical thinking process in designing of statistics courses in which they could be encouraged to think about both proper and improper examples of newspaper articles about diverse topics, rather than just focusing on the computational procedures.

An interview study on reading statistical representations in biology education

Christine Plicht, Markus Vogel and Christoph Randler

University of Education Heidelberg, Heidelberg, Germany, plicht@ph-heidelber.de

In an interdisciplinary research project of mathematics and biology it is focussed on how graphs, charts and diagrams are used in biology classes. The aim of this research approach is to get a better understanding of how students read statistical representations used in biology schoolbooks. Therefore, an interview study was conducted. In this paper the theoretical background and some empirical findings of this study will be presented. The results refer to the reading activities of students and yield a concept of reading comprehension which contains influencing factors that were identified. The paper concludes with a discussion of the results and a short outlook on following steps of the research project.

Keywords: Reading statistical representation, interview study, statistic education in biology.

INTRODUCTION

Graphs, charts and diagrams are omnipresent in everyday life, but also in classrooms a main tool to illustrate relations and structures. Reading and creating graphs is an essential part of mathematics education and it demands semantic and syntactic requirements, for encoding the information given in the representation and to engage the context of it. Students have to focus on syntactic requirements and necessaries like: What are the necessary parts of graph or diagram? How to read the data points? Which conclusions can you draw from it? But not only in mathematical lessons this kind of representation are used and you can also focus more on semantic aspects than concerning about the syntactic elements. For example biology uses diagrams as an instrument to visualize data and context specific correlations of biology (Kattmann, 2006). Therefore, there are curricular requirements to illustrate data on measurable parameters with linguistic, mathematical or visual design elements (e.g., KMK, 2005).

The project "Statistische Representationen im fachübergreifenden Unterrichtskontext von Mathematik und Biologis" (engl. "statistical representations in an interdisciplinary approach of mathematic and biology in school") at the University of Education in Heidelberg aims to explore the use of statistical representations at the interface between mathematic and biology. The interview study that is described and discussed in this paper is one of three steps to the analysis of reading comprehension of graphs, charts and diagrams being used in biology education in schools. Preliminary there was an inquiry on statistical representations in schoolbooks resulting in a classification on charts, graphs diagrams. A summary will be presented before the paper focuses on the interview study. Afterwards there is a short outlook on the last step of the project, which focuses more on examine reading comprehension of representation in actual biology classes.

THEORETICAL BACKGROUND

Charts, graphs and diagrams imply syntax and semantic information. In addition to information you get by dealing with data points, there is other information representing the background of the data. To access this information you have to relate it to its inner context (Friel, Curcio, & Bright, 2001). Therefore, reading and interpreting data is a process consisting of various components. Curcio (1987) differentiated a level model ("Reading the Data"-Model) with different degrees of requests: Two levels, *reading the data* and *reading between the data* are mostly related to syntax features and focus on reading and comparing data points to identify trends and turning points. In contrast, another level, *reading beyond the data*, considers more the context to employ further predictions. This model is complemented with a fourth level, *reading* *behind the data* (Shaughnessy, 2007). In this level information is taken with account to the specific dataset context, such as the collecting of the data or existing comparable data, to explain variation of the data.

Other relevant work about diagrams with biological content proposes a structural model of diagram competences for diagnosing the ability to construct diagrams (Lachmayer, 2007). Furthermore, there are studies about mistakes by science students when constructing diagrams (Kotzebue, 2014). The integrated model of text and picture comprehension by Schnotz and colleagues (2002, p. 390) focus more on how "descriptive" and "depictive" representations are proceeded and based on this how knowledge is gained from representations in general.

Charts, graphs and diagrams represent relations, have an iconic character (Bakker & Hoffmann, 2005) and are constituted as part of a depictive system that follows rules (Hoffmann, 2005). In the present research, charts, graphs and diagrams are defined as *statistical representations visualizing data* and in particular, data from biological settings. This definition serves the purpose to investigate representations in a biological setting and is framed in appropriate width to allow for applications in a learning environment of this research approach.

A CLASSIFICATION OF DIAGRAMS AS (CONCEPTUAL) BASIS FOR FURTHER WORK

The first step to gather information about reading comprehension of statistical representation in biology courses requires investigating the representations individually. For a systematic and qualitative analysis of graphs, charts and diagrams in biology schoolbooks, we did a classification to get an idea which representations are being used at all and to make assumptions about influencing factors for reading them (Plicht, 2013). This classification is also used for a conceptual distinction in the further research, differentiating the graphs, charts and diagrams when using them as research objects.

The diagrams used in a biological context can be divided into those which

a) focus mostly on structure and data
b) focus mostly on context and biological background.

A second high-level classifying characteristic is the diagram design. There are several levels how graphical elements are an integrative part of the representation. For an example see Figure 1: the cows and the milk cans are graphical element in a chart. They are part of the representation, but not necessary needed for accessing information from the chart. After the inspection of over seventy representations in school books an assumption arose concerning the use of graphical elements: an increased number of included graphic elements affects how a diagram or graph is read, because it can change the semantic interpretation or change the syntactic proportions of scale and size. In Figure 1 it is obviously that the size milk cans do not fit to the numeric value of the data.

RESEARCH QUESTIONS

Only little research focuses on the connections between mathematics and biology with their specific requirements in education - especially in reading comprehension of graphs, charts and diagrams including the involvement of a specific context with its semantic extent. Based on the result of the developed classification, in the next step the reader and the reading process of different kinds of diagrams, charts and graphs were included in the investigation. With these considerations, it was necessary to formulate research questions that capture the dimensionality of reading statistical representations in context of the connection between mathematical and biological education.

The following research question emerged from these requirements:

— How do children read statistical representation with biological content?

— What are the influencing factors when they read charts, graphs and diagrams?

These research questions were investigated with a qualitative research design that leaves room for open-ended analysis with an explorative character.

METHODOLOGICAL APPROACH

The interview study that emerged from these questions with an insight into the methodological approach and the analyzing process will be described here before the results are presented and discussed.

Sample and data collection

Twelve interviews were conducted with students (aged 10–12 years; from secondary school). To get a pleasant atmosphere and make it easier for the students to answer they were interviewed in pairs for about thirty minutes (Selter & Spiegel, 2001, p. 106). The interviewer questioned the students about three to four statistical representations; the interviews were videotaped and transcribed afterwards. We selected the test samples (graph, charts and diagrams), varying in design and material content based on the developed classification, from common German biology textbooks. An interview guideline for the half-hour conversation with open-ended questions served as a dialogue support and further questions regarding the four levels of reading the data (Shaughnessy, 2008) were used to help the students read the graphs. The interviews were to be conducted as openly as possible to capture the original ideas and interpretations of the children. It was important for the researchers to hear the children's spontaneous interpretations and to leave room for what else they had to say on the subject. For example these questions were used to start and carry on the interview:

— What is the diagram about?

— What do you see there?

— Is there anything else you notice?

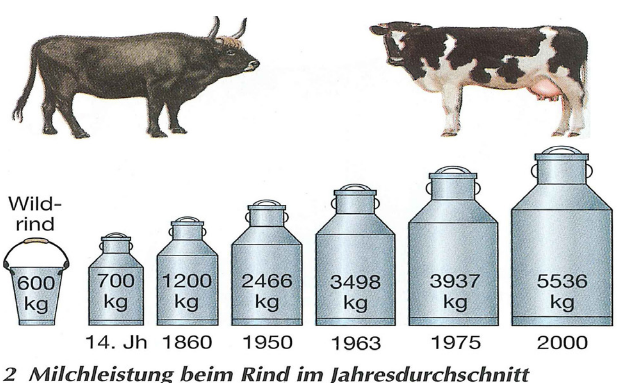

Figure 1: Chart about milk production (Source: Erlebnis Natur & Co 3, Schroedel) that was used in the interviews

Data analysis

The analysis was based on the Grounded Theory Methodology (GTM; Strauss & Corbin, 1990) with an open inductive approach to find categories to generate hypotheses about reading statistical representations.

In the GTM there are three steps of coding before finding a general theory (Strauss & Corbin, 1990). The coding process in this project was performed on a computer with MAXQDA 10. The first step, the *open coding* was supplemented with memos and working hypotheses. To become aware of the reading process and starting to describe the phenomena, sentences and words of the transcript became codes. After generating several codes they were linked and set in relation in a circular work process during the *axial coding*. There the main categories were formed and the subcategories arranged to them. As a result of the last step, the *selective coding*, two different category systems and a concept of reading comprehension (Figure 2) that combined them was developed and will be presented in the following chapter.

TWO DIFFERENT CATEGORY SYSTEMS

Analysing the transcripts with the GTM revealed two viewing directions, which have been studied in detail. On the one hand, the analysis specified what children do while reading diagrams. Four main categories were explored that describe the *activity of reading* and interpreting statistical representations. On the other hand, categories were formed and identified as *influencing factors* to the reading comprehension related to the abilities of the child.

Areas of reading activities

1) READING
2) REASONING
3) APPLYING
4) JUDGING

READING[1]: Children READ, when they refer to or express information directly from the diagram. This includes reading single and multiple data points, the reading of labels or mentioning the general topic of

1 Note that the main category READING is different and more restricted than the competence in reading or reading comprehension in general.

the diagram. Describing the content or the graphic elements is also a subcategory of READING.

> Cw4, 12y.[2]: It is about, how it, so, there is a wild cow and it has, so, it brings 600kg milk per year and you see here in 1400, 1860 and then so on and goes on higher.

REASONING: Children REASON, when they justify their interpretation of correlation or data of the graphs, charts and diagrams. Their interpretation can be supported by the representation itself or from their prior knowledge ideas about the content. Children also REASON about the background or causes of the data collection.

> Aw1, 10y.: Yeah, because I think, because they [the cows] have always been more and more cultured, so they should give more milk.

APPLYING: Children apply the graph or diagram when they consider the meaning of it for themselves personally or in general. They draw conclusions from the graph like projecting the data in the future and consequences of that. These statements usually come from referencing to (their own) life and the environment.

> Aw1, 10y: The cow has become pretty old.

JUDGING: This category includes positive or negative statements of children that JUDGE the diagram itself or the data behind it. Beside the presentation they also valuate and discuss the date collection. They even doubt the correctness of the data. These judgments are mainly justified by reference to their own experiences.

> Bm5, 11y.: It is obvious that here is somehow a huge distance between the year 1400 and 1860. I don't quite understand why there is such a huge distance.

Individual differences as underlying factors driving reading comprehension

During the analysis the question arose what factors driving reading comprehension might be. There were several codes that did not describe the activity of reading but seemed to describe how the students read and what they need to understand it. This included codes about skills children used to read the charts and diagrams. These skills could be, for example, mathematical and biological abilities and experience from their own world. These codes do not describe individual actions, but rather the abilities or tools children used to read. They were labelled during the process with the title "individual abilities of the children". These are possible influencing factors who affect reading graphs, charts and diagrams.

These codes and categories contain the interdisciplinary competences students apply when working with a diagram. We differentiated between *mathematical skills for* reading the syntax of the diagram, and *biological skills* to assess the content. Moreover, the specific *domain knowledge* could further influence how students read and understood diagrams. Other concepts students used were everyday ideas or *naive concepts* to explain the data. They tried to fit their experiences or imagination and the data together even if that was contradictory to the presented data. These categories can be summarized as *influencing factors stemming from the subject*, the reader of the diagram, and affect how the diagram is read.

CONCEPT OF READING COMPREHENSION AND OTHER INFLUENCING FACTORS

The results of the analysis with the GTM revealed two different category systems: The *activities fields of reading* and the *influencing factors stemming from the subject*.

There is a clear connection between these two category systems: The statements depend on the background of the student. For example, they JUDGE the diagram by using their everyday ideas or own experiences.

> CW4, 12y[3].: No, that's not quite right, because the/

> CW5, 11y.: Yes, that's too much...

> CW4, 12y.: ... for a person for a daily water use. Because *my* laundry is not washed every day.

2 All quotes were original in German, the authors translated them for this paper and refer to Figure 1.

3 The quote is from an interview about a chart concerning the daily water consumption.

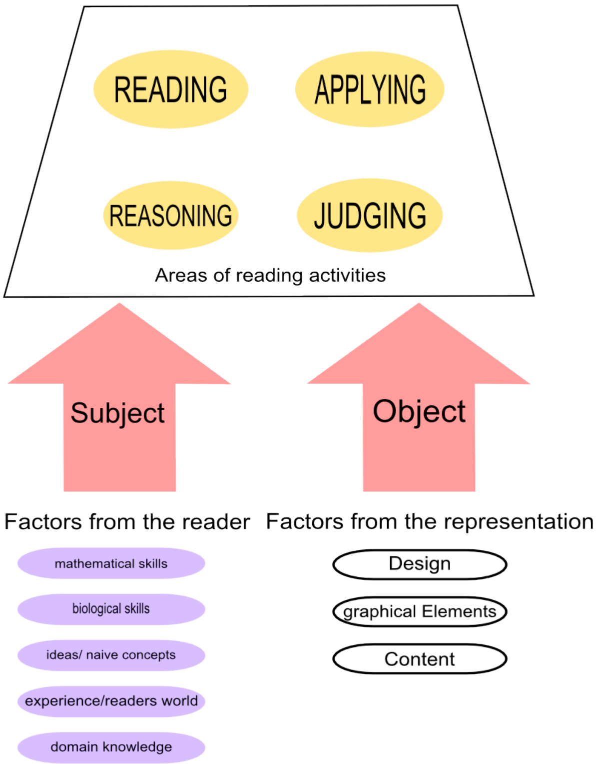

Figure 2: Concept of reading comprehension

Considering the previous work - the analysis of the graphs, charts and diagram in school books - it appears that the influencing factors concerning the readers might not be the only factors that affect reading comprehension. There are features of the object that also determine the reading comprehension. The classification showed relevant criteria to divide the objects and we concluded that the design containing the use of graphical elements and the content define the diagram itself. The content determines whether students can REASON when drawing conclusions; the design and syntax can help to READ data points. Therefore, the content, the graphic elements and the type of diagrams may also be *influencing factors stemming from the object* for the activity fields. Combining these results yields a concept of reading comprehension (Figure 2) with two kinds of influencing factors (subject and object) that affect the areas of reading activities.

DISCUSSION

In the analysis an open and unprejudiced access generated the results concerning a deeper understanding of how children read statistical representation with biological content. Nevertheless, there are other known concepts (e.g., Shaughnessy, 2007; Shah, 2002) how to read data and good scientific practice especially in a qualitative research design demands a sceptical glance on theories that were developed in a different context with different research questions. The "Reading the Data"-Model was introduced earlier and it has to be discussed, with this model as an example, how we coped with other concepts concerning the developed one.

It was not the goal to use or confirm the "Reading the Data"- model of Curcio/Shaughnessy in this study. Therefore, in this study, previous concepts were not used as a basis for coding. Rather, we employed an inductive procedure to find concepts. A post-hoc comparison of our results with existing theories such as "Reading the Data"-model indicate overlaps. The "Reading the Data"-model aims to consider the context of the representation, but it does not specify how the context might affect the reading comprehension and it is not very explicit how the context is involved in the whole reading process. However, there is a close connection between our work and this model. It provides a basis that could be considered in the present research and the similarities of the two models are therefore not surprising. It is even possible to find the levels of data reading in the concept of reading activities. Obviously, the levels *reading* and *reading between data* are included in the category READING. The other levels can be found in phases where students REASON, APPLY or JUDGE (with) the diagram. When reader check with their own experience or make a strong reference their world to REASON the data, that's in the level *reading behind the data.*

In contrast to the "Reading the Data"- model the concept of "the areas of reading activity" is not build on levels, but rather application-oriented. It is possible to describe the main categories of the reading activity as either object or context focused. READING is more focused on the object, JUDGE, APPLY and JUSTIFY is more focused on the context of the representation.

In this study the reading comprehension was not examined in an authentic education environment. Statistical representations are used in schools in a situational context where teachers control the setting. As teachers choose the representation and the content of the diagram and prepare the classroom setting in which the graphs, charts and diagrams are used they determine the domain knowledge and the professional skill of the children that affect the activities of reading. So in an authentic educational environment teachers can control the influencing factors stemming the students and the representation.

FURTHER RESEARCH

Our aim is to get more information about how statistical representation could be used in a learning environment effectively and to get further information how to apply them in biology classes constructively. Therefore, we must understand how students read diagrams with a biological content and especially schoolbook diagrams that are used authentically. After investigating diagrams in a non-school setting to get a conceptual basis and used as distinction for the discussed interview study in this paper, the next step is to investigate the use of graphs, charts and diagrams in actual classroom situations. Our results from this study and the classification, indicating factors influencing diagram reading will be used to design a classroom study to get further information on how students actually learn from statistical representations.

Interest in statistics: Examining the effects of individual and situational characteristics

2 Queen's University, Belfast, United Kingdom

Statistic lessons are often considered difficult and unpleasant. One reason for this is that many learners do not find statistics intrinsically interesting and engaging. Nevertheless, interest in a particular teaching session does not only depend on the characteristics of learners, but also on the characteristics of the session itself. The aim of the present study was to investigate the relationship between learner's characteristics (i.e., individual interest and intrinsic motivation) and situational interest. Participants were university students who participated in a tutorial activity. The results provided support for a moderated mediation model which showed that the relationship between individul and situational interest was dependent both on students' intrinsic motivation and the perceived appeal of the activity. The discussion underlines the importance of the interaction between individual and situational factors in the process of teaching statistics.

Keywords: Learning statistics, individual interest, intrinsic motivation, situational interest, moderated mediation model.

INTRODUCTION

Statistics is commonly viewed as a difficult and unpleasant topic and students often perceive statistics courses as a burden, they sometimes fail to pass the exams and, as a result, some of them might even abandon their academic and professional aspirations. Indeed, individuals are not always interested in what is being taught as part of their course (see Matarazzo, Durik, & Delaney, 2010), and this is especially true for domains that are unappealing or feared by students (e.g., Middleton & Spanias, 1999; Zeidner, Roberts, & Matthews, 2008). Low interest in a learning activity might also undermine students' persistence and performance (e.g., Durik & Harackiewicz, 2007). As a consequence, it is desirable that research focused on improving statistical education identifies variables that can promote or undermine statistical interest.

THEORETICAL FRAMEWORK

In the educational literature, several studies have focused on the concept of *interest* in college subjects . Recent reviews (see Linnenbrik-Garcia, Durik, Conley, Barron, Tauer, Karabenick, & Harackiewicz, 2010; Matarazzo et al., 2010), described two different types of interest: *individual interest* and *situational interest*. *Individual interest* is an enduring predisposition to engage in certain content domains, and it is accompanied by concentration and positive feelings (Hidi & Renninger, 2006). Once developed, individual interest is relatively stable across time and situations. High individual interest involves high levels of knowledge, experience, and the attribution of high value to the domain of interest (Hidi & Renninger, 2006; Renninger, 2000). In contrast with individual interest, *situational interest* is a short-term state of focused attention and affective engagement (Matarazzo et al., 2010), which might be triggered by the characteristics of the learning situation (Hidi & Harackiewicz, 2000).

In the domain of mathematics, Durik and Harackiewicz (2007) found that situational interest was positively influenced by individual interest in mathematics. Moreover, these authors found that an important process which was related to both individual and situational interest was *intrinsic motivation*, i.e. the desire to engage in an activity for the value inherent in doing it (Deci & Ryan, 1985). According to

Harackiewicz and Sansone (1991), the experience of intrinsic motivation during task engagement reflects the importance that a person places on competent performance, refers to the extent to which an individual feels focused on and absorbed in an activity during task engagement, and concerns an individual's self-assessment of competence while performing an activity.

Interest (individual and situational) and intrinsic motivation are closely related (see e.g., Deci, 1992; Ryan & Deci, 2000). Thus, it is important to understand the underlying mechanisms of how students become involved and interested in their courses. To the best of our knowledge, until now no study has investigated individual interest in statistics and its relationship with intrinsic motivation and situational interest in the context of a statistics class . The aim of this study was to fill this gap by investigating how individual interest and intrinsic motivation were associated with situational interest in the domain of statistics. Specifically, our research questions were the following.

First, we wanted to investigate the relationships between individual interest, situational interest, and intrinsic motivation in statistics. We hypothesized that there would be strong, positive correlations between these characteristics. Additionally,

we wanted to test a mediation model explaining the underlying mechanisms by which these individual characteristics are related to each other. We hypothesized that the relationship between individual interest and situational interest would be partially mediated by intrinsic motivation; that is, that higher individual interest would be directly related to both greater intrinsic motivation and greater situational interest in the learning situation (Durik & Harackiewicz, 2007), but there would also be an indirect link between individual interest and situational interest through intrinsic motivation.

Second, we wanted to test a model explaining the underlying mechanisms by which a characteristic linked to situational factors, i.e. the *perception of the appeal of the activity* or, in other terms, the extent to which participants like the activity, interacts with the other variables in the mediation model explaining the relationships between individual interest in statistics, intrinsic motivation, and situational interest in statistics. Specifically, given that Durik and Harackiewicz (2007) found that making the teaching materials appealing by using nice and colourful pictures had a positive effect on situational interest in mathematics, we hypothesized that the perception of the appeal of the activity, which was elicited by making the teaching materials as appealing as possible through the inclusion of pictures, images and colours, would have a significant positive effect on situational interest in the activity. We also predicted an interaction between intrinsic motivation and the appeal of the activity. In particular, we aimed to verify that the relationship between intrinsic motivation and situational interest was moderated by students' perception of the appeal of the activity. To provide evidence for these hypotheses, we tested a moderated mediation model in which individual interest in statistics affects situational interest in a statistic learning activity through intrinsic motivation, and this mediation effect is moderated by students' perception of the appeal of the activity.

METHOD

Participants

The participants were 127 psychology students attending the University of Florence in Italy, who enrolled in an undergraduate introductory statistics course. The participants' age ranged from 19 to 44 (Mean=20.44, *SD*=3.19). Most of the participants were females (79%). Students participated on a voluntary basis and they received course credit for their participation.

Materials and procedure

Participants were invited to engage in a statistics tutorial activity during one of the lectures of their introductory statistics course. The activity, which was introduced in the academic year 2013–2014 (and took place in November 2013), was conducted by a trainer who was different from the course lecturer. The activity started with the explanation of the phenomenon of *collective statistical illiteracy*, defined as a widespread lack of understanding of health statistics in society, and, ultimately, the tendency to draw invalid conclusions regarding the meaning of statistical information without noticing (Gigerenzer, Gaissmaier, Kurz-Milcke, Schwartz, & Woloshin, 2008). To illustrate this phenomenon, a real-world example of collective statistical illiteracy regarding birth control was presented[1]. Then, the activity was organized in explanation of specific critical arguments particularly biased in health statistics, i.e. absolute and relative risk in medical fields and conjunctive and conditional probability of epidemiological data presented in contingency tables. The explanation was conducted using power point slides with imagines, animations and graphical examples. It was followed by demonstration of some exercises regarding real-life situations about the medical field. Each student received an individual workbook which contained, along with the exercises, a series of scales developed for the purpose of this research.

The following scales were developed for the purpose of this research.

At the beginning of the session, individual interest in statistics (IIS) was measured using a seven-item scale that tapped into the general evaluation of statistics (e.g., "I find statistics enjoyable"). Participants indicated from 1 (*strongly disagree*) to 7 (*strongly agree*) the extent to which they agreed with each statement. A total score on the scale was calculated so that high scores corresponded to high levels of IIS. The internal consistency of this scale was good (Cronbach's α = .89).

During the activity, when students were presented with practice exercises, they were invited to assess their intrinsic motivation (IM) in solving them. IM was measured using a twelve-item scale measuring self-reported competence valuation (e.g., "It is important to me that I perform well"); task involvement (e.g., "I got caught up in doing this exercise") and perceived competence (e.g., "I think I did well in the exercise"). The scale had a 7-point Likert response scale (from 1 = *strongly disagree* to 7 = *strongly agree*). Cronbach's α was .86 indicating good internal consistency. A total score on the scale was calculated so that high scores corresponded to high levels of IM.

1 "In October 1995, the U.K. Committee on Safety of Medicines issued a warning that third-generation oral contraceptive pills increased the risk of potentially life-threatening blood clots in the legs or lungs twofold—that is, by 100%. This information was passed on in "Dear Doctor" letters to 190,000 general practitioners, pharmacists, and directors of public health and was presented in an emergency announcement to the media. The news caused great anxiety, and distressed women stopped taking the pill, which led to unwanted pregnancies and abortions (Furedi, 1999)." (Gigerenzer et al., 2008, p. 54).

Finally, after the activity, situational interest (SI) and perceived appeal (PA) of the activity were assessed. SI was measured through an eight-item scale (Cronbach's α = .91) referring to the student's specific interest in the ongoing learning activity (e.g., "I have found this activity very interesting"). PA was measured by a four-item scale (e.g., "I liked the slides very much") (Cronbach's α = .93). For both scales, participants indicated from 1 (*strongly disagree*) to 7 (*strongly agree*) the extent to which they agreed with each statement. A total score on the scales was calculated so that high scores corresponded to high levels of SI and PA.

In line with the usual course lessons, the total duration of the activity was two hours.

RESULTS

Relationships between individual interest in statistics, situational interest in statistics, and intrinsic motivation: To analyze the relationships between individual interest in statistics, situational interest in statistics, and intrinsic motivation, correlations between the variables were calculated (Table 1). Situational interest was significantly and positively correlated with individual interest in statistics and intrinsic motivation. Moreover, there was a significant positive correlation between individual interest in statistics and intrinsic motivation.

To evaluate the adequacy of the hypothesized mediation model explaining the underlying relationships between individual interest in statistics, intrinsic motivation, and situational interest in statistics, we tested the extent to which the relationship between individual interest in statistics and situational interest was mediated by intrinsic motivation. Specifically, we verified whether individual interest in statistics had both a direct and an indirect effect on situational interest in the statistics tutorial activity through

	1	2	3

Table 1: Summary of Intercorrelations, Means, and Standard Deviations for Scores of the individual interest, situational interest, and intrinsic motivation

intrinsic motivation. We used the INDIRECT macro for SPSS (Hayes, 2013), which tested the hypothesized mediation model using the bootstrapping procedure (with 5000 bootstrap samples) to estimate the 95% confidence interval (95% CI; for more details, see Preacher & Hayes, 2008). The bootstrapping procedure is considered to represent the most reliable test for assessing the effects of mediation models (Hayes & Scharkow, 2013). As shown in Figure 1, the mediation model was estimated to derive the total, direct, and indirect effects of individual interest in statistics on situational interest in the activity through intrinsic motivation. We estimated the indirect effect of individual interest in statistics on situational interest in the activity, quantified as the product of the ordinary least squares (OLS) regression coefficient estimating intrinsic motivation from individual interest in statistics (i.e., Path a in Figure 1) and the OLS regression coefficient estimating situational interest in the activity from intrinsic motivation controlling for individual interest in statistics (i.e., Path b in Figure 1). A bias-corrected bootstrap 95% CI for the product of these paths that does not include zero provides evidence of a significant indirect effect (Hayes, 2009; Preacher & Hayes, 2008). Results showed a significant positive direct effect of individual interest in statistics on situational interest in the activity (point estimate = .19, 95% CI = [.02, .35]). Moreover, results showed a significant positive indirect effect of individual interest in statistics on situational interest through intrinsic motivation (point estimate = 0.16, 95% CI = [0.06, 0.31]).

To evaluate the adequacy of the hypothesized moderated mediation model explaining the role of the perceived appeal of the activity in the above described mediation model, we tested the extent to which perceived appeal had a positive main effect on situational interest and whether the mediation of intrinsic motivation between individual interest in statistics and situational interest in the statistics activity was moderated by the perception of the appeal of the activity. In order to verify this model, we conducted a moderated mediation analysis as suggested by Preacher, Rucker, and Hayes (2007). Similarly to the mediation analysis, this analysis tested the hypothesized model using the bootstrapping procedure (with 5000 bootstrap samples) to estimate the 95% confidence interval. As shown in Figure 2, the results confirmed a significant positive direct effect of individual interest in statistics on situational interest (point estimate = 0.16, 95% CI = [0.04, 0.28]). The results also showed a significant main effect of the perception of the appeal of the activity on situational interest in the statistics activity (OLS coefficient=2.35; *SE*=.65, *p*<.001) as well as a significant interaction between intrinsic motivation and the perception of the appeal of the activity on situational interest in the statistics activity (OLS coefficient=-.01; *SE*=.01, *p*<.05). Given the evidence for this interaction, we estimated the conditional indirect effect of individual interest in statistics through intrinsic motivation on situational interest at various levels of the perceived appeal of the activity. We found that the indirect effect of intrinsic motivation on situational interest was significant only for low (point estimate = - 0.11, 95% CI = [0.03, 0.23]) and medium (point estimate = 0.08, 95% CI = [0.03, 0.16]) levels of perceived appeal of the activity. The effect was not significant for high levels of perceived appeal of the activity (point estimate = 0.04, 95% CI = [-0.01, 0.12]).

Thus, the results suggested that the positive indirect effect on situational interest through intrinsic motivation (controlling for individual interest in statistics) was significant for low and medium levels of perceived appeal of the activity but not for high levels of perceived appeal. In other words, among students who perceived the activity as poorly or averagely appealing, results showed significant differences in

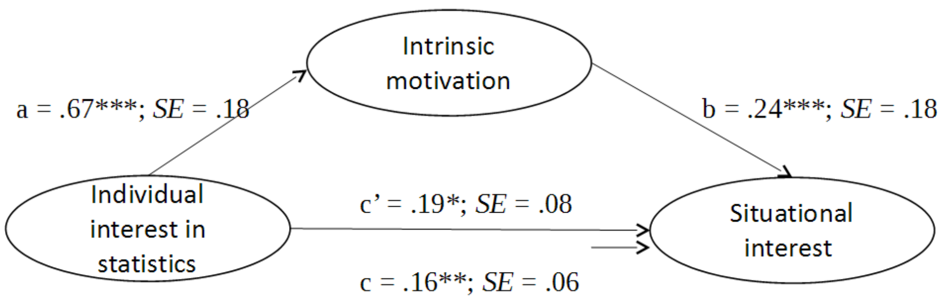

Figure 1: Path coefficients for mediation analysis on situational interest in the statistics activity. Dotted line denotes the effect of individual interest on situational rest in the statistics activity when intrinsic motivation is not included as a mediator. a, b, c, and c' are unstandardized ordinary least squares (OLS) regression coefficients. *p < .01 **p < .001 ***p<.001

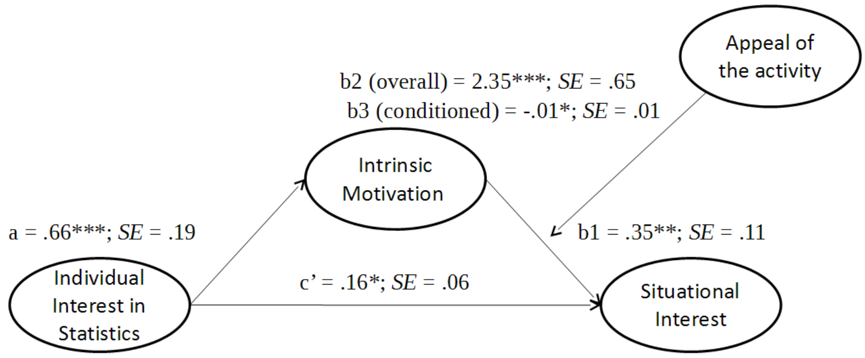

Figure 2: Path coefficients for moderated mediation analysis on situational interest. a, b1, b2, b3, and c' are unstandardized ordinary least squares (OLS) regression coefficients. *$p < .05$, **$p < .01$, *** $p < .001$

situational interest between those with low, medium, and high motivation. By contrast, among students who perceived the activity as highly appealing, there was no significant difference on situational interest between those with low, medium, and high motivation. This meant that if a statistics activity is perceived as highly appealing by the students, it is likely that they will perceive the activity also as highly interesting, regardless of their motivation.

DISCUSSION AND CONCLUSION

Given the relative lack of studies on interest in the statistics domain, the present work was aimed at investigating the relationship between individual interest and situational interest in the statistics domain. Specifically, our aim was to develop and test a model explaining how specific features of the teaching session, as perceived by students, act in concert with some individual differences in individual interest, intrinsic motivation, and situational interest. Overall, three important findings emerged from this study.

First, individual interest was found to have a direct effect on both situational interest and motivation in the statistics domain. This result is in line with Durik and Harackiewicz's (2007) earlier findings in the mathematics domain. Second, our study is the first to provide evidence that intrinsic motivation mediates the relationship between individual interest in statistics and situational interest in a statistics activity. More specifically, greater individual interest in statistics appears to be related to greater intrinsic motivation, which, in turn, is related to a greater likelihood to show interest in the activity. Third, our results suggest that the indirect effects of individual interest in statistics on situational interest through intrinsic motivation is moderated by the perceived appeal of the activity. In other words, the extent to which intrinsic motivation mediates the relationship between individual and situational interest, interacts with how the student perceives the appeal of the activity. Specifically, if a student perceives a statistics activity as highly appealing, even if he/she was poorly motivated to participate in the lesson, he/she is likely to be very interested in the statistics activity.

These results have important implications. First, these results indicate that intrinsic motivation plays an important role in the relationship between individual interest and situational interest in statistics, Thus, interventions aimed at increasing students' interest in statistics activities could be focused on improving intrinsic motivation, for example by highlighting the importance of statistics in everyday life and in the profession of a psychologist. Second, as our study shows that students' perception of the aesthetical appeal of teaching materials moderates the effect of intrinsic motivation on situational interest, educators who are interested in finding ways to involve the highest possible number of students (including the less motivated ones) in statistics learning, could aim to prepare teaching materials with the highest possible level of esthetical appeal.

Affective exhibition during the interpretation of statistical data

Tamires Queiroz[1], Carlos Monteiro[1], Liliane Carvalho[1] and Karen François[2]

1 Federal University of Pernambuco, Recife, Brazil, tamires_nq@hotmail.com, cefmonteiro@gmail.com, lmtlcarvalho@gmail.com

2 Free University of Brussels – VUB, Brussels, Belgium, karen.francois@vub.ac.be

In recent years, research on the processes of teaching and learning of Statistics emphasises that the interpretation of data is a complex process that involves cognitive and technical aspects. However, the interpretation of statistical data is a human activity that also involves affective aspects. However these aspects were not sufficiently investigated. This paper discusses some elements from an empirical pilot study that explores the idea of affective expression during the interpretation of statistical data by undergraduate students of statistics and pedagogy. Although the participants had different academic background their interpretations of media statistics data did not follow patterns that were influenced by the university courses they attended.

Keywords: Affective exhibition, interpretation of statistical data, statistics education.

INTRODUCTION

Several studies on statistics education have given evidence that the interpretation of data is a complex activity which is associated with several aspects. Gal (2002) argues that *statistical literacy* consists of two types of components: cognitive and dispositional. The cognitive components, such as mathematical and statistical knowledge, are related to reasoning aspects that enable readers to technically interpret data. The dispositional components refer to more subjective elements related, for example, to beliefs, attitudes and emotional aspects of the individual that is reading the data. Based on Gal´s perspective, readers can discuss and communicate their conclusions about statistical data using their expertise on specific area, as well as their personal and social experiences.

Arcavi (2003) emphasises that the interpretation of (statistical) data is not the result of a simple decoding of graph components. Although Arcavi is mainly working on mathematics learning he also refers to allied disciplines (e.g., data handling or statistics) and the way of data representations and date graphing (Arcavi, 2003, p. 217).

Since "we live in a world where information is transmitted mostly in visual wrappings, and technologies support and encourage communication which is essentially visual" (Arcavi, 2003, p. 215) human being is encouraged to interpret visual representations. He emphasises the complexity of the phenomenon of interpreting visual representation, e.g. graphical display. It is not only related to what comes "within sight", but we are also encouraged and aspire to 'see' what we are unable to see. Referring to Goethe he explains the quote "We don't know what we see, we see what we know" (Arcavi, 2003, p. 230) stressing the last part of the expression "We see what we know". Arcavi argues that the same visual objects may have different meanings in different contexts. He therefore proposes to classify three types of 'difficulties', see cognitive, sociological and cultural.

Lima (1998) and Monteiro (1998) suggest that during the interpretation of data, the way readers use their mathematical and/or statistical knowledge is a complex aspect which is not the result from only one aspect, such as their academic background. Lima (1998) analyses the interpretation of data developed by designers and mathematics teachers. The author concluded that the interpretations of the participants were different in the way they read the data, however both groups were similar in the use of mathematical knowledge during the interpretations. Monteiro (1998) investigates the processes of interpreting graphs of printed media by a group of businessmen with different academic backgrounds and a group of economists. The author did not identified differences in relation to the strategies of problem solving, although the group of economists tended to produce more estimates in their interpretations.

Monteiro (2005) develops the idea of *critical sense* during the process of interpretation of statistics media graphs that is related to mobilisations and balance of several elements. The term mobilisation (Monteiro & Ainley, 2003) is related to the possibility of re-using or re-sourcing (Adler, 2000) previous knowledge and experiences during the process of interpretations of media graphs. This mobilisation seems to be a process in which readers explore the data, confronting it with their own perspective, and their previous experiences related to the data interpreted. However, the process of mobilisation in interpretation of media graphs does not 'naturally' happen. In order to mobilise their previous knowledge and experiences to interpret a media graph, readers need to establish a certain level of engagement in the task, which then leads to the articulation in which they make a recontextualisation of the knowledge and experiences mobilised, comparing them to the data. The reader also needs to balance different elements. Therefore, there is no direct application of knowledge and experiences for the process of interpretation. This complex process of mobilise and balance different elements during the interpretation of statistical data displayed in the graph is called *critical sense*.

McLeod (1992) did an extensive review of the literature in mathematics education that addresses the affective domain. The author states that, among other factors, most of these studies did not impact mathematics education because they were focused only on stable aspects of affectivity. In other words, these studies were more concerned with the products and not with the processes involved. Most studies reviewed by McLeod seem to conceive narrowly affectivity, merely investigate more specific concepts such as beliefs and attitudes. In addition, the studies did not make a link between affective and cognitive factors. Therefore, similar to those studies that investigated only cognitive aspects, the studies that addressed only affective aspects seem to have no impact on the learning and teaching of mathematics curriculum content. McLeod suggests that beyond a deepening of theoretical questions about the definition of affectivity and their relation to cognition, studies need to be based on research approaches that combine quantitative and qualitative methods.

Based on this literature review we can conclude that Gal (2002) provided statistical literacy principles comprised of cognitive and dispositional elements. Arcavi (2003) emphasised the importance of people's social and cultural background in the interpretation of data, which is also exemplified by Lima (1998) and Monteiro (1998). Finally, Monteiro (2005) added the notion of 'critical sense' based on statistical literacy principles, however emphasising the complex interrelation between components and processes involved. Research on the specific affective influences in statistics interpretation is still lacking. Looking at the field of mathematical literacy, affectivity has the rather narrow meaning of attitudes and beliefs. With the concept of affectivity we will include the dispositional elements that are take part at the interpretation of statistical data.

In the field of statistics education, it is necessary to develop a similar literature review that investigates the number of studies focused on the affective aspects, and how they can make impact on the teaching and learning of school statistics. Besides we need empirical evidence based on quantitative and qualitative approaches to better understand the interpretation of statistical data.

RESEARCH QUESTION

The research question in this exploratory study is if the affective expressions of students in situations of interpretation of statistical data are related to the students' background in the teaching and learning of statistics. Therefore we investigated the interpretations of students from two different backgrounds in the teaching and learning of statistics, viz. (i) bachelor in statistics and (ii) degree in pedagogy. We expected that the differences related to the type of course in which the participants were enrolled might influence their affective expressions on their interpretations.

METHODOLOGY

This pilot study was a qualitative investigation based on standardized open-ended interviews. In order to investigate aspects about the affective expression and statistics literacy, we invited first year students from two different university courses from the same Brazilian Federal University: two undergraduate students from an education course (P1 and P2) and two students from a statistics bachelor course (S1 and S2).

We chose a group of students from education because they are pre-service primary school teachers, and also because in this course has disciplines, such as Psychology which addresses affective aspects. The first year education students already attended those disciplines. The choice for students from bachelor in statistics was because this course has a curriculum focused on disciplines such as probability, data analysis, and stochastic phenomena. The first year students already had such disciplines and they will not have any discipline that approaches the affective aspects as part of their course. The first author contacted the students in their classroom and explained the research. The students interviewed were volunteers. Data collection was conducted in November and December 2013. The Pedagogy students P1 (57 years old, female) and P2 (33 years old, male) completed two disciplines that approaches affective aspects associated with teaching and learning. They did not attend any statistics course during their first year. The statistics students S1 (17 years old, female) and S2 (18 years old, female) completed five specific disciplines related to statistics.

DATA COLLECTION

The data collection was developed from individual standardized open-ended interviews which were composed by four tasks related to statistics data from different publications. Statistical data had the following topics: (1) on mammography examination, (2) on traffic accidents, (3) on life and health insurance, and (4) on high school students´ handguns. (Due to lack of space in this paper, we report on 2 and 4).The main reason to choose these cases was that the topics had a certain level of polemic. We expected that this type of data would motivate participants to make comments related to technical aspects as well as to their emotional reaction to the data. During the interviews, each task was presented to the student on a printed sheet. The researcher read the specific questions for each task. Interviews were recorded, and transcribed. The protocols were originally in Portuguese, fragments for this paper were translated by the authors.

Task 2 was comprised of questions about a line graph (Figure 1) that shows the percentages of deaths among Brazilian youth population caused by traffic accidents between 1998 and 2008. This graph was originally published in a report from the Brazilian ministry of justice (Waiselfisz, 2011).

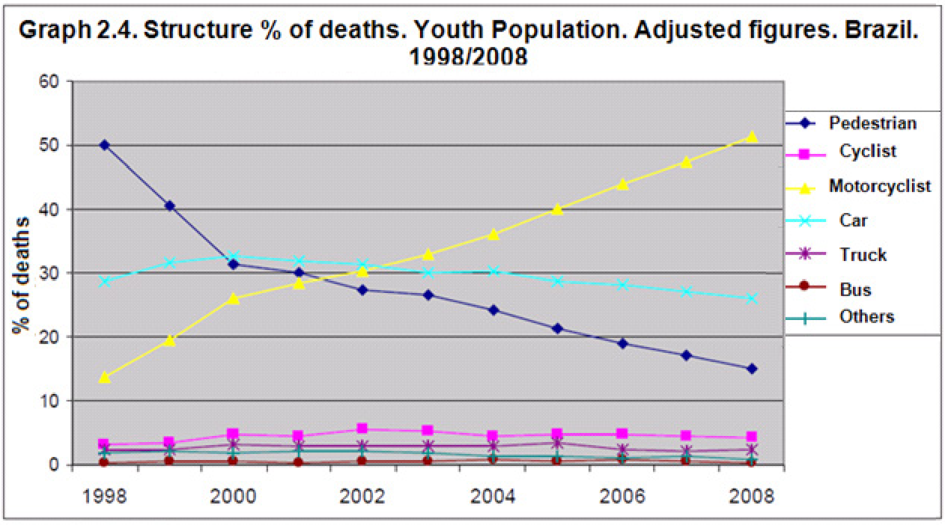
Interview questions related to task 2 (Figure 1) were:

1) What can you conclude from the results presented in this graph?

2) If you could ask a question to whoever built this graph, would you do? Which one(s)?

3) What would you say? What elements which would you emphasise?

4) What do you think these data are between 2008 and 2013? Why do you think that?



Source: SIM/SVS/MS

Figure 1: The percentages of deaths among youth Brazilian from 1998 until 2008

Task 4 was used by Watson (2005). It is a fragment of media news about the use of handguns by high school students:

> About 6 in 10 United States high school students say they could get a handgun if they wanted one, a third of them within an hour, a survey shows. The poll of 2,508 junior and senior high school students in Chicago also found 15% had actually carried a handgun within the past 30 days, with 4% taking one to school.

Interview questions related to task 4 were

1) What can you conclude about this research?

2) What do you think about the data collected in this research?

3) Do you have any questions or comments about this research? Which one(s)?

THE ANALYSES OF PARTICIPANTS' RESPONSES

The transcriptions of audio records were organized in protocols which were base to the data analyses. The participants' responses were analysed by a categorisation which emerged from a qualitative approach. Initially, we categorised their responses for each task and item. In order to discuss aspects from the data collected in the following sections we exemplify with some extracts from the interviews.

TASK 2 – DEATHS AMONG BRAZILIAN YOUTH POPULATION

In order to answer the first item of this task (What can you conclude from the results presented in this graph?) all participants made initially general comments related to the graph itself. However, they also made some observation which could make explicit their personal reaction to the data displayed. The extract from the interview with P1 can exemplify this:

S1: Here, the person [who reads the graph] realizes that motorcyclists [figures] rose so much. The pedestrians, I think, they became more conscious in relation to that, before used to be something that nobody cared. Nowadays have footpath, have road sign, have zebra crossing, have more... much care. While, the motorcyclists [figures]... is getting worst day by day. While the cars has a decrease but it is not much. While the ones [figures] of pedestrians remain all in one pattern, a little less.

The second question (If you could ask a question to whoever built this graph, would you do? Which one(s)?) motivated P2, S1 and S2 to ask questions related to the survey itself. They asked questions about the data collection, sampling and where the survey was conducted. Those questions indicated concern about the reliability of the research, e.g. S2 asked how the data were collected, as illustrated below:

Researcher: If you could ask a question to whoever built this graph, would you do?
S2: I would do... How the data was collected ... Only.
Researcher: What do mean?
S2: Kind of... If it was a street survey... Asking how many accidents you have in one year or if it was a survey... For example... Within the IML [Institute of Legal Medicine] which is the agency responsible for deaths.

The questions formulated by participants suggested that they were mainly concerned about technical aspects related to the data. Maybe they needed this type of information to be more comfortable to make other comments about the data. In some way, we could say that their questions were also expressions of their feelings about the data, because they made explicit some scepticism about the data displayed on the graph.

The responses to question 3 (What would you say? What elements which would you emphasize?) were complementary to those of question 2. The questions motivated the students to make more observations related to the data displayed. Generally, the participants now responded as a rereading of the graph. They pointed to specific figures (as they did when answering question 1). The most frequent responses were related to the increase in deaths of motorcyclists, followed by references to the decrease in pedestrians' deaths. P1 developed a more extensive response, questioning more explicitly, as illustrated in the following extract of her interview:

Researcher: Ok. It is... if you were going to comment to someone about this graph, which points would you think that should be important to discuss about it? What are the points that you would emphasise, that you would discuss more about?

P1: I think that it would be really to make relations between these categories... of pedestrians, motorcyclists and drivers. Why these categories are most affected in the traffic? Look at the difference of others, of the trucks, of the cyclists... Cyclists also do not have an incentive, don't they?... for the use of cycleway. But, it would be to make relation between these categories.

We can observe that P1 emphasises the importance of analysing the graph as a whole, as P1 attributes importance to the relationships between the categories. P1was interpreting beyond the data displayed when she was referring to specific issues which are part of her daily experiences and observations (e.g. when she talked about the situation of cyclists). P1 seems to be preoccupied with the effects on people rather than the performance effect of the figures.

From the analyses of protocols we identified more variety of participants' responses to the fourth question (What do you think these data are between 2008 and 2013? Why do you think that?). All participants justified their answers based on *contextual reference* (Monteiro, 2005), that is when they contextualise the data displayed on the graph making references which are related to their formal knowledge in different areas and their opinion.

On the one hand, P2 and S2justified their answers talking about a possible increase in numbers of accidents based on information that they had from two media reports.

Researcher: In the case, these results were from1998 until 2008, right? What do you think these data are between 2008 and 2013?

S2: I think that tends to increase the number of deaths of cyclists [but really referring to motorcyclists], well... for my knowledge of the world, right? Because... kind... the rates of IPVA [Brazilian tax on the ownership of motor vehicles], these things have decreased and more people are buying cars and... by this graph, it tends to increase even [the number of accidents].

On the other hand, P1 and S1 were more positive, they referred to the effectiveness of dry law that prohibit people to drive after drink any amount of alcoholic. The following extract gives an example of this type of approach:

Researcher: In this case, this... This report was made from 1998 to 2008. What do you think these data are between 2008 and 2013?

S1: Guy, I think it must have dropped. Slowly, but it is dropping. Our conscience is more... we have the dry law then we are taking more care, aren´t we? I believe that is a little bit better than two years ago.

From our analysis of the question 4 responses, we can infer that these participants also expressed different feelings about the same data displayed. These different affective expressions certainly are related to individual aspects from those who interpret the data. Hence there is also evidence that the interpretation of statistical data is composed of affective elements which need to be considered.

TASK 4 – THE USE OF HANDGUNS BY HIGH SCHOOL STUDENTS

Most of participants' responses to the first question (What can you conclude about this research?) tended to express feelings about the survey. The following extract from P1 interview is an example:

P1: I was shocked with the facility of armaments and weapons that the American population has. Because it is not just at school, no, any citizen, isn't it? Have in their home one or two weapons. ...The poll of 2,508 junior and senior high school students of the first and the last year of high school students... ...said that 15% of them had a gun in the last 30 days, with 4% having taken to school... [reading the task]. From these 15%, 4 [%] led to the school, didn't they? Other day I was commenting on that... so... some of them have their jets, their imported cars, their helicopter; others live picking up litter, don't they? And, for the world to arm itself is also very fast. It's just you do your atomic bomb, to make intimidations with each other. It's shocking. I find shocking.

P1 tended to interpret the news report basing on an emotional reaction to the theme, although she considered the statistical figures related to the poll. S1 and S2 interpretations were quite similar to P1 when they responded this question. We can infer that the theme related to this task was more explicitly polemic, and may have influenced these participants' interpretations. Only P2 had a more descriptive reading of the data which did not seem to have had any personal reaction about the news report. As we can see the excerpt from his interview:

P2: I conclude that... it was done a piece of research, a poll... that from 2.508 high school students from the United States... it was detected that 60% of these students say they could get a gun if they wanted. Then, moreover, this 60%... it is... a third of these students could get a gun within an hour, and moreover, it... yet... students from first and last year of high school [rereading the task]... that means... it has here... at first, the research was done with high school students. Making a correction! And... this research has reached that percentage of 6 out of 10 could have access. After that, it was done a research investigating this number of students 2.508, of the final years of high school and among these ... it is... it was found that 15[%] of them carried a handgun... carried a handgun in the last 30 days and 4% of them had already led gun to school.

In this part of the interview, P2 was trying to understand the details about the procedures related to the data collection, and other details of the news data. His concerns to specific aspect of the news did not allow him to question or expose his point of view.

The second question of task 4 intended to explore more specifically the participants' interpretation about statistical data involved (What do you think about the data collected in this research?). The participants' responses seemed to be complementary to their comments on the first question. Therefore, P1, S1 and S2 who did not make observations about the figures, responded here by making observations concerning quantitative data as well as expressing the personal point of view, e.g. the following extract form the interview:

Researcher: What do you think about the data collected in this research?

S1: I found it very serious. Because if among... 2,500 students, 15% of them have revolver, that is too many... if 4% can take it to school, imagine how many people within that school have a revolver. Any time something happens... Nowadays, in the ways those things are... any... "step on somebody's toes", you are already assaulting somebody... this is a very dangerous thing and has to have drastic measures.

On the other hand, the interpretation of P2 was more explicitly related to his personal opinion about the data.

P2: These data here, it shows and proves about the reality of a country that has a policy of well open access to weapons, right? And at the same time, there is no much control and no much oversight, right?

Finally, the third question was an opportunity to the participants to make final remarks about the data (Do you have any questions or comments about this research? Which one?).

P2 and S1 questioned about the survey sampling, the sites where the poll was taken and how the research was done, pointing out some possible biases. According to them, the information provided about the survey was insufficient to answer their questions, however, none of them expressed they didn't trust the research. The comments of P1 and S2 were based on their opinions about the situation, taking into account their knowledge about social, economic and political aspects which might be related to the theme, and which could eventually influence the interpretation of the data. These two participants did not ask for further information.

FINAL CONSIDERATIONS

This study explored aspects of the exhibition of affective components in the interpretation of statistical data. Specifically, the empirical research data was generated from situations in which the participants interpreted statistical data. The participants were students engaged in different processes of teaching and learning related to affectivity and statistics. Students of Pedagogy attended courses only related to affectivity, and students of statistics had approached various contents related to data analysis, and they did not attend courses that comprise the theme of affectivity as curriculum content.

The research tasks were associated with statistical data of controversial themes. Our expectation was to propose research situations that could provide possibilities for the participants to present more personal expressions during their interpretation of the data. We also expected that participants' academic background could influence how they would interpret and to express their affectivity in relation to the data.

The analyses of protocols suggest that the interpretation of statistical data is a dynamic process, which do not follow predictable patterns. Participants responded in different ways during their processes of interpretation to most of the questions. They mostly expressed their opinions and feelings in responding to the questions, or at some moments they mixed their objective analysis related to the statistical knowledge with the subjectivity of their impressions about the data. Even more technical oriented questions (see task 2 question 2 and task 4 question 2) can be interpreted as expressions of feelings (e.g. scepticism) or expressions of a personal point of view.

In line with the theoretical investigations on interpreting statistical data, these preliminary data gave evidence that the process of interpretation is a complex process consisting of cognitive and dispositional components. Based on the preliminary research findings, we have no clear evidence that these components were determined by the curriculum background of the students (pedagogical versus statistical). However our findings make clear that a broader discussion about the processes of data handling and the interrelation with affective aspects is an important issue in the further development of teachers' understanding of statistical literacy. Further investigations have to reveal possible differences between first year students and students in a final stage of the courses.

Individual concepts of students comparing distributions

Susanne Schnell and Christian Büscher

TU Dortmund University, IEEM, Dortmund, Germany, susanne.schnell@tu-dortmund.de, christian.buescher@tu-dortmund.de

While distributions were long understood as "fundamental given of statistical reasoning" (Wild 2006, 10), recent research uncovered students' difficulties in acquiring the underlying conceptual structure and making statistically sustainable inferences when comparing distributions. Research so far describes informal strategies such as using 'clumps' as productive when learning to compare distributions. However, more insights are needed regarding why some of these strategies are chosen in certain situations in order to fully relate students' informal strategies to statistical concepts and measures in task design. This paper aims at clarifying the students' reasoning behind what to focus on for comparisons. We will present empirical snapshots from students in grade 8 (13–15 years old) who focus almost exclusively on absolute frequencies of dots and specifically determined intervals for comparing distributions.

Keywords: Statistical reasoning, comparing distributions, design research.

INTRODUCTION

Comparing empirical distributions has a high value for statistics education: "Concepts and judgments involved in comparing groups have been found to be a productive vehicle for motivating learners to reason statistically and are critical for building the intuitive foundation for inferential reasoning" (Ben-Zvi, 2003, p. 1; also Bakker & Gravemeijer, 2004). A combination of descriptive and inferential reasoning is needed in order to make sense of differences and commonalities of two (or more) distributions and go beyond the data at hand. Thus, this activity is an important part of data analysis. The necessary concepts and insights are "multifaceted" (Ben-Zvi, 2003) as properties of and between distributions have to be considered. The aim of this paper is to explore students underlying informal resources and rationales as well as conceptual difficulties as starting points for establishing a suitable learning environment.

PROPERTIES OF AND BETWEEN DISTRIBUTIONS

From a normative perspective, comparing distributions statistically requires students to perceive a distribution as an "organizing conceptual structure with which they can conceive the aggregate instead of just the individual values" (Bakker & Gravemeijer, 2004, p. 148). Wild (1999) calls a distribution a lens, through which variation is looked at by "set[ting] aside case labels" (p. 11). This short descriptions already points out that a distributions is in fact a net of different intertwined concepts: Centre, spread, density and skewedness are *properties of* a distribution and constitute its shape (ibid., Ben-Zvi, 2003). "The concept of distribution has a complex structure, but this concept is also part of a larger structure consisting of big ideas such as variation and sampling (…). [One can] deal informally and coherently with all these big ideas at the same time with distribution in a central position." (Bakker & Gravemeijer, 2004, p. 149).

These properties can be approached formally (e.g. calculating arithmetic mean, mode and median as measures for the centre), but also in more phenomenological and visual ways (e.g., determining intervals with high density, gaps and clusters; cf. Pfannkuch et al. 2010 for the visual approach). For clarification, this paper uses 'properties' to refer to statistical concepts and 'features' to more visual aspects of a distribution.

Inherent in the statistical concept of distribution is the necessity to not only focus on single data points or small groups (so-called local view; Ben-Zvi & Arcavi, 2001), but to perceive a distribution as a whole, allowing to "search for, recognize, describe and explain general patterns in a set of data" (so-called global view;

Ben-Zvi & Arcavi, 2001, p. 38). Especially the latter is fundamental to statistical reasoning, but also challenging for students to acquire (ibid.).

When comparing two or more distributions, properties have to be put *in relation between* the distribution, adding further relative insights such as overlap, shift and unusual features (e.g. outliers; Pfannkuch et al., 2010; cf. Ben-Zvi, 2003 for comparing measures of variation within and between groups). The comparison can then also allow for new insights into the peculiarities of the initial distribution: For instance, looking at a set of temperatures from July 2014 on the mountain Zugspitze could become an indicator for the effects of global warming when put in relation to the distributions of the 1900s.

INDIVIDUAL APPROACHES TO COMPARING DISTRIBUTIONS

It is not surprising that this complex interplay of concepts is challenging for students: Recent research points out that taking a global view on distributions rather than focussing on single data points or groups is especially challenging (Ben-Zvi & Arcavi, 2001; Bakker & Gravemeijer, 2004). Problems persist even after instruction in statistics (Ben-Zvi, 2003; Konold et al., 1997): students who are familiar with formal measures such as mean and median for single distributions do not make use of them when comparing distributions (e.g., Watson & Moritz, 1999; Konold et al., 1997). As Konold and colleagues (1997) argue, this might indicate a lacking understanding of averages as properties that represent a distribution.

However, some informal strategies were repeatedly shown, which offer productive starting points for structuring learning pathways: Focussing on visually remarkable aspects of distributions (e.g., represented as dot plots), learners make use of informal concepts such as 'clumps', 'hills' or 'chunks' to describe and compare distributions (Bakker & Gravemeijer, 2004; Konold, 2002; Cobb, 1999). Konold (2002) for instance describes how students use ranges of data in the heart of the distribution ("modal clumps"), which he interprets as vehicles for describing the centre (average) and at the same time the variation of data points. Bakker & Gravemeijer (2004) show that students divide given distributions in three groups (low, middle and high), which are then interpreted in the given context and compared. They understand this as steps from a local to a more global view.

While many studies reproduced the use of informal descriptors such as 'bumps', it remains open what underlying rationale guides students in choosing or dismissing features such as modal clumps in situations involving the comparison of distributions. Understanding *why* certain foci are chosen to compare might provide further insights into how task design has to be structured to promote development of statistical reasoning. These questions call for research on the micro-level and reconstructing step by step the individual concepts activated by students and the foci they take on the distribution.

METHODOLOGY AND DESIGN OF THE CASE STUDY

The presented study is part of a larger design research project using the methodological framework of topic-specific Didactical Design Research (Prediger & Schnell, 2014; Prediger et al., 2012), which has two intertwined aims: (1) designing a teaching-learning arrangement to facilitate the acquisition of the concept of distribution by comparing distributions and (2) deepening the understanding of the processes of conceptual development on an epistemological level. The design research is conducted by iterative cycles of design experiments, consisting of closely related phases of (re-)structuring learning goals, (re-)constructing the teaching-learning arrangement, conducting and analysing the design experiments and developing local theories. By combining process-oriented analysis and construction of teaching-learning arrangement, this framework provides for the need of research on the micro-level outlined above. Situated early in the research process, this first design experiment cycle aimed to explore how students in German middle schools (informally) compare frequency distributions (represented as stacked dot plots) and identify individual approaches as starting points for task design. Specifically, the research aimed at finding answers to the following questions:

- (RQ1) Which individual concepts do students use to compare distributions?
- (RQ2) Which rationales guide students in choosing certain foci for comparing distributions?

Data collection

To investigate the complex processes of comparing distributions, we conducted and videotaped design experiments (45 to 60 minutes) in a laboratory setting (cf. Cobb et al., 2003) with three pairs of students, aged 13 to 15. To make sure that students were familiar with distributions as a prerequisite for the activities, we chose students who had learnt about box plots in class a few weeks before the experiments. With statistics playing only a small role in German mathematics education, the students learned to construct boxplots and interpret them in a course over six lessons. The focus was on formal methods, e.g., for determining the five parameters. There was only limited attention given to informally examining variation in terms of centre and spread. The students were not familiar with stacked dot plots. Guiding the experiments was the July climate task, comparing stacked dot plots of temperature on a mountain in July in different years (Figure 1).

Students were tasked with comparing the temperatures in July on the top of the Zugspitze in the years 2002, 2004 and later 2007 in order to determine the warmest month. Although the graphs were created in Tinkerplots, the students at this point had only access to the plots printed on paper to encourage informal statistical reasoning without focussing on pre-given measurement and tools. Later in the experiment, the students were also given boxplots that had to be matched with the according dot plots.

Data analysis

The fine-grained analysis is conducted under an interpretative paradigm using the framework of Vergnaud's Theory of Conceptual Fields (Vergnaud, 1996). To give insight into students' individual concepts, we adapted the theoretical construct 'concept-in-action', which is defined as "categories (objects, properties, relationships, transformations, processes, etc.) that enable the subject to cut the world into distinct elements and aspects, and pick up the most adequate selection of information" (Vergnaud, 1996, p. 225). The reconstructed concepts-in-action are symbolised as ||...|| and can provide for different functions: They can be the guiding category in *how* to compare distributions such as the ||*absolute frequency*|| *of dots under zero* (see episode 1 below). Furthermore, we found concepts-in-action which guide the students in *why* they choose certain aspects to compare, such as an ||*individual representativity of chosen intervals for the specific properties of a distribution*|| (see episode 2 below).

Concepts-in-action are not necessarily in line with normative mathematical ideas but guide the students' individual process of making sense of the situation. They are shown through action (ibid.) and can be uncovered through interpretation of the students' behaviour.

The in-depth analysis is so far limited to the case of Annika and Bastian; preliminary analysis showed that the other pairs are comparable in terms of focussing on visual features of the dot plots and determining absolute frequencies, but were less able to explain their reasoning behind certain actions and communicate their ideas and strategies. In the first step of the analysis of our data, we reconstructed the nature of this case from video, identifying crucial episodes of the students' reasoning process. These scenes were transcribed verbatim and annotated by both researchers separately. The goal of the analysis was to infer a) students' individual concepts-in-action when

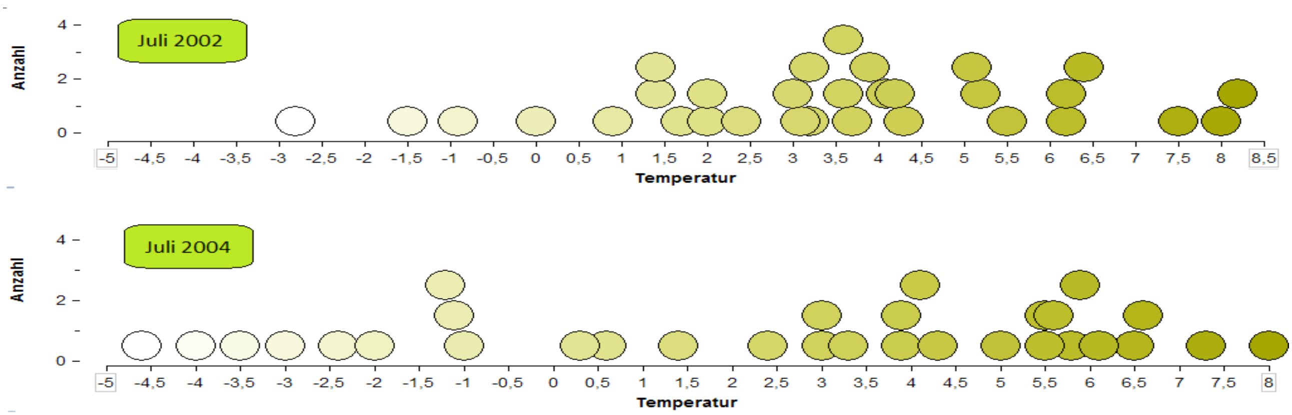

Figure 1: The stacked dot plots of the July climate task (July 2002 and 2004)

comparing the given distributions and b) students' underlying reasons for choosing specific foci on the distribution(s). The results of the analysis were then compared and discussed until a consensus on the interpretations was reached.

EMPIRICAL RESULTS

Annika and Bastian finished a lesson on statistics using box plots, but are unfamiliar with the representation of stacked dot plots. In line with other studies, they use exclusively informal methods to compare the presented distributions of temperatures. While they mention that it would be convenient to "have the arithmetic mean" or "use box plots" for "a better comparison", they are not making an effort to generate them. When presented with boxplots in the end of the interview, they have no trouble interpreting and matching them with the dot plots. This activity is rather superficial though and stays on a level of formal procedures rather than connecting insights acquired in the informal analysis of the dot plots. As mentioned above, this is in line with recent research. We will thus focus exclusively on the comparing activities concerning the dot plots.

Throughout the interview Annika und Bastian make use of various concepts-in-action guiding for comparing the distributions, which we present in Table 1 (RQ1). The concepts-in-action of ||*density*||, ||*value*||, and ||*spread*|| only appear rarely, as Annika and Bastian mostly focus on the ||*absolute frequency*|| and ||*position*|| of groups of dots. For this, they create so-called "sections" (intervals with groups of dots) within the distribution; this activity is mostly guided by the visually perceived 'hills' (a modal interval), which the students call "agglomeration area" (a geographical term, which might indicate that they also take the density into account). In Figure 2, we marked the sections, which the students address verbally or by gestures[1]: They first focus on the visual hill in 2002 (see Figure 2, section 1_{2002}). The number of dots in this interval is then compared with the number of dots in the same interval in 2004 (Figure 2, section $1_{2004;}$ episode 1 below gives more details on this comparison activity). Section 2 is defined by the agglomeration area in 2004; section 3 consists of the 'most right dots' (also right of the border of section 2) and section 4 is defined as left of the agglomeration area of 2002. In other situations in the interview, the students also make use of the scale and the context by looking at dots under or around 0°C or "dots in the colder interval".

The students focus almost exclusively on such groups of data points in a local view. However, the in-depth analysis uncovers that the students have features of the whole distribution in mind when comparing sections, as we will show in the next segment.

Episode 1: Comparing and equalising sections of distributions

25 minutes into the experiment, Annika is summarizing previous arguments of her and Bastian in favour of calling July 2002 the warmer.

1 Annika: If these were 11 dots in the agglomeration area *[circle in section 1_{2002}]*, and here are 8, then *[points to section 1_{2004}]*. Then that's a difference of 3 [...]

2 Annika: But .. Bastian says here *[points to section 2]* is also a difference of 3. So here in the agglomeration area *[in section 2_{2002}]* are 3

1 Dotted lines, circles and section numbers added by authors for clarification; circled are the previously identified 'agglomeration areas'; numbers indicate the order in which the sections are addressed by the students.

Concept-in-action	Activity
||Absolute frequencies of dots in certain intervals||	Comparing the (difference of) the amount of data points in chosen intervals
||Density in certain intervals||	Comparing the number of dots in relation to the width of the interval
||Position of certain (intervals of) dots||	Comparing the relative position of data points by 'left of'/'right of' or 'higher'/'lower than'
||Value of certain (intervals of) dots||	Comparing the temperature values of data points
||Spread of dots in certain intervals||	Comparing how spread out the data points are

Table 1: Concepts-in-action activated in comparing activities

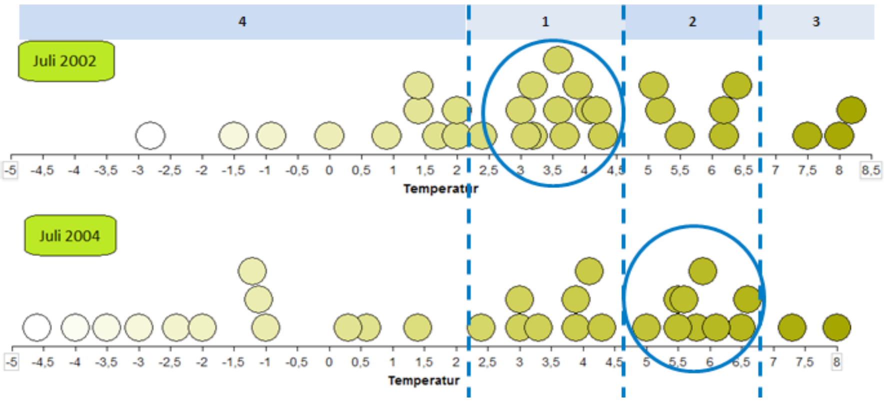

Figure 2: Annika & Bastian's sections when comparing the distributions

fewer and here in this agglomeration area *[in section 1_{2004}]* are also 3 fewer, so to say. Thus, it is even again, Bastian said.

In line 1, Annika compares the ||*differences of absolute frequencies*|| starting with the visual hills (circled in Figure 2): Each distribution's agglomeration area has three dots more than the corresponding section of the other distribution. Not activating a concept of ||*values*||, Bastian's reasoning as repeated by Annika seems to be that the differences between the distributions thus even out for these two sections (line 2). Therefore, the agglomeration areas alone might not be suitable to determine the warmer month and – according to Annika – other features have to be taken into account:

3a Annika: Thus I argued that – up here *[points to section 3_{2002}]* has one dot more; they are higher, too.
3b [cont'd] And all these dots *[points to section 4_{2002}]* are much more spread downwards *[points to section 4_{2004}]*. That is why in my opinion 2002 is warmer.

Annika now compares the distributions by the ||*absolute frequency*|| and ||*position*|| *of dots with highest value* (maxima; section 3, line 3a). In line 3b, her gesture pointing at the dots in section 4 of 2002 and saying "all these dots are much more spread downwards [in 2004]" seems to indicate that she assumes the same absolute frequency for the sections. Thus, it is the ||*spread*|| in combination with the ||*position*|| of the dots which makes the difference and lets her back up her argument that 2002 is warmer.

We call Annika's strategy 'equalising': When agglomeration areas are not useful for comparison as they are 'equal' in terms of absolute frequency, the other intervals have to be taken into account. In regard to RQ1, this episode highlights how the students use different concepts-in-action to compare distributions. Concerning RQ2 and the question of underlying rationales, we uncover how Annika seems to choose the outer intervals of the distribution and concepts-in-action other than ||*absolute frequencies*|| because she perceives the agglomeration areas – in this case of 'equal absolute frequencies' – as not helpful for the comparison.

Episode 2: Discussing the width of intervals for comparing

The determination of sections plays a crucial role throughout the students' comparative actions. At first, Annika and Bastian choose them spontaneously according to the perceived visual features of the distributions. When after 36 minutes the third distribution is discussed, they are asked to give a general rule for comparing distributions. Annika explains her strategy as "count how many dots are in the lower section and how many are in the higher section and compare them", stating that it is not useful to look only at the agglomeration areas as was established in episode 1. The interviewer then prompts the students to consider the choice of sections explicitly:

4 Researcher: And these sections you pick out, where do they come from? [...]
5 Bastian: What you just said about counting the dots *[points at Annika]*; I would definitely use the same distances. That means always 5, so to say: minus 5 to 0, 5 to 8.5 or 10 *[draws imaginary vertical lines through all distributions, indicated with dotted lines in Figure 3]* [...] because you always need equal sections [...]

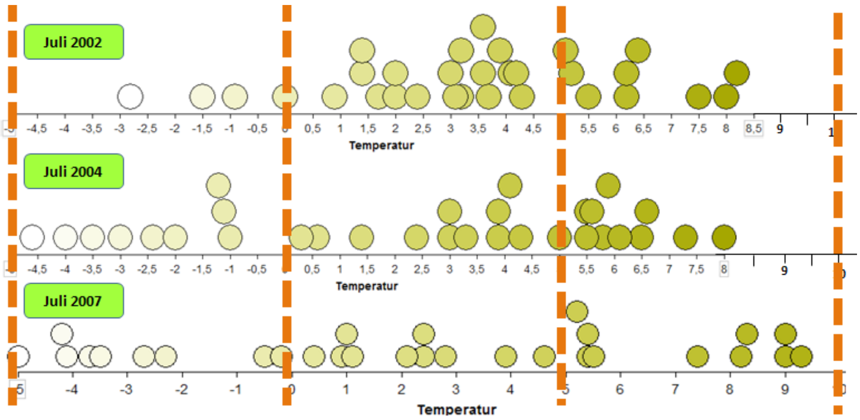

Figure 3: Bastian's proposed sections

6a Annika: Yes... *[5 sec]* I have to think about that again. *[looks at distributions, 27 sec]*

6b [cont'd] Well, I'm kind of undecided. On the one hand, I think that it makes sense. On the other hand I think why not take sections of different size? But then I think, then you can't compare it that well with the other sections, but can compare it still with the sections of the other years *[moves hand vertically over the three distributions]*. [...]

6c [cont'd] Well here, from minus 5 to 0, we simply use the step of 5 now. [The step] to [plus] 5 is not fitting though, because these dots *[points to dots just above 5° in 2007, circled in Figure 3]* are close to those under 5. [...] and that is why it is sometimes better to use different sections, because then points still just belong to it and are not already in another section.

In line 5, Bastian proposes an approach of choosing sections within a distribution due to a fixed width of the interval of 5. Annika however seems torn between the ideas of fixed and dynamic interval width (line 6b). To her, there seem to be instances where interval width can be chosen arbitrarily (from -5 to 0, line 6c), and where interval borders have to respect features of the distribution (from 0 not to 5, line 6c). Her reason "these dots are close to those under 5" might refer to the visual impression of 2007: the group of five dots around 5° (circled in Figure 3) are separated from others by gaps and thus form a visual unit. We interpret this as an indication of an underlying concepts-in-action: To compare different distributions, one has to take the gaps and groups into account. Thus, sections have to represent the specific visual features of a distribution, which we call an individual concept-in-action of || *representativity of a distribution's features*||.

In line 6b, Annika utters the underlying reason for her conflict: Annika seems to explicitly differentiate between comparing sections *within* a distribution and comparing sections *between* distributions: Sections of different widths (as in Figure 2) are worse for comparing them within a distribution, but due to their ||*individual representativity*|| better for comparing them with other distributions. This indicates a global view on the distribution which is Annika is dealing with by the informal approach of determining absolute frequencies in sections of different width.

CONCLUSION AND OUTLOOK

Consistent with literature (e.g., Bakker & Gravemeijer, 2004), the students organised the data through visual features such as modal clumps. The partition of the data however did not necessarily follow the structure of low-middle-high, but was informed by complex interplay of various concepts-in-action. The empirical snapshots show that these students are mostly focusing on the ||*absolute frequency*|| instead of the position of certain features in relation to each other and values of data points. Elaborate strategies such as 'equalising' combine different concepts-in-action and create individual rules of which features to compare in certain situation. The choice of sections in which absolute frequencies are determined are guided by an individual concept-in-action of ||*representativity*|| which does allow seeing the characteristic properties of one distribution but might be an obstacle to put different distributions in relation with each other.

The episodes shown in this paper are not intended to highlight deficits of the lessons students had for acquiring underlying concepts underlying box plots. Rather, the intention is to give insights into students' hidden individual concepts and reasons in order to understand the rationality of their activities. The presented reasoning processes have a lot of potential for a deep understanding and statistical reasoning, as a rich repertory of (in itself mathematically sustainable) concepts is activated and consciously combined.

Even though this phenomenon was so far discovered in the design experiment with only one pair of students, we take its possible impact on learning pathways seriously: In the next design experiment cycle, we will make room for students to explicitly address the question if and in how far it is necessary to represent a distribution's features for comparisons. We will carefully consider tasks to guide students in the shift from focusing on absolute frequencies to ordinal views of the relative position of features. Furthermore, our further research aims at uncovering other concepts-in-action guiding students in comparing distributions.

Changing beliefs about the benefit of statistical knowledge

Alexandra Sturm[1] and Andreas Eichler[2]

1 University of Education Freiburg, Freiburg, Germany, sturmfr@ph-freiburg.de

2 University of Kassel, Kassel, Germany, eichler@mathematik.uni-kassel.de

In this day and age, statistically-based information is nearly omnipresent in daily media like newspapers or TV. Therefore, people need skills to read and interpret such information adequately. Due to the fact that previous research shows that sometimes statistical knowledge was improved without seeing the usefulness of this knowledge, we focus on improving both statistical knowledge and beliefs about the benefit of statistical knowledge. We examine whether a short-term (two hours) intervention has measurable influence on knowledge and beliefs of students at school and university, who have different mathematical foci. In this paper we discuss the design of our study and mainly focus on the intervention.

Keywords: Statistics, beliefs, attitudes, intervention study.

INTRODUCTION

The ability to read, to understand and to judge statistical information adequately has become increasingly important in our information society for everyone. The National Council of Teachers of Mathematics [NCTM] (2000, p. 48) highlights this significance in its 'Principles and Standards for School Mathematics': "The amount of data available to help make decisions in business, politics, research, and everyday life is staggering." Accordingly, the NCTM emphasizes that statistics skills are necessary for students "to becoming informed citizens and intelligent consumers" (ibid.).

There is a wide consensus that the ability to properly interpret quantitative data and, thus, to properly interpret statistical data in daily life is based on knowledge elements, but also on beliefs about the importance of statistics for society or the own life. For example, Wallman (1993) describes the term statistical literacy as "the ability to understand and critically evaluate statistical results that permeate daily life, coupled with the ability to appreciate the contributions that statistical thinking can make in public and private, professional and personal decisions" (p. 1). Emphasizing knowledge elements as part of statistical literacy seems to be self-explaining. Further, Gal (2004, p. 69) suggests dispositional elements including "the willingness to invest mental effort" to be a second part of statistical literacy. It can be assumed that beliefs and attitudes have consequences on using knowledge learned before: Schau and Emmioglu (2012, p. 86) suggest "that students who leave their statistics courses with negative attitudes are unlikely ever to use what they have learned. That is, they will not intelligently and literately use statistics in their professional and personal lives or in any educational venture".

Accordingly, an educational goal all over the world is developing statistical literacy including both knowledge elements and dispositional elements (Shaughnessy, 2007). But research shows that students being schooled in statistics before could have improved knowledge, but not improved beliefs (Schau & Emmioglou, 2012; Eichler, 2011). Therefore, a possible assumption is that statistical literacy is only sustainably developed if both parts, i.e. knowledge elements and dispositional elements, are developed appropriately.

As a consequence of the discussion above and taken into account that research shows that even adults are predominantly in a struggle with handling statistical information (Gal, 2004), our research project aims to investigate the relation of knowledge elements and dispositional elements when developing statistical literacy. For this reason, we developed an intervention aiming to improve both knowledge elements and dispositional elements. Students' beliefs, their perception referring the significance and benefit of statistics for both society and their own life, are a main focus of our research. We investigate students' perception referring to different samples. Firstly, we investigate students at university that use mathematics in a different way: Students of mathematics education, students of health education that have to apply mathematics and students of pedagogy that do not use mathematics in their university studies. Each subsample will comprise at least 60 participants. Further, we will investigate students at school (grade 11, age 17) in a second step of our study.

In the first part of this report, we outline the main constructs of our research by describing a model of statistical literacy and by specifying the construct of beliefs. Subsequently, we present a specific statistical topic which we address, i.e. theorem of Bayes, and partly the problems of the area of 'risk communication' respectively 'health literacy' used in our intervention. Afterwards, we outline such a statistically-laden situation and its visualization before discussing methods aiming to investigate knowledge and beliefs as a part of statistical literacy. Finally, we present first results of the intervention with 118 students of health education.

A MODEL OF STATISTICAL LITERACY

We use the construct of statistical literacy to describe students' ability to cope with statistical-laden situations. For describing statistical literacy, we primarily refer to the model of Gal (2004, p. 51; cf. Table 1). Gal's model describes both knowledge elements and dispositional elements as constituent parts of statistical literacy, similar to Wallman (1993). The left side of the model comprises five components which are briefly presented in the following, starting with the three non-mathematical and non-statistical aspects. Literacy skills are necessary to perceive information through an oral or written text, whereas context skills are necessary to perceive a certain context in which data are produced. Critical questions include the ability to be aware of possible manipulations in reports that are based on statistics. Further, Gal (2004) distinguishes between mathematical and statistical knowledge. We avoid this distinction in our research approach and subsume mathematical knowledge to statistical knowledge, although it's possible to differentiate these components by defining certain mathematical procedures as parts of a specific statistical knowledge (Gal, 2004).

Since we focus especially on the dispositional elements of statistical literacy, beliefs and attitudes, we will briefly outline our understanding of these constructs to discuss the right side of Gal's model.

BELIEFS AND ATTITUDES AS ELEMENTS OF STATISTICAL LITERACY

Following Hannula (2012), beliefs and attitudes are parts of mathematics-related affect. We understand the term belief as an individual's personal conviction concerning a specific subject, which shapes an individual's way of both receiving information about a subject and acting in a specific situation (Pajares, 1992). Although sometimes beliefs are understood as stable, we are aware that stability is no inherent and definable characteristic of beliefs (Liljedahl, Oesterle, & Berèche, 2012). In contrast to rather cognitive beliefs, attitudes embrace the more affective part of mathematics-related affect (cf. Hannula, 2012). According to McLeod (1992, p. 581), attitudes could be defined as "affective responses that involve positive or negative feelings of moderate intensity and reasonable stability". For example, beliefs about the benefit of statistical knowledge can be measured by items as "statistics is necessary to understand decision making in society", because it's an indicator of an individual conviction and, thus, a belief. By contrast, agreeing "I like statistics" indicates a favor towards an object, statistics, and, thus, an attitude (cf. Eagly & Chaiken, 1998).

Knowledge elements of statistical literacy	Dispositional elements of statistical literacy
Literacy skills	Beliefs and Attitudes
Statistical knowledge	Critical stance
Mathematical knowledge	
Context knowledge	
Critical questions	

Table 1: Aspects of statistical literacy

Concerning beliefs, which are our main focus in comparison to attitudes, we further distinguish between beliefs towards the world and beliefs towards the self. For example, it is possible that a student believes that statistics provides a benefit for the society in a global sense on the one hand, and evaluates further his ability to use statistics in his own life on the other.

Research referring to stability of beliefs in mathematics education shows that positive influences on beliefs are partly very rare (Eichler, 2011; Maaß, 2010). Therefore we discuss in the following ideas which we used in our intervention to address positive beliefs towards statistics.

PROMOTING KNOWLEDGE AND DISPOSITIONAL ELEMENTS

Principles of the intervention

Principles for the design of our intervention are based on possible reasons why students' do not appreciate the benefit of statistics for society or their own life. Firstly, it is possible that statistics is not part of the curriculum (cf. Burrill, 2011). A second possible reason is that statistics is part of the curriculum, but teachers do not teach it, because of a self-estimated lack of time or feeling uncomfortable with statistics (Eichler, 2011). Another possible reason is that statistics is taught, but in an inappropriate way of teaching: using not-application-oriented contexts and problems (we point out an example in Figure 2).

In our intervention, we try to meet requirements for application-oriented contexts that potentially highlight the relevance of statistics for students sustainably. Further, we formulated three requirements for an appropriate subject matter that

1. emphasizes the benefit of statistics for both society and, in particular, individual's life;
2. focuses on an issue that is not common for students;
3. focuses on an issue for that exist elaborated strategies for designing a potentially effective short-term intervention.

In our opinion, the Bayes' theorem fulfills all these requirements.

Firstly, the Bayes' theorem is existent in daily media (cf. Figure 3) which is in our opinion an indicator for emphasizing the benefit of statistics for the society and an individual.

Further, concerning the second requirement, the Bayes' theorem or rather Bayesian thinking is not commonplace (Sedlmeier & Gigerenzer, 2001) and it is taught at school rarely. Thus, this subject potentially gives evidence about the benefit of statistics in a field in which adults without training in Bayesian thinking mostly fail to give correct estimations of probabilities (Sedlmeier & Gigerenzer, 2001).

Finally, as a consequence of findings in educational research, there are different strategies to improve understanding referring Bayesian problems. E.g., Sedlmeier and Gigerenzer (2001) found that representing the statistical information in a problem as natural frequencies increases the rate of correct estimations. Further there is evidence for the efficiency of two visualization-forms in short-term interventions: The tree with natural frequencies (ibid.; Wassner, 2004) and the unit square (Bea, 1995).

The intervention

As mentioned above, we laid emphasis on an authentic and application-oriented context. An analysis of textbooks showed a considerable amount of less authentic contexts. For example, the question in the task referring Bayes formula shown in Figure 2 seems

Excercises

A car dealer recieves cars from two different factories (A and B). 65% of the cars from factory A and 75% of the cars from factory B have no failure in the guarantee period.

What is the probability that a car was produced in factory B given a failure in the guarantee period?

Figure 2: A task with a context that is not authentic

HIV-rapid-test for a home usage: An effective less-than-ideal- solution

From Irene Berres

The Food and Drug Administration (FDA) permits a HIV-rapid-test for a home usage. The simplified method could yield an increased number of persons that using a HIV-test. However, missing guidance includes risk ...

Figure 3: Headline in a German online-newspaper (translated)

to be irrelevant, since the car dealer could know the answer of this question without using Bayes' formula.

By using actual newspaper articles and leaflets (Figure 3), we tried to present the students an authentic situation, i.e. a situation that could potentially be a real problem for the student in their future life.

This material should also contribute to recognize and emphasize the significance of the content. Based on the appropriate examples of Boer (1993), Wassner (2004), Pinkernell (2006) and Beckmann (2013), the intervention involves three main-contents: HIV-Testing, breast-cancer-screening and prenatal screenings.

A second characteristic of the intervention should be its comprehensibility. For this, we use natural frequencies additional to relative frequencies or rather probabilities for the representation of quantitative information in the tasks. Natural frequencies simplify the Bayes' theorem for students, who have only to relate numbers to each other instead of calculating a complex formula that entails three multiplications. The research of Gigerenzer and Hoffrage (1995) shows that representing statistical information as natural frequencies increases the ability to solve Bayesian problems. A possible reason for this effect is that the nested sets structure becomes more salient. Nonetheless, in newspaper articles, TV and other everyday situations probabilities are often used, so that we didn't want to drop probabilities.

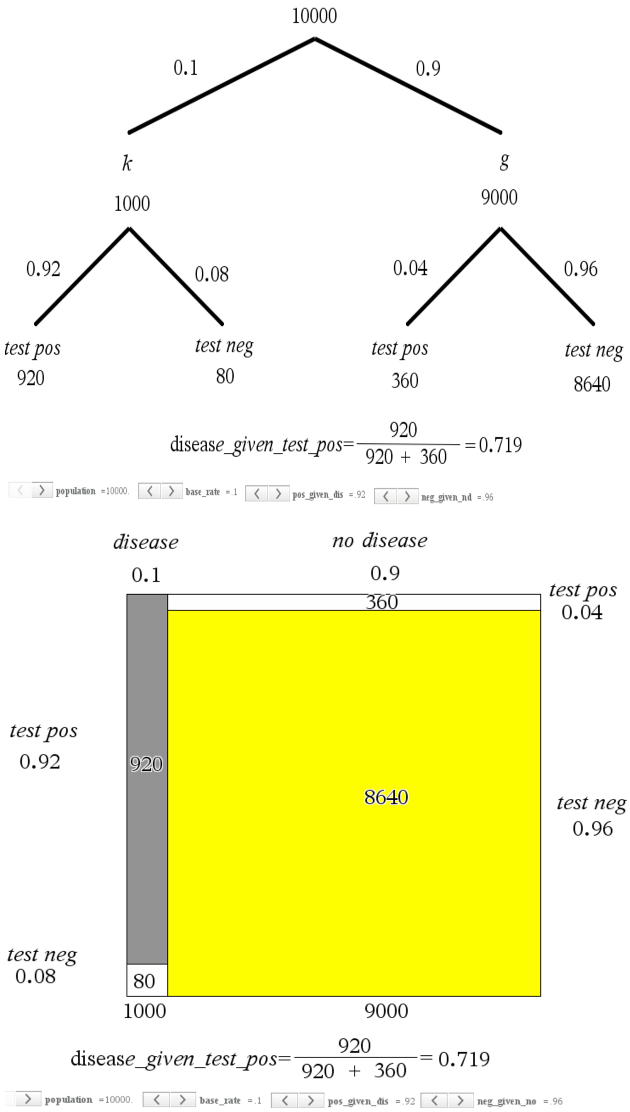

Figure 4: Tree diagram and unit square with natural frequencies

We further use the tree diagram (Wassner, 2004) and the unit square (Bea, 1995) with natural and relative frequencies that we illustrate in Figure 4 for a fictive situation of a disease-test.

Both diagrams are helpful to apply and understand the Bayes' theorem (Sedlmeier & Gigerenzer, 2001). While the advantage of the tree diagram is visualizing the chronological sequence of the given information, the advantage of the unit square is visualizing the proportions. This aspect seems to be especially helpful in cases when parameter were changed (Eichler & Vogel, 2010). Furthermore, we avoided using formal Bayes' theorem and difficult terms like sensitivity or specificity to support the comprehensibility.

As mentioned above, the three main-contents of our intervention mainly refer to a diagnosis of a disease (HIV-Testing, breast-cancer-screening and prenatal screenings) and the problems could be solved by using Bayes' theorem. In each problem, a base rate of a disease or an infection and conditional probabilities representing the right-positive rate (probability of a positive test result given a disease) and representing the false-positive rate (probability of a positive test result given no disease) have to be arranged according to Bayes' theorem to compute the probability of disease given a positive test. We think that a further interesting content are doping-tests. They have a high significance in sports and provide a great basis for modeling, because the base rate is unknown (estimated 20–35 %, cf. Pitsch, 2009) and the sensitivity- and specificity-values of used doping-tests are not published by WADA (World Anti-Doping Agency), so they must also be estimated (Pitsch, 2009). But in respect on this complexity it's not appropriate for our short-term intervention.

The tasks potentially promote a critical stance as a crucial part of statistical literacy. For example, possible critical questions could refer to the following issues:

— What happens, if the sensitivity of the test would be better (the probability to get a positive test result given the HIV infection)?

— What happens, if the test is used in another country like Germany (the base rate for HIV is 0.4% in US, but 0.1% in Germany)?

— What happens if the specificity of the test is not as good as the producer of the test indicates (the producer indicates that a person that is not infected gets in 99.98% of the cases a negative test result).

Other questions that integrate context in a broader sense could be: "Why could a confirmatory test be necessary?" or "Should the German administration permit the approval of HIV-rapid-tests for home usage? Which reasons are arguments against it, which do support the approval?"

As the context like disease could be potentially significant for students, we hypothesise that particularly critical questions could improve the students' beliefs referring the relevance of statistics for both society and the students' own life.

First results of the ongoing study

In November 2014, 118 students of health education (age: mean=21.72, sd=2.9) were assessed pre- and post-intervention and after two week follow-up. Their beliefs and attitudes were measured by a questionnaire which comprised e.g. two components of the Survey of Attitudes Towards Statistics (SATS-36©): value and interest of statistics (Schau, 2005). The range of coefficient alpha values for the interest-component varies from .868 to .879 for the different measurement times. The scale shows thereby a high internal consistency. The mathematical and statistical knowledge elements of statistical literacy were assessed by Bayesian-situation-tasks. Students were asked to estimate the right percentages of those people who are infected given a positive test result. As expected, students showed a low performance before the intervention and a high performance after the intervention for these tasks.

DISCUSSION AND CONCLUSION

There seems to be a discrepancy between the enormous relevance of statistics in our society and the poor relevance of statistics often assigned by students and adults. It is on the one side possible that these students (or adults) have little statistical knowledge and, hence, do not appreciate the benefit of statistics for both, society and own life. However, research shows that even students with considerable statistical knowledge assign statistics little or rather no relevance outside school mathematics (Eichler, 2008).

As a consequence to these findings the main aim of our research is to investigate the relation of developing knowledge elements and developing dispositional elements of statistical literacy. For this reason a main challenge of our research is to develop an intervention that potentially improves both elements of statistical literacy, i.e. knowledge elements and dispositional elements. We provided the example of the HIV-test that potentially fulfills three requirements of the intervention that we defined. Firstly the HIV-test represents an authentic context that is controversially discussed in daily newspapers and official statements. Further the context of Bayesian problems is not common for most of the students or adults and, thus, could serve as a new example showing the significance of statistics. Finally, there exist elaborated and empirically proved ways to teach Bayesian thinking that facilitate an intervention that is not linked to a regular statistics course at school. In this paper we provided the tree diagram and the unit square connected with natural and relative frequencies as possible strategy to represent the information in a Bayesian problem appropriately.

To investigate the mentioned connection of the development of knowledge elements and dispositional elements we vary the population in different samples. Since we regard students at school as possible future audience for our intervention, we regard also students at university that show different characteristics that are, from a theoretical perspective, important referring the status of statistical literacy: The first sample consists of prospective mathematics teachers who potentially have a considerable amount of mathematical knowledge as part of statistical literacy. The second sample consists of students of health education who potentially hold context knowledge referring to the HIV-test and who potentially need this knowledge in their professional careers. Students of both samples could either show positive beliefs or negative beliefs about the relevance of mathematics or statistics. However, first results show that it seems to be possible to influence the statistical literacy referring to his dispositional elements in a short term intervention as our investigation referring the students of health education imply. We expect to present further results of the impact of our intervention described in this paper at the conference.

Understanding the knowledge demands of teaching statistics: Insights gained from examining practice

Aisling Leavy

Mary Immaculate College, University of Limerick, Limerick, Ireland

This research examines the knowledge demands placed on 73 pre-service teachers who are observed as they plan, teach and re-teach data lessons in classrooms. Problems of practice are identified and categorized using the Ball, Thames and Phelps (2008) subdomains of common content knowledge (CCK), specialised content knowledge (SCK), knowledge of content and students (KCS) and knowledge of content and teaching (KCT). The results provide insights into the specific knowledge demands placed on early career teachers when teaching data and statistics and identifies the ways in which these knowledge demands are revealed as pre-service teachers engage in Japanese Lesson Study. The results illustrate that development of understandings in one knowledge subdomain can motivate and impact learning in another subdomain. These interrelationships were found to exist both within and between the domains of content and pedagogical content knowledge.

Keywords: Teacher knowledge, statistics, teacher education, lesson study.

BACKGROUND

The publication presents the research findings on the knowledge demands of teaching elementary school data lessons and illustrates how particular stages of the research process (Lesson Study) provides insights into specific subdomains of knowledge required to teach statistics.

THEORETICAL PERSPECTIVE

This research uses the Ball and colleagues' (2008) practice-based theory of content knowledge for teaching to identify the mathematical knowledge needed for teaching primary level statistics. These insights into the knowledge components of statistics teaching were generated from looking at *teaching in action* in classrooms and are motivated by the belief that the knowledge teachers need to teach well is embedded in practice (what Cochran-Smith and Lytle (1999) term 'knowledge-in-practice'). Hence the study uses the classroom as the unit of analysis. It is through using the mathematics lesson, and its enactment, as the focus of pedagogical and mathematical inquiry, that insights into particular knowledge demands placed on teachers when teaching statistics are revealed.

METHODOLOGY

The use of lesson study (Lewis & Tsuchida, 1998) provides an avenue to reveal knowledge demands as they arise in the context of planning and teaching primary level data handling lessons. This paper reports on the findings from three years of research carried out with 73 Irish pre-service primary teachers , detailed findings can be sourced from the original publications (Leavy, 2015; Leavy, 2010).

SUMMARY FINDINGS

- The research revealed was the complexities of teaching statistics for early career teachers in particular in terms of the wide and varying knowledge demands placed on them.

- The knowledge needed for teaching primary level data needed to be more flexible, robust and interconnected. Evidence of knowledge needs arose in the pedagogical knowledge subdomains of *knowledge of content and students* and *knowledge of content and teaching*.

— Addressing knowledge demands as they arose in one knowledge domain lead to development of understandings in the other. Attention to pedagogical knowledge (in this case *knowledge of content and teaching*) lead to knowledge developments in 'pure' content knowledge (in this case *specialized content knowledge*).

— Tackling the questions and misconceptions posited by the children, and reconsidering teaching activities and representations in light of these questions, precipitated pre-service teachers in really tackling and unpacking (Ma 1999) their own content knowledge understanding of statistical concepts.

— Lesson study as a valuable site for examination of the knowledge demands of teaching statistics.

Developing statistical literacy: The case of graphs with preservice teachers

Ana Paula Canavarro

University of Évora, Évora & University of Lisbon, Research Unity of Institute of Education, Lisbon, Portugal

The poster identifies the dimensions of graph exploration and analysis of 18 pre-service primary teachers using Tinkerplots. Although some students use the software to explore different graphs and reveal some creativity, the majority seems not to "understand data", nor to "think about data".

Keywords: Statistical literacy, dimensions of graph exploration/analysis, TinkerPlots.

FOCUS AND RELEVANCE

This study focuses on the statistical literacy of pre-service primary teachers, namely in what concerns their use of statistical graphs for interpretation of real life situations. It is our purpose to analyse the graphs they create and use when they are asked to represent and to give meaning to particular situations based on numerical data and to identify the dimensions they reveal in what concerns the exploratory data analysis in the context of the graphing environment TinkerPlots: Dynamic Data Exploration. Statistics technologies offer extended possibilities to statistics education of all persons of the society. It is very important that future teachers learn how to use statistics software not only to draw graphs but also to improve their statistical literacy, in which data and graph sense are essential aspects.

BRIEF THEORETICAL FRAMEWORK

Statistical literacy is a key issue in the orientations of the current mathematics curricula. It comprises the capacity of interpreting, critically evaluate and make judgments concerning statistical information and messages based in data or chance phenomenon (Gal, 2003). Research shows that both students and teachers experience many difficulties with statistical literacy, namely when the situations in study appeal to a more sophisticated use of statistical knowledge, associated with the interpretation and attribution of meaning to statistical information, expressed as numbers or graphs. These difficulties also arise when the situations require assessment and critical judgment of conclusions derived from statistical studies (Shaugnessy, 2007).

The use of software that allows exploratory data analysis can help to further extend the analysis of a given situation. Fitzallen (2013) developed a framework for analysing the way in which the students worked within learning environments like TinkerPlots to create and interpret graphical representations, based on previous studies by Friel, Curcio, and Bright (2001), Moritz (2004), Pfannkuch and Wild (2004), and Shaughnessy (2007) in relation to graphing and graph sense-making. She proposes four interrelated dimensions for analysing the graph exploration of the students when using Tinkerplots: "Generic knowledge", "being creative with data", "understanding data", and "thinking about data" (Fitzallen, 2013).

METHOD

We adopted the design of a case study of pre-service primary teachers. Data were collected in the context of their classes of Didactics of Mathematics, where these students were asked to produce written responses concerning the analysis of different situations involving data exploration and analysis. One example is the study of the weight of backpacks of children. Data analysis was based on Fitzallen's framework.

PRESENTATION OF RESULTS

In the poster we include some written responses of the pre-service teachers, showing the diversity of graphs they produced to represent the situations of the tasks.

CONCLUSIONS AND IMPLICATIONS

Although some pre-service teachers used Tinkerplots to explore different graphs and revealed some creativity, the majority seems not to understand data, nor to think about data. This stresses the importance of including technology in teacher training.

ACKNOWLEDGEMENT

This study is supported by national funds by FCT – Fundação para a Ciência e Tecnologia through the Project Developing Statistical Literacy (contract PTDC/CPE-CED/117933/2010).

Statistical variability: Comprehension of children in primary school

Erica Cavalcanti and Gilda Guimarães

Universidade Federal de Pernambuco, Education Center, Recife, Brazil, erica_cavalcanti@yahoo.com.br, gilda.lguimaraes@gmail.com

This study examined the understanding of 48 Brazilians students of 2nd and 5th grades (seven and ten years old) of statistical variability of data in bar charts. A Piaget's clinical interview was conducted involving four activities of variability: description or explanation of the variability; representation of variability; prediction results from the variability of the data; comparison between data sets. Students showed ease in recognizing endpoints, but did not make predictions based on what they had observed. The representation of the variability was shown to be an important factor in data interpretation. Make comparison between data sets was complex for most students. Therefore, it is necessary to promote interrelationship among different aspects in order to make students reflect on the data and predictions.

Keywords: Data variability, teaching of primary school, graphs.

CONCEPT OF STATISTICAL VARIABILITY

The variability concept is essential to statistics, since there would be no need to do statistics if the data does not vary. Despite the centrality of the concept, few studies systematically investigated conceptions of students from primary schools, with activities involving different aspects of variability with the same students. According to Garfield and Ben-Zvi (2005), a deep understanding of the concept of variability requires the exploration of its components since the early years, which justifies the need of the present study. Aspects of such components were selected and explored in four activities with students of public schools in Recife - Brazil. These activities were adapted from previous studies of Watson & Kelly (2002), Watson (2009) and Kader & Perry (2007).

The first activity consist of a bar chart about children's arrival at the school and explored the explanation of variability, mode, prediction from the mode and comparison of categories. In the second activity, manipulated cards were offered to the students. These cards represented a number of books read by the children. They were asked to explain variability and make predictions. The third activity was asked to compare quantitative data sets presented in bar graphs and in the fourth activity was asked to compare qualitative data.

A description or explanation of the variability shown in graphic was possible for most individuals in the 5th grade, but not for individuals in the 2nd grade ($t (46) = 3.93$, $p < 0.001$). When the activity discussed representation of data explanation, both groups were able good performance.

The representation of the data variability was also significantly easier for students in the 5th grade ($t (46) = 2.75$, $p = 0.009$). It was noted that only individuals in the 5th grade were able to organize cards by drawing a bar graph.

Although students in the 5th grade had shown a significantly superior performance compared to individuals in the 2nd grade when asked to identify the mode on the graph ($t (46) = 2.75$, $p = 0.009$), at the moment of the prediction from the mode, the performance was as low as it was for the group in the 2nd grade. Regarding the prediction of results in situation of representation of variability (from the highest point), half of students in the 5th grade were able to prove them appropriately, with a significant difference to the 2nd grade ($t (46) = 2.17$, $p = 0.035$).

Finally, there is the aspect related to comparison between data sets. For both groups, these activities were complex, regardless the type of data presented to be qualitative or quantitative. Kader & Perry (2007) argued that the comparison of qualitative data (categorical) would be something intuitive. Thus, a better performance from students in the 5th grade could be expected in the comparison between these sets, but that was not confirmed. Hence, this may suggest that even in the case of qualitative data, comparisons between sets are not as intuitive as they could imagine.

This study has as main contribution the analysis of different aspects related to variability investigated with the same students, showing degrees of difficulties within the aspects observed. We emphasize the need to lead students to establish the relationship between different aspects of variability so that they are able to make prediction results from what they observe.

Difficulties in learning statistics: An experiment with young children

Susana Colaço

Escola Superior de Educação do Instituto Politécnico de Santarém, Santarém

Universidade de Lisboa, Centro de Investigação Operacional, Lisboa, Portugal, susana.colaco@ese.ipsantarem.pt

The poster presents the main difficulties of 2nd grade students in an experiment which involves tasks of collecting, organization and analysis of data. The results show that the main difficulties of these students are related to representing the data using charts and their interpretation. Using real contexts may facilitate the interpretation of data but may provide the existence of misinterpretations, derived from the students' own experience.

Keywords: Statistics, learning, first grades, charts.

LEARNING STATISTICS IN THE FIRST GRADES

The teaching of statistics in the early years must take into account that the collection of data should be meaningful to the children and a set of decisions must be taken, by the children, to represent the data and to be able to interpret it (Pereira-Mendoza, 1986). Gil & Ben-Zvi (2011) claim that knowing and understanding the real contexts of a statistical task plays an important role in students' performance. Also, Langrall, Nisbet, & Mooney (2006) say that this knowledge is important to engage students in statistical tasks. The same authors, on the other hand, report that in some situations conflicts exist between the knowledge about the real context and statistical data.

Several studies investigated difficulties in graphing and interpreting graphs. Curcio (1987) presented three levels of students' comprehension, namely, reading the data, reading between the data and reading beyond the data. Additionally Friel, Curcio, & Bright (2001) identify critical factors that appear to influence the graphs comprehension. Moreover, these authors mentioned the importance of context in graph comprehension.

METHOD

This poster presents one experiment of collecting, organization and analysis of data performed in a 2nd grade class. The goal was to understand what were the main difficulties of the students during this experiment, from the initial question: Will we weigh more than last year? And understand to what extent the real context may or may not be a facilitator in this process.

The main instruments of data collection consisted of two lessons that involved Collecting, Organizing and Data Analysis (CODA), observation, video recording and documents produced by students.

RESULTS

The experiment, began with the contextualization of the initial question. It was the first time that these students worked with CODA. Several difficulties were identified in these experiments: 1) data collection: recording of current weight rounded to one decimal place; confusion on how to register the data when faced with more than one answer; 2) data organization: were unable to choose a proper scale for the bar graph; 3) data analysis: when discussing the data represented several questions arose – confusion regarding the number of answers when compared with the number of participants.

DISCUSSION

It was found that using a real context with which the participants identified and sometimes resorting to their own experience ended up making the formulation of the problem and the planning of data collection easy to understand. On the other hand, misinterpretations were introduced due to the real context/experiences that were not explicit in the data, for example confusion between height and weight. These "conflicts" between the data and real context are similar to what is described in Langrall and colleagues (2006) and Ben-Zvi, Aridor, Makar and Bakker (2012).

An obstacle to teaching hypothesis testing to future managers: The plurality of conceptions related to the concept of variable

Roxane Jallet-Cattan[1] *and Corinne Hahn*[2]

1 ESSCA & ESCP Europe

2 ESCP Europe, Hahn@escpeurope.eu

The teaching of hypothesis testing is an important part of business statistics curricula but it is most of the time reduced to its operational dimension. We claim that other historical and systematic dimensions should be better taken into account. We have focused our research on exploring the teaching and learning of hypothesis tests for the difference between two means. In our poster, we present the results of the first stage of our research: we have studied how this test was introduced in business statistics books and how it was integrated into the structure of each book.

Keywords: Hypothesis testing, business statistics, variable

For the past few years in France the teaching of statistics has been reduced in many areas of higher education, particularly in management sciences. It is often replaced by learning to use technological "black boxes", reducing the teaching of statistics to learning a set of techniques and emphasizing what Fabre (2010) calls the operational dimension of knowledge. We claim that it is important to take into account the other two dimensions, historical and systematic, as well.

THE NOTION OF HYPOTHESIS TESTING

We have focused our research on statistical hypothesis testing. We have known for a long time that it is a difficult notion (for an extensive review see Batanero, 2000). Some authors have recommended abandoning it in favor of confidence interval (Cumming & Finch, 2005). Misconceptions by students and professionals or statisticians, have been widely studied (see for example Batanero, 2000, Falk & Greenbaum, 1995, Sotos et al, 2009). It seems to us that most of these misconceptions can be explained by the primacy given to the operational dimension. History tells us that the commonly taught hybrid form incorporates elements of Fisher's theory and elements of Neyman-Pearson's. This dual epistemology, rejected by some elsewhere as impossible to combine, is rarely made explicit and leads to confusion between pvalue and significance level (see Hubbard et al, 2003, Lehman, 1993).

SYSTEMATIC DIMENSION

Beyond this extensively documented error, it seemed that the systematic dimension, i.e. the entry into a structured corpus of knowledge, also posed problems given the different statuses that some concepts can take in descriptive statistics and inferential statistics. Some authors challenge the very notion of the existence of two different areas within statistics (Konold and Pollatsek, 2002). We feel that to not identify descriptive statistics leads to deny the complex epistemology of the discipline. Standard deviation can be viewed either as an indicator of the intensity of noise (inferential statistics) or as an indicator of the amount of information (descriptive statistics). The question is how we link the two conceptions.

THE RESEARCH

We have focused our research on exploring the teaching and learning of hypothesis tests for the difference between two means. In our poster, we present the results of the first stage of our research: we have studied how this test was introduced in 8 business statistics books and how it was integrated into the structure of each book. A central element seems to be the way the author "gives meaning to the letters," in the words of Malisani and Spagnolo (2009), and incorporates the concept of variable in its different forms. To perform the structure analysis, we relied on the typology proposed by these authors and have adapted it to the field of statistics.

Students' beliefs about statistics: Lessons from a journalism statistics class

Dun Nkhoma Kasoka

University of Malawi, The Polytechnic, Zomba, Malawi, dkasoka@poly.ac.mw

The poster summarises and presents findings, in part, of my classroom study on students' beliefs about statistics. Specifically, the poster presents some statistical evidence of the existence of students' beliefs about statistics and how these changed over the study period towards greater disagreement with the belief that statistics was just a 'subject' forced on students studying for a diploma in journalism. The students became more appreciative of statistics in journalism by the end of the study period.

Keywords: Statistics, beliefs, journalism.

INTRODUCTION

The application of statistics in the society today is common and obvious. In particular journalists use statistics for handling, interpreting data and decision making. Unfortunately, most diploma in journalism students at the Polytechnic seem unaware of the obvious role of statistics in their profession. This can be attributed to several factors such as teaching methods, beliefs and attitudes, modes of assessment and students' background. For students, beliefs and attitudes shape their cognitive developmental processes and their ability to learn statistics (Bartsch, 2006; Ramirez, Schau, & Emmioğlu, 2012; Schau & Emmioğlu, 2012). Griffith, Adams, Gu, Hart and Whitehead (2012) observe that learning and success in statistics are influenced by not only cognitive, demographic and pedagogical factors, but also by "affective and attitudinal factors among students" themselves (p. 46). As argued by Ramirez, Schau and Emmioğlu, positive attitudes help learners use what they have learnt hence journalism students' attitudes and beliefs are significant in their learning of statistic. Furthermore, Kesici and Erdogan (2009), and Torner (2002) suggest that when students hold and use motivational beliefs, their level of success increases. While considerable research has been carried out on students' beliefs in Malawi, the focus has mostly been on primary and secondary school mathematics.

THE STUDY

The study involved 102 diploma in journalism students in three cohorts who took an introductory statistics module. A questionnaire was constructed based on theoretical considerations and previous studies (Bond et al., 2012; Ramirez, Schau, & Emmioğlu, 2012). The questionnaire had 18 items covering students' beliefs about the nature of statistics, teaching and learning methods, students' statistical competency, the role of lecturer, and importance of statistics. All the students completed the 'statistics beliefs' questionnaire twice; at the begging and end of the semester. Component analysis, correlation and reliability tests were performed. Results from the analysis are presented as factors to be retained, loading for each factor, correlation between factors and internal consistency of reliability.

RESULTS AND DISCUSSION

The analysis showed that there were four factors that could be extracted; Lecture and learning statistics, usefulness of statistics, statistical competency, and statistical excellence. Furthermore, the analysis of loading on each item strongly converged on the first and second factors. However, there was an imbalance of items among the factors. This suggests a need for improving the questionnaire. The first factor comprised of seven items that formed a cluster of two components of beliefs about how statistics is learnt and the role of lecturer. The observation is in line with Schau and Emmioğlu (2012) classification of students' attitudes towards statistics. Item weighting showed that the role of the lecturer in the learning processes is seen as very supreme. The students strongly believed that 'drilling' is a very significant.

In conclusion, data analyses suggest that the questionnaire was fairly good in describing students' beliefs from which lessons can be drawn about how to approach statistics classes for journalism students at the Polytechnic. However, more work is needed so that the questionnaire comprehensively accounts for its theoretical underpinnings. Further rigorous analysis and improvement of the questionnaire are required to make it a more reliable and comprehensive instrument.

Attitudes to statistics and affective expressions in use of graphs developed by primary school teachers

Maria Niedja Martins and Carolina Carvalho

University of Lisbon, Institute of Education, Lisbon, Portugal, marianiedjamartins@campus.ul.pt, cfcarvalho@ie.ulisboa.pt

This study aims to investigate the attitudes towards statistics and affective expressions in use of graphs developed by primary school teachers. The study participants will be 206 primary school teacher of Pernambuco - Brazil. The approach of this investigation is based on a mixed methodology of data collection and analysis, composed of three complementary datasets: questionnaires, attitude scale and interviews. For the quantitative analysis, we will use one-dimensional parametric and non-parametric methods and factorial analysis. To do the analysis of the teachers' interpretation will be used the content analysis.

Keywords: Attitudes towards statistics, affective expressions, primary school teachers.

INTRODUTION

The conceptualization of attitude is investigated by increasingly number of studies in education field (Gleitman, Fridlund, & Reisberg, 2011). For example, in mathematics education and statistics education, studies investigate the close relationship between negative attitudes and low academic performance. According to Gal, Ginsburg, and Shau (1997), the main concerned is to analyse the relationships between affectivity and learning in these two areas from the study of students' attitudes. However, attitude towards statistics scales usually disregard affective expressions that may emerge during the interpretation of statistical data.

Evans (2000) argues that when people interpret graphs, they can express pleasurable and/or painful feelings related to previous experiences of their lives. Authors such as Monteiro and Ainley (2010) suggest that statistical literacy is comprised of these affective elements. Others authors argue that the previous experiences and feelings about the topics related to the data can also be a negative influence during the process of interpretation (Cooper & Dunne, 2000).

The aim of this study is to investigate the relationships between attitudes, statistical knowledge of primary school teacher and their interpretation of graphs. We also intend to investigate which elements might influence the mobilization of teachers' affective expressions during their selection of graphs to work in classrooms.

METHODOLOGY

The study will be conducted with teachers of municipal schools in the Metropolitan Region of Recife - Pernambuco, Brazil, with a sample of 209 teachers. The methodological approach is mixed, with questionnaires, Likert Attitude scale and interviews. The study will be composed of three complementary datasets: questionnaires, attitude scale and interviews. The questionnaire items will be related to individual information's' and graphical knowledge. The attitude scale will have a 4-point Likert format scale, with 10 positive statements and 10 negative, developed and validated by Cazorla and colleagues (1999).

Based on the results, we will select 20 teachers who have more negative attitude towards statistics; and 20 teachers who have more positive attitudes towards statistics. In the third stage, semi-structured individual interviews will be held with those 40 selected teachers. They will discuss data represented by graphs which present data about relevant topics as well as usual and unusual representations published in the media.

For data analysis, we will use SPSS and NVivo. The statistical analyses with SPSS will be useful to identify possible differences and similarities between the situations presented in order to emerge affective expressions from participants' interpretations. The NVivo will be utilised in the analysis of qualitative data from interviews with participants.

3 UTAD, CIDTFF, Vila Real, Portugal

Changes within teaching of statistics in elementary education in Portugal, lead to this research on the attitudes of teachers towards statistics. This study focuses on the measurement and characterization of attitudes towards statistics of Portuguese teachers from the 1st and 2nd cycles of basic education (ages 6 to 11). With this work we hope that paths may be devised to introduce an attitudes' pedagogy and the interventions to prevent negative attitudes and/or correct them, thus positively contributing to the professional development of teachers as well as to students' success in statistics education.

Keywords: Attitudes, statistics, teachers, basic education.

INTRODUCTION

Nowadays statistics is recognized as a key knowledge area with gradually integration in the mathematics curriculum, and in particular in Portuguese basic and secondary school levels. Nevertheless, despite the curriculum guidelines, there are factors that may endanger its implementation. On the other hand, in Portugal, research of attitudes towards statistics has not being done, and there was no research about Portuguese teachers' attitudes towards statistics. So, the main objective in this study was to do a 1st assessment and characterization of Portuguese teachers' attitudes towards statistics, of basic education. The specific objectives are: Studying this attitudes as a global measure, as well as in their components; Determine if there are significant differences between these attitudes in the two cycles; Inquire about the existence of significant relationships between teachers' attitudes and the demographic and school training variables.

METHODOLOGY AND RESULTS

The research method was a mixed study, with a stronger quantitative component, and a concurrent analysis for the countries comparisons. The instrument used is the Estrada's Scale of attitudes towards statistics, EAEE (Estrada, 2002; with a fully English presentation in Martins, Nascimento, & Estrada, 2012). It is an attitudes five-point Likert scale with 25 items that was specially design for teachers and presents good psychometric properties. In a cluster sampling from 3 Portuguese regions, 1135 teachers were surveyed resulting in 1098 valid questionnaires. The sample has a variety of cases relevant for the study. For the quantitative analysis the descriptive statistics were computed as well as one-dimensional parametric and non-parametric methods, multidimensional clusters analysis and factorial analysis. To do the analysis of the teachers' explanations the content analysis was used (Martins et al., 2012). This study confirmed the high internal consistency of the instrument with a Cronbach alpha of 0,869. The multidimensional aspects of the EAEE emerged. Teachers' attitudes towards statistics were positive. This study highlighted in a positive way the cognitive and social components and in a less positive way the behavioural and instrumental components. The comparison with others studies reinforced the admissibility of these results (Estrada, Bazán, & Aparicio, 2010). Attitudes towards statistics of these teachers: were not significantly related with their gender and were significantly related with the cycle of teaching, the teaching experience, their training area, the training in statistics and the teaching of statistics.

CONCLUSION

In conclusion, teachers have a clear conception that statistics is useful and they value its role in the citizens' daily life and they also have a clear sense of the importance of including it in current curricula. At the same time they did not emphasize collaborative work and didn't refer sharing statistics difficulties with other teachers. Outside the school, teachers do not see statistics as a tool in their own daily life and they express a feeling of disbelieve towards the use of statistics and the information in television. As actions to improve attitudes toward statistics we mention the improvement in training (initial and in-service) at several levels and the promotion of the collaborative work amongst teachers. It is also important to guarantee the reinforcement of statistical education in schools, from the early years, as well as in the training of future teachers and of in-service training in statistics for teachers.

The development of informal inferential reasoning via resampling

Jeffrey A. McLean and Helen M. Doerr

Syracuse University, Syracuse, USA, jamcle01@syr.edu

This study focuses on the development of secondary and tertiary students' informal inferential reasoning while engaging in data driven sampling and resampling activities. Through the use of hands-on manipulatives and simulations with technology, the participants will construct empirical sampling distributions in order to investigate the inferences that can be drawn from the data. Data collection and analysis will begin during the fall of 2014. Results and initial analyses will be presented in this poster.

Keywords: Statistics education, resampling, modelling.

RESEARCH TOPIC

A trend in statistics education is the shift from a focus on theoretical distributions and numerical approximations into an emphasis on data (Cobb, 2007). Cobb asserted that many statistics curricula are outdated and based on how statistics could be learned prior to the computing power of modern times. Technology is now capable of collecting many samples nearly instantaneously and this advance in technology should have an impact on the statistics curriculum. New curricula for introductory statistics courses, such as the CATALST (Change Agents for Teaching and Learning Statistics) curriculum at the tertiary level (Garfield, delMas, & Zieffler, 2012), emphasize the ideas of data creation, exploration and simulation with methods of sampling and resampling. This study aims to continue in the direction of such curricula and investigate how students develop their reasoning of resampling methods, the reasoning that develops as students move from using sampling methods to resampling methods, and the reasoning that is revealed and supported by moving from use of hands-on manipulatives to computer simulations during sampling and resampling activities.

THEORETICAL FRAMEWORK

The focus of analysis for this study will be the models of sampling and resampling that the students will create while engaging in a model development sequence (Lesh, Cramer, Doerr, Post, & Zawojewski, 2003). This study defines models as "conceptual systems … that are expressed using external notation systems, and that are used to construct, describe, or explain the behaviors of other system(s)" (Lesh & Doerr, 2003, p. 10). Teaching and learning from a modeling approach shifts the focus of an activity from finding an answer to one particular problem to constructing a system of relationships that is generalized and can be extended to other situations (Doerr & English, 2003). Students' mathematical models are useful for research since they provide a means for investigating students' developing knowledge.

DESIGN AND METHODOLOGY

This study is a mixed methods case study with an intervention and a pretest, post-test, and delayed post-test. I will collaborate with two introductory statistics instructors (one each at the secondary and tertiary levels) to create an instructional unit that will consist of two model development sequences. During the unit, I will videotape four focus groups of students, collect student work from all participants, and videotape whole class discussions and presentations. Select students from the focus groups will participate in interviews to discuss their thinking while participating in the instructional unit. I will analyze the pretest, post-test, and delayed post-test quantitatively to investigate changes in students' understandings. The development of participants' reasoning collected from the videos, student work, and interviews will be analyzed with qualitative methods in order to construct the development of models of inferential reasoning used by participants.

POSTER PRESENTATION

The poster will discuss details of the two model development sequences, including how the hands-on manipulatives and simulations with technology were used. Student work and the initial analyses of their models of inferential reasoning will also be presented.

Core competencies for the professional use of applied statistics in business administration, how to promote them in the classroom?

Vanessa Serrano Molinero and Lucinio González-Sabaté

University Ramon Llull, IQS School of Management, Barcelona, Spain, vanessa.serrano@iqs.edu, lucinio.gonzalez@iqs.edu

The main purpose of this paper consists in determining the competencies for the professional use ofstatistics, highly appreciated to obtain a job in the field of Business Administration. A second objective is to propose a short activity in an Applied statistics class to identify the level of the students' top-rated skills and promote them. Applied statistics is understood as an instrumental subject of statistics taught in numerous degrees that do not seek to train professional statisticians. As a consequence, it may not be separated from the context of its degree.

Keywords: Competencies, applied statistics, business administration.

Batanero (2002) highlighted the important role that statistics carried out in the development of modern society and the need to introduce statistics at school arose. In accordance with the European Space for Higher Education (ESHE) and the market itself, it is necessary to train the future users of this discipline in competencies as well as instructing them in the usual contents. In order to achieve this, it is essential to determine which competencies are the most relevant in the professional environment.

The model proposed by Serrano, Puig & González-Sabaté (2010), consisting of 27 competencies, has been taken as the starting point. In order to simplify this model a validation technique through triangulation (Ghrayeb, Damodaran, & Vohra, 2011) was used together with an adaptation of the Delphi method in two rounds in three groups of experts: Business Administration graduates with professional experience, Statistic's teachers and Human Resources (HR) specialists. According to Astigarraga (2010), the Delphi method is based on the systematic use of intuitive judgment issued by a group of experts. The method would thus consist in asking experts questions by successive questionnaires in order to highlight convergences of opinions and deduce possible agreements. After this, the initial model was simplified to a new one composed by 12 competencies. Later, a final classification was elaborated using the opinions of a new group of 66 HR professionals who were contacted thanks to the IQS Business Alumni. In result, the skill that seems to be most important is how to "Interpret the results", defined as the ability to interpret the results obtained in a study in order to use them in their context. The next two competencies are "Decision-making" and "Critical thinking".

In the learning process based on competencies, activities reflecting the conditions in which they will be put into practice are necessary (Villardón Gallego, 2006). Nevertheless, due to the limited amount of time the subject of statistics usually has at its disposal, a short activity has been proposed for the proper development of the top-rated skill. In this case, the students were invited by the teacher to write a short report that summarized the information contained in a box-plot graph related to the income of a company. A sample of students of the degree in Business Administration carried out this activity during the academic year 2013/14. The results obtained were compared with those proposed by the teacher, thus highlighting the fact that both the students and the teacher develop the skill through the activity. The ideas that arose from the exercise were classified in four typologies: description, calculation, errors and interpretations. Students were informed of the main ideas drawn in order to improve their ability to interpret results in future activities. Most of the students explained the graph in statistical terms but decontextualized from the situation described. However, just a small number of them tried to interpret the results observed within the framework of the statement. Very few students made calculations to give consistency to their explanations. Lastly, only one student identified an error in the graph shown; this is related also with the "Critical thinking" skill. In addition, some errors appeared in students' reports. The teacher concluded that was necessary proposing new activities to improve the skill "Interpret the results".

Applications and modelling

Introduction to the papers of TWG06: Applications and modelling

Susana Carreira[1], Berta Barquero[2], Gabriele Kaiser[3], Thomas Lingefjard[4] and Geoff Wake[5]

THE OVERARCHING THEMES OF TWG06 PRESENTATIONS

The contributions that formed the working basis of the Thematic Working Group on Applications and modelling were characterized by a strong diversity in the topics and issues that were addressed. The group's research field has thus shown to be both active and fruitful whilst maintaining its distinctive facet of being inclusive in terms of the different theoretical, methodological and philosophical perspectives taken by its researchers.

One of the overarching themes illustrates just how important it is to debate and theorize the very notion of mathematical modelling and the concept of mathematical application, namely the question of *perspectives and conceptualisations on modelling* as an important issue addressed by the group. Although it may be useful to emphasise differences and distinguish between modelling problems and mathematical application situations, there are also proposals to blend modelling and applications. The concept of model becomes in both cases a keyword and in general the distinction refers to the need to create a model not available at the outset as opposed to using a model that is previously known. However, there are perspectives for which a common conceptualisation of modelling requires assuming that there are no completely independent mathematical models nor totally disconnected models and that modelling means not only create models, but also integrate and coordinate models somehow contradicting the idea that applications are simply a limited portion of the modelling cycle.

Another emphasis in the discussion refers to areas that might be considered as neighbouring mathematical modelling and potential connections that eventually can be found between mathematical modelling, problem solving, project work and Ethnomathematics. One way to link these different areas can be found in the fact that all these fields are associated to certain types of teaching practices with common characteristics, namely, discovery teaching, inquiry based learning and generally views that put the individual learner actively involved in seeking solutions to real world situations based on mathematics.

One open question stemming from the work that was presented in the group's discussions is whether it will be possible to move towards a comprehensive theory about the teaching and learning of modelling and applications and if such an aim is desirable. Indeed, one other important issue that has much impact in relation to this argument is the growing emphasis on mathematical modelling in the implicit and explicit rhetoric across countries, as portrayed by the most recent frameworks from the OECD's PISA study. Some reluctance towards a pseudo-modelling reflected in certain problems and the need to account for the cyclical nature of the modelling process as a distinctive characteristic, stress the importance of keeping in mind the contrast between mathematical modelling as a pedagogic activity and its professional counterpart.

This topic leads to another overarching theme concerning *the nature of modelling tasks* for school mathematics. The need to converge in a vision on what to consider as good modelling tasks has often been raised. A seemingly relevant item is directly associated with the degree of difficulty of modelling tasks and problems.

Results of research studies indicate that much rests on the students' previous experience, background and pre-knowledge when it comes to modelling tasks; however, it is considered important that modelling tasks reflect authenticity and bring the opportunity to seek, investigate and explore. It is also relatively clear that modelling tasks are still rare in daily school lessons, in part due to the fact that teachers have a restrained attitude towards implementing modelling tasks, sometimes based on the perception that they are too difficult for many students. One of the suggested and analysed difficulties lies on the student's need to picture or imagine a particular real situation, which can be described as creating a situation model. Ideas on the wording of the problems and on how this variable may be of significance were offered and may induce further thinking on the study of task variables in modelling problems.

Modelling contexts and environments was also a developed theme in the working group. On the one hand, the importance of using specially tailored problems for specific areas of knowledge was advocated, as in the case of engineering studies. Emphasis was given to the fact that students often value the specificity of the problems addressed and their relevance to other disciplines in a particular field. On the other hand, it was endorsed the educational wealth of multidisciplinary approaches in allowing integrating tools from different disciplines and subjects, namely mathematical modelling, especially when developed within inquiry teams that are more able to generate questions of real interest.

On the theme *didactic issues in mathematical modelling*, one of the queries was the transposition of the concept of mathematical modelling, as it is usually described in academic literature, to textbooks. This transposition seems to be marked by a poor representation of a holistic view on the modelling process and by leaving aside the critical sense that is inherent to the modelling process. Fragmentation of the model development into a step-by-step model construction tends to prevail and there seems to be a tendency to divide the model into mathematical and non-mathematical parts. Apparently, the widely disseminated design of the modelling process largely supported by studies and research contributions suffers considerable distortions on the route to the textbook and ultimately to the teacher.

Along with this question, the role of mathematical knowledge followed the examination of the differences between experts' and novices' modelling approaches. For some presenters, the differences can be traced by the kind of representations and strategies used by each of them, in close liaison with the mathematical knowledge that they differently dominate. But for others, those differences in fact set the need to clearly understand how mathematical modelling is related to mathematics as a science, and to the many mathematical practices appearing in society outside school. And this implies considering variable features of the modelling activities for the class, namely the design of the activity, its goals, organization, autonomy of the students and adaptation to the local constraints.

One of the more prevalent themes within the participants' contributions – *students' modelling activity* – was investigated in several directions and with different foci. Although a review of this diversity is not easy, it is possible to highlight the importance given to the idea of mathematisation in several papers. For example, this strand appeared with respect to the importance of making assumptions when tackling a mathematical modelling problem. This interpretive flavour of the mathematical modelling activity is also linked to the need for interpretation of the mathematical model back into the original real context. Students' contextual approaches to mathematical notions, concepts and results were widely illustrated at various times, including situations involving experimentation with daily objects and artefacts. To a large extent, the viewpoint of contextual modelling came up strongly represented in a number of studies conducted with students of lower secondary school. In what concerns studies involving upper secondary and tertiary levels, the students' modelling activity was mainly analysed in terms of its relationship to cognitive structures and competing models, formal and non-formal concepts, understanding of scientific concepts and everyday interpretations, and more generally to the mathematical framing of the real world situation.

In the sphere of teacher education and professional development, two themes were discussed: *issues in learning to teach modelling* and *teaching practices and beliefs*. For these themes, investigations have emerged based on different training models, such as the 'lesson study' and the 'study and research path for teacher education'. In both cases, a particular attention has been placed on the planning of the lesson and on the design of the modelling tasks. The planning of the activities to be carried out in classes of mathematical modelling seems to be a central factor in the shaping of teaching and learning and has a great influence on questioning the usual ways of teaching, namely content-centred practices, and the official curriculum. On the other hand, teaching mathematical modelling in school requires the teacher to realise that many of the steps of the modelling process, such as the simplification of the real situation, are not simple matters and cannot be undervalued.

In regard to teachers' beliefs on mathematical modelling, methodological approaches to obtain data in international comparison studies were presented and examined. As for the teachers' practices, it was stressed the strong influence that beliefs have on practices but it was also highlighted the dilemmas that can be quite evident in mathematical modelling lessons. For example, the demands the teacher faces when getting substantially different models from students and also the need to find appropriate ways of dealing with possibly inadequate models that may emerge during the course of a class.

CONCLUDING IDEAS

The conclusions that emerge from the group's work point to three broad categories: various signs of diversity and plurality of views; some elements of uniformity; and major elicited questions.

The diversity

The diversity is easily detectable in the foci and research questions pursued by the group members in their studies. For example, a quick list illustrates this variety of interests and research aims: to deepen and clarify the meaning of modelling and model; to learn more about the design of modelling tasks; to scrutinize the pedagogical resources in the teaching of mathematical modelling; to see how modelling is translated to learning and to competencies development; to analyse forms of teachers' professional development around the implementation of modelling tasks and to better realise the teachers' beliefs about modelling in teaching practices across countries.

There is much diversity in the theoretical frameworks used by researchers in the field: the range covers many theories and perspectives from the more cognitive oriented to the more epistemological/anthropological approaches.

With regard to the school levels represented in empirical studies, there was also some diversity, although it should be noted an absence of studies in primary school.

Finally, it is evident that there is plurality in the visions and arguments of researchers from different countries about the purposes of including modelling in the mathematics curriculum and in regular classroom activities.

The uniformity

In contrast with the above mentioned tendency of diversity there are also several signs of uniformity through the studies presented in TWG06. In terms of methodological approaches, for example, there are predominantly qualitative and small-scale studies. It further appears that the modelling cycle and the modelling phases represent the most common conceptual tools in informing the research. There are also shared concerns related to the contexts of mathematical modelling problems and the authenticity of the tasks. Finally, there are prevailing references towards the assessment of mathematical modelling activity, particularly the external and internal assessment of performance, competence, effectiveness, student's involvement, etc.

Major questions

Given the collection of papers and the discussions developed in the working group, we identified a set of big questions that may help us to put in perspective the future development of the TWG and of this area of research.

Some of these big questions immediately capture the diversity of theoretical perspectives represented in the research of the TWG. This diversity, as already pointed out, ensures an enriched agenda and extends the scope of the research but it also has consequences for impact because of diversity in the likely resulting studies and results. Therefore, the following questions and sub-questions point to the importance of reflecting on this particular factor:

1) How to cope with diversity within the research community and how is such diversity enabling/

disabling the growth of research on mathematical modelling in education?

2) How to induct young researchers into the complexity of the field (theories, terminology, contexts of tasks,...)?

3) What is the influence and the tension between the theoretical approach and the nature of the modelling tasks in mathematics teaching and learning?

— At the level of design/selection;

— At the level of implementation;

— At the level of analysis of empirical data.

To conclude, another question emerges from the awareness of the importance of broader and larger scale studies that may systematize or add confidence to the more localized studies grounded on small experiments or particular cases:

4) How to facilitate the transformation of local practices with mathematical modelling into large scale integration of modelling at all school levels?

To this respect, ideas were suggested in the contributions offered, namely concerning efforts to be invested in the initial and continuing training of teachers, renewed attention to resources to support teachers and strengthening the interaction between researchers and practitioners.

Research papers

Mathematization and modelling of physical phenomena: Analysis of two proposals

Jose Benito Búa Ares[1], Maria Teresa Fernández Blanco[2] and Rubén Figueroa Sestelo[2]

1 IES Ramón Cabanillas, Cambados, Spain, bua@edu.xunta.es

2 University of Santiago de Compostela, Santiago de Compostela, Spain, teref.blanco@usc.es, ruben.figueroa@usc.es

The manifold factors involved in mathematical modelling render this activity a complex process. The teaching of mathematical modelling assumes, at least in part, such complexity, though adding some elements inherent to a didactic environment. This paper presents two proposals for the classroom which have led to interesting conclusions, both from the point of view of the construction of mathematical knowledge (in this case focused on the content of the curricular topic of functions) and from the process itself of drafting the models, as well as suggesting some reflections on our own teaching practice.

Keywords: Modelling, functions, GeoGebra, physical phenomena, upper secondary.

INTRODUCTION

In a synthetic way, Blum and Niss (1991, p. 39) characterize a mathematical model as a triple:

> To be a bit more precise, a mathematical model can be viewed as a triple (S, M, R), consisting of some real problem situation S, some collection M of mathematical entities and some relation R by which objects and relations of S are related to objects and relations of M.

Likewise, they make a distinction between mathematization and modelling:

> While mathematization is the process from the real model into mathematics, we use modelling or model building to mean the entire process leading from the original real problem situation to a mathematical model.

Thus, mathematical modelling presents a situation in which the real world (identified with the extra-mathematical) relates to something that is mathematical (identified with the intra-mathematical). Hence, work takes place at the heart of mathematics that is closely connected to the initial extra-mathematical situation or problem, where all such elements are intensely interrelated by means of complex processes.

In line with the degree of importance attributed to each one of the present elements (the processes that take place and the aims intended and assigned to such processes), different approaches and perspectives appear in the way that modelling is taught and learnt (Borromeo, 2006; Kaiser & Sriraman, 2006; Kaiser, Sriraman, Blomhøj et al., 2007). A broad variety of schemes result from here (e.g., Perrenet & Zwaneveld, 2012), which describe the elements present in modelling and the relationships established among them, sometimes distinguishing between which elements are most appropriate for researchers, teachers, and students (see, e.g., Blum & Borromeo, 2009). Such schemes undertake the characteristics of a modelling cycle.

We use the cycle of Blum and Leiss (2007) which is divided in seven steps: 1 Constructing; 2 Simplifying/Structuring; 3 Mathematising; 4 Working mathematically; 5 Interpreting; 6 Validating; and 7 Exposing.

The aim of this paper is to illustrate the complexity of the relations established by the students between the extra-mathematical and the intra-mathematical worlds, and between the mathematical model itself and the mathematical model interpreted in the context of the situation from which the model issued (Blum & Leiss, 2007).

Our work shows an example of modelling that prompts students to obtain data that is subsequently processed with a computer, enabling to obtain the model, which take the form of a function in one variable (see, e.g., Lingefjärd, 2011). Once such a function is obtained, the aim will focus on analysing the students' answers to questions about the interpretation of the mathematical model against the original real context, the relevant concepts, notions and basic knowledge on functions, and about knowledge that is not directly related to functions.

METHODOLOGY AND DESCRIPTION OF THE ACTIVITIES

The two activities we describe below were proposed during two consecutive years (academic years 2010–2011 and 2011–2012) to students of the course Mathematics I in the 1st year of Science and Technology Baccalaureate (aged 16–17 years), as a voluntary practice to be performed after the regular class hours. Participating students of the first year are designated as A1,..., A13, and participating students of the second year as B1,..., B12 (total of 25 students). The activities were performed one after the other, with a two-week interval in between. Students were distributed into working groups G1, G2, etc., (3–4 students per group) and their work was recorded in audio and video.

As a previous step to the proposed activities (two weeks before), the students learnt how to use GeoGebra to obtain the analytical expression of an adjustment function starting by dumping the data from a table as points in a Cartesian plane (adjustment of a function from a set of points on the plane using sliders).

We divide the development of both activities (herein after *Spring* and *Oil and water*) in three different phases: (Phase 1) data collection at the laboratory, (Phase 2) data dumping and obtaining the adjustment function using a computer and (Phase 3) asking questions about the obtained model. At the end, the students answered two questions about their opinions on the activities and the phases into which these had been divided.

In the following, we describe the different phases.

Phase 1. The first phase of the activities was proposed with the following statements:

> *Spring*: "Let's study how a spring stretches when we hang a weight from it. Take all the data you consider necessary, and do it the way you think is best."
>
> *Oil and water*: "Let's study how the diameter of an oil slick on water varies when we add more oil. Take all the data you consider necessary, and do it the way you think is best."

Each group had their own materials to collect the data: weights, weight stand, spring (different in each working group), tub, detergent, oil, 2-ml, 5-ml and 10-ml syringes, rulers, tape measure. They had to decide how many data should be collected and the way to do that.

Phase 2. The second phase was proposed in the following manner in both activities:

> "Dump the data you have obtained at the laboratory into the computer and try to obtain a function by adjusting the data using the GeoGebra program."

Each group was provided with a computer and a photocopy containing the graphs for the fundamental functions: affine, quadratic, inverse proportionality, square root ($f(x)= k \cdot \sqrt{x}, k \in R$), exponential with bases greater than and less than 1, logarithmic with bases greater than and less than 1, sine, cosine and tangent. As in the precedent phase, students did their work in an autonomous and open way. The adequate function for the case of *Spring* is the linear function $f(x)=ax$ or affine function $f(x)=ax+b, a,b \in R^+$, depending on whether only the length of the stretched spring is measured or the full length. In the case of *Oil and water*, the adequate function is $f(x)= k \cdot \sqrt{x}, k \in R^+$.

Phase 3. In the third phase, the questions asked about both models were proposed so that each student would reply individually and in writing, except for the last three questions about the model *Oil and water.* These three questions represented the previous necessary step to apply the model to a hypothetical real situation, i.e. the last phase of modelling the behaviour of oil on water. Below we reproduce the questions asked to students. When analysing their answers, we will only refer to some of them.

Spring

1) What type of function have you obtained? Interpret the result. 2) Which variable is dependent and which is independent in the function? 3) In the function you

have deduced, is there any parameter? If the answer is yes, what does it mean in the experiment you are conducting? 4) How much does the spring stretch with 370 g of weight? 5) Which weight corresponds to a length of 21 cm of the spring? 6) What length of the spring do you obtain from the function if you do not put any weight on the stand? Interpret your result. 7) According to the function you have obtained, is it possible to stretch the spring indefinitely? Interpret this result, though taking into account the specific experiment you have conducted. 8) Try to deduce how to calculate the weight applied if you know the length of the spring. 9) Do you think the function you have obtained describes well the behaviour of a spring to which a weight has been attached? 10) The obtained functions are different. What do you think the reason for this is?

Oil and water

1) The function describing the data is always expressed as $f(x)= k \cdot \sqrt{x}$, k being a constant, x the amount of oil in ml, and $f(x)$ the diameter in mm. k is different depending on each case. In this respect, k varies. Would it be appropriate to call it a 'variable'? Why? Would you use another name? Why do you think k varies in each case studied? 2) One data is the diameter. How would the function change if we had used the radius instead of the diameter? 3) One data is the diameter. How would the function change if we had used the area of oil on water instead of the diameter? 4) What function would we obtain if we represent the diameter on the x-axis and the amount of oil on the y-axis? (Or the area and the amount of oil).

Application of the *Oil and water* model to a hypothetical real situation:

Figure 1: Hypothetical image of an oil spill (its original size has been reduced)

The photograph below is a satellite view of an oil spill off the coast of Cambados.

1) Determine the scale of the photograph. 2) Determine the area of the polluted surface. Use any instruments and knowledge that you consider necessary or suitable. 3) Apply the model you have obtained to determine the amount of fuel in the spill.

In order to determine the scale of the photograph, the students were provided with a photocopy of a nautical chart on a scale of 1:30,000 of the same coastal area, and with material for technical drawing (ruler, compass, set-square, etc.).

ANALYSIS OF STUDENTS' ANSWERS

Here we highlight some general considerations about the development of the activities:

The working environment was relaxed in all the phases, the available time was enough and there were no delays. During the phase of data collection and obtaining the adjustment function all the students participated actively, deciding the distribution of tasks by consensus and assuming the relevance of performing correct measurements and adjustments. The students called the teacher on very few occasions, and most of the questions were related to mere technical issues, which led us to assume that they were committed to perform the work autonomously.

The time employed is one of the obstacles mentioned about the introduction of modelling either in school or university (see, e.g., Blum & Niss, 1991). Regarding this issue, no time limit was fixed to perform the successive phases. The time used by each group to obtain the data table was in no case longer than 18 minutes, in the case of *Spring*. In the case of *Oil and water* it varied to a greater extent, ranging from 30 to 55 minutes. Some groups took longer due to the difficulty of pouring oil on water using a syringe. The time employed for adjusting the function using the computer did not exceed 15 minutes in any group. Most of the time was consumed entering the data from their tables into the computer. The time used to answer the questions posed about the obtained model was approximately the same: 35 minutes in the case of the spring, 40 minutes in the case of the first question and the discussion about *Oil and water*, and 70 minutes in the case of the application of the oil and water model.

Data table and adjustment function

The number of data and the titles of columns each group assigned in their data table varied considerably: in the case of *Spring* the number of data varied from 9 to 32; in the case of *Oil and water* they obtained between 9 and 23 data pairs. The groups referred the measurements they made in the first row of the table as Weight and Length (groups G1, G2, G3 and G6) or *x* and *y* (group G5). Group G4 did not write anything to describe the columns. So, students identified the real-life variables (Weight, Length, etc.) with mathematical variables (*x* and *y*) because they wrote data using the usual representation of a data table of a function. So, we may consider that this phase includes the steps 1 Constructing, 2 Simplifying/Structuring and 3 Mathematising (Blum & Leiss, 2007).

In the case of *Spring*, group G1 (Figure 2) obtained the equation of a straight line determined from two data from their table, and another group (G5) modified the parameters a and b in the equation of a straight line on the plane, $y=ax+b$. The remaining groups performed a similar procedure using the functional expression $f(x)=ax+b$. In the case of *Oil and water* all the groups provided a function of the kind $f(x)= k \cdot \sqrt{x}$ as the solution, with different values for k in each group. So, we could say that, when each group inserted the appropriate function, they had previously decided the functional variables x and y (identified with weight and length and volume and diameter, respectively) and the necessary parameters they had to use. Therefore, this second phase should include the steps of 3 Mathematising and 4 Working mathematically (Blum & Leiss, 2007). Since they had previously identified real-life variables with mathematical variables, the mathematical model and result (the obtained function) should be interpreted as a real model and result (5 Interpreting).

Answers to the questions about the obtained model

63.6% of the students did not identify the variables correctly (question 2 about *Spring*; Figure 3a). Also, 95.5% of the students did not recognise the parameters (question 3 about *Spring*).

In the first question about the model for *Oil and water*, 52.2% of the students characterized k as a variable (Figure 3b) and 34.8% as a constant. 16% of the students initially asserted it was a variable and subsequently contradicted themselves and sustained it was a constant.

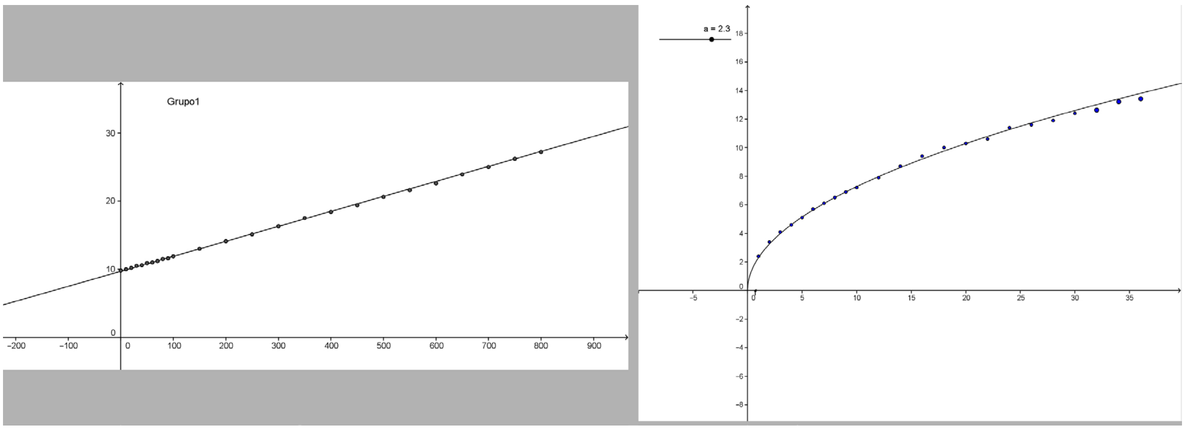

Figure 2: Data and functions obtained by group G1 [y=0.02x+9.7; f(x) = 2.3 √x]

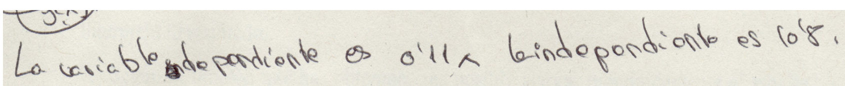
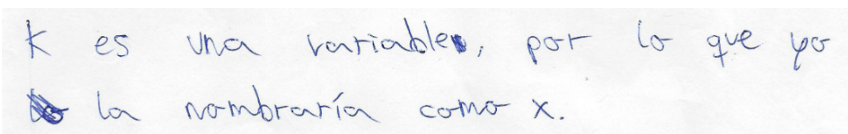


Translation:
Dependent variable is 0'11x the independent one is 10'8.

Figure 3a: Variables and parameters



Translation:
k is a variable, so I would call it x

Figure 3b: Variables and parameters

So, regarding the variables and parameters, students did not identify the variables correctly and made confusion between the dependent and independent variables and the parameters.

In *Spring* they had obtained a function that enabled to obtain the length given the weight (mass); however, surprisingly, in questions 4 and 5 half of the students used the rule of three in one or both questions (Figure 4). Only 27.3% of the students used the function in both questions and another one used a rule of three and the function, without questioning themselves why the obtained results were different. Therefore, they associated the graph of the function (straight line) with direct proportionality, and direct proportionality with the constant rate of change.

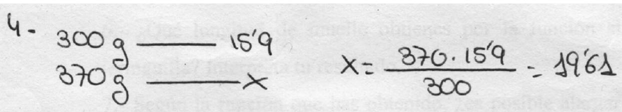


Figure 4: Use of the rule of three

Sometimes, students designated the function as an equation and the variables as unknowns (Fig 5).

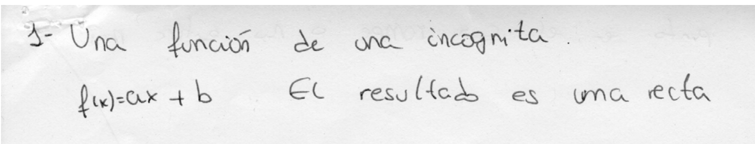
In questions 5 and 8 for *Spring*, the students did not mention the inverse function in their answers, and they performed the calculations with the function expression as if it were an equation which they must *solve* to obtain the unknown. In the discussion about oil, the first-year students almost immediately reached the conclusion that the function requested in the fourth question was the inverse function. One of the second-year students, after a few minutes, provided the way to calculate this function without realising it was the inverse function. Another student (B8) reached the conclusion that it was the algorithm they learnt to obtain the inverse function:

> Student B8: It's the inverse of the function. That is the inverse. When we look at the composition. Change *x* for *y* and solve for *y*.

Regarding the discussion about the adequate expression for the radius, there are differences from one academic year to the other. For example, the first-year students discussed for six minutes whether the adequate expression is $\frac{f(x)}{2}$ and about the consequences of dividing only one member of an equality by a number. The second-year students discussed for 10 minutes whether the expression of the radius should be $\frac{2.1}{2}\cdot\sqrt{x}$, $2.1\cdot\frac{\sqrt{x}}{2}$ or $\frac{2.1\cdot\sqrt{x}}{2}$. Neither the first-year nor the second-year students denoted the new functions they obtained in the discussion about *Oil and water* in a different way, and they always designated the results as *f(x)*.

Regarding the application of the *Oil and water* model to a hypothetical case of a pollution spill, we highlight the following results:

- One fourth of the students determined a value close to the right one for the scale. The remainder either used an inadequate system (55%), or failed to determine the scale (20%).
- Only two students achieved a correct calculation method to estimate the value of the spill area on the photograph. 55% of the students drew a circle on the picture and measured the radius or the diameter, in a clear relation to their observations of the behaviour of oil during the first phase.
- The students had many difficulties in the application of the model: they did not remember basic formulae to calculate areas, they confused the names of geometric figures, they misused the units of area or volume, etc.
- In no case they interpreted both images (map and photograph) as a similarity, so they failed to use the relationship between areas and volumes of similar figures.
- From all the students, only two achieved to provide a volume for the spill following a calculation system that may be considered acceptable.



Translation:
A function of one unknown f(x)=ax+b. The result is a straight line

Figure 5: Function equality as an equation and identifying the expression with its graph

Opinions and valuations of the students

From the analysis of the opinions and valuations by the students, we highlight below the aspects that we consider as the most relevant.

83.3% of students stated that the modelling for *Oil and water* was the one they liked most or found most interesting, often mentioning the discussion as a very positive way to learn from their peers and exchange ideas among themselves (41.7%).

Regarding the phases, the students considered all of them important, with special mention to the data collection at the laboratory (62.5%) because this makes the model becomes *their* model. One third of the students highlighted the application of the *Oil and water* model as interesting and enabling to apply the model to a real, socially problematic situation, and so they valued the model obtained as being useful.

Overall, they considered it very important to perform this kind of activities (that they sometimes referred to as *experiments*), however, at the same time, they thought that this kind of activities had nothing to do with *mathematics teaching*. They acknowledged that the kind of teaching they receive is based on learning algorithms.

In order to illustrate the comments above, we present a sample of the interviews made to the students:

Student B6: (...) I didn't know how to measure an oil slick or spill on water and, for example, that was one of the things I enjoyed most, wasn't it? Because you ask yourself: how is it possible to measure that on water? And then, you even see how the shape is formed and everything.

Student B3: (...) working on a problem is finding the solution and the same goes for equations. But here it's all about finding the data and then you have to find out something else; it's different, these are different steps you have to take with your own observations and collecting data. In class they give them to you, you don't have to do it for yourself.

Student A1: (...) You can't spend all the time doing experiments, you must have class.

Student B3: Well, in maths, when you have class it's basically doing exercises and learning what you have to know. This is something on the side that helps but it has nothing to do with the class, at least for me it has nothing to do with maths, with the class, I mean, because it's something different.

Student A1: (...) Because the problem with maths is that some people see it as something they're never going to use in their lives. A lot of people say: why would I want to know how to solve an equation? Why do I want to know about what a function is? I don't know, if you actually see it in real life then at least it should stir your curiosity.

CONCLUSIONS AND ELEMENTS FOR DISCUSSION

The issue that we consider essential is that the students succeeded in obtaining a model (a function) at the end of the second phase. However, their answers to the questions in subsequent phases lead us to think that the mathematising process (step 3, modelling cycle, Blum & Leiss, 2007) has been performed in a very limited manner. Consequently, it could be questioned whether the obtained function actually represents a mathematical model and result (Blum & Leiss, 2007). However, if we see only the mathematical result obtained by the students, it is possible to think they completed at least four of the seven steps of the modelling cycle. Therefore, when we propose to students to develop a mathematical model in an autonomous and open way, it is necessary to set questions related to important mathematical concepts and notions during the modelling process and not just at the end of it.

Moreover, for this result to become a solution to the originally proposed problem, students should interpret the mathematical result they obtained as a real result (step 5, Blum & Leiss, 2007). In fact, two functions coexist in both modelling processes with different domains and paths (the mathematical function and the function that relates mass to length and volume to diameter).

We must also add to the above the differences between both academic years regarding the development of the discussion as well as the problems that arose in the application of the *Oil and water* model. Modelling introduces some elements of uncertainty about what the teacher may expect to encounter in the classroom, such as the students' answers. The difficulties that arise during the process are not entirely predictable and consequently teaching becomes more open (see, e.g., Blum & Borromeo, 2009). Moreover, both models start from extra-mathematical situations inherently linked to physical laws and magnitudes of certain relevance (difference between mass and weight, Hooke's Law, behaviour of fluids of different densities, Archimedes' Principle, surface tension, etc.). Therefore, a series of questions arise that the teacher has to consider; the answers to those will determine a different kind of modelling and, consequently, a different modelling cycle. To give just a few examples: one could opt for omitting the data collection phase (by considering it to pertain to experimental science) and focus the modelling on such aspects perceived as more appropriate to mathematics, or we could also opt for using the obtained model to introduce some magnitudes and laws of physics; the degree of difficulty of obtaining the adjustment function could be increased by not providing a photocopy of the graphs for the fundamental functions; the square root may be presented on the photocopy as $\sqrt{x}$ or as $k\sqrt{x}$, etc. Likewise, answers to the questions raised to the students could be approached in a joint discussion; or by distributing the students into smaller, independent discussion groups; or individually in writing.

Finally, if we focus on more general objectives, modelling can be proposed as a means to introduce key concepts and notions about functions, or also to detect difficulties and obstacles in students who have already studied such content previously.

Therefore, modelling introduces some elements that force teachers to make previously meditated and reflected decisions about their teaching methods (see, e.g., Doerr, 2006). Such decisions will affect the kind of modelling proposed, the ways in which it is developed, the answers of students and the steps of the modelling process.

At the core of modelling: Connecting, coordinating and integrating models

Jonas Bergman Ärlebäck[1] and Helen M. Doerr[2]

2 Syracuse University, Department of Mathematics, Syracuse, USA

This theoretical paper introduces the notions of connecting, coordinating and integrating models to analyse and reflect on how models are created and developed. We define, discuss and apply these constructs to some theoretical perspectives in the present modelling discourse. We draw on an example from a model application activity within a model development sequence to illustrate these constructs. Our hope is to spark a discussion that will enhance our understanding about the nature of mathematical modelling and the teaching and learning of, and through, modelling.

Keywords: Modelling, theory, model development sequences, variation theory.

There are many different perspectives on modelling that researchers can adapt when studying the teaching and learning of mathematics (Kaiser & Sriraman, 2006). One commonly made distinction in the literature is the one between modelling and application. Often this characterisation is based on a philosophical stance about the nature and relation between 'mathematical knowledge' (mathematics) and 'knowledge about the rest of the experienced world' (reality) (Blum, Galbraith, & Niss, 2007). Stillman (2012, p. 903) describes this distinction as follows:

> With applications the direction (mathematics → reality) is the focus. "Where can I use this particular piece of mathematical knowledge?" The model is already learnt and built. With mathematical modelling the reverse direction (reality→mathematics) becomes the focus. "Where can I find some mathematics to help me with this problem?" The model has to be built through idealising, specifying and mathematising the real world situation. Both types of task have their place in school classrooms.

Research on modelling perceived in the latter characterisation often uses, or is based on, an idealized conceptualization of modelling as a cyclic process (e.g., Blum & Leiβ, 2007; Borromeo Ferri, 2006).

The role and function of applications and modelling in the teaching and learning of mathematics is also an important dimension in the on-going discussion – is teaching modelling a goal in itself, or is modelling a vehicle for teaching and learning mathematics? Both modelling as described by Stillman as well as most modelling perspectives represented by a cycle diagram of the modelling process include, or at least point out, the potential driver in modelling for teaching and learning mathematics.

Another perspective on modelling is the models and modelling perspective (Lesh & Doerr, 2003b), which provides a coherent framework to think about multitude aspects involved in teaching and learning. Central in the models and modelling perspective (MMP) are the students' previous experiences and knowledge, and how contexts are chosen and used in modelling tasks. Whereas perspectives aligning with the cyclic view on modelling (c.f. Blum & Leiβ (2007) and others) clearly are modelling according to Stillman's distinction, it is not in our view possible to situate the MMP in this dichotomy. Rather, MMP blends applications and modelling to form a modelling-based pedagogy, and through this use of modelling and applications students arguably learn both mathematics and mathematical modelling.

Although our overall research interest aims to better understand the teaching of mathematical modelling, and the teaching of mathematics through modelling, in this paper we ask more fundamental questions about the nature of modelling. We also wish to initiate a discussion about the nature of mathematical modelling, as well as teaching and learning mathematics through modelling, by examining the constructs of connecting, coordinating, and integrating models.

Before addressing the notions of connecting, coordinating and integrating models, we will discuss some of the central ideas in the models and modelling perspective. Our initial thinking is based on our work within this perspective, and the examples used for illustrational purposes are from this context.

THEORETICAL FRAMEWORK

In the models and modelling perspective, "*[m]odels* are conceptual systems (consisting of elements, relations, operations, and rules governing interactions) that are expressed using external notation systems, and that are used to construct, describe, or explain the behaviours of other system(s) – perhaps so that the other system can be manipulated or predicted intelligently. A *mathematical* model focuses on structural characteristics ... of the relevant systems" (Lesh & Doerr, 2003a, p. 10, italics in original). It is by engaging in learning activities that students' models are developed, modified, extended and revised through "multiple cycles of interpretations, descriptions, conjectures, explanations and justifications that are iteratively refined and reconstructed by the learner" (Doerr & English, 2003, p. 112).

A well-established line of research within this perspective has focused on model eliciting activities (MEAs) in multiple contexts with learners from primary school through university (see references in Ärlebäck, Doerr, and O'Neil (2013)). MEAs are activities where students are confronted with a problem situation in which they need to construct a model in order to make sense of the situation. There are six well-established principles for designing MEAs. The six design principles are: the reality (or sense-making) principle; the construction principle; the self-evaluation principle; the documentation principle; the simple prototype; the generalization principle (Lesh & Doerr, 2003a; Lesh, Hoover, Hole, Kelly, & Post, 2000). However, isolated MEAs can fall short of supporting students developing a generalized model that can be used and re-used in a range of contexts (Doerr & English, 2003). What is needed are multiple structurally related modelling activities offering multiple opportunities for the students to explore, apply and test relevant mathematical constructs in different situations and contexts. This is the idea and function of model development sequences (Doerr & English, 2003; Lesh, Cramer, Doerr, Post, & Zawojewski, 2003).

Model development sequences begin with a MEA to confront the student with the need to construct a model to make sense of a problem situation. The MEA is then followed by one or more model exploration activities and model application activities (see Figure 1). Model exploration activities (MXA) focus on the underlying structure of the elicited model in the MEA with special attention to the use and function of different ways to represent the elicited model. The initially elicited model is further developed by examining the strengths of various representations and ways of using representations productively. Model application activities (MAA) engage students in applying their model to new situations and contexts, thereby refining their language for interpreting and describing the context.

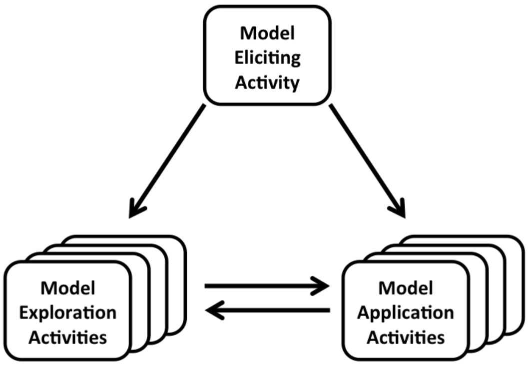

Figure 1: The general structure of a model development sequence

When students work through the model development sequence, they engage in multiple cycles of descriptions, interpretations, conjectures and explanations, resulting in iteratively refining and developing their models. In this process, interacting with other students and participating in teacher-led class discussions are key practices for facilitating this development.

A model development sequence focusing on the average rate of change

We now turn to briefly describe a model development sequence focusing on average rate of change consisting of one MEA, two MXAs, and two MAAs (see Figure 2). For a more detailed description see Ärlebäck, Doerr and O'Neil (2013). From this point an onwards, references to the particular activities in this sequence will be indicated with an asterisk (*). In the MEA* of this sequence, students analysed their own bodily motion along a straight line. They experimented with motion detectors attached to graphing calculators generating position vs. time graphs, created linear graphs based on written specifications, replicated the motion behind given position vs. time graphs, and generated written descriptions of how they moved. Within this context, students' initial thinking and models about function values (position), average rate of change (average velocity), sequences of differing values of average rate of change (sequences of differing average velocities) and the relationship between these quantitates were elicited.

In the two MXA*s the students explored various representations to describe and interpret changing phenomena using their emerging model of average rate of change. Using two different computer environments, the students generated motion of animated characters by creating velocity vs. time graphs, created position graphs from velocity information, investigated how the average rate of change of a function is represented as table values, graphs, and equations, and explored representations of exponential growth and decay.

In the two MAA*s that followed, the students used their models to make explicit interpretations, descriptions and predictions about the behaviour of, first, the intensity of light with respect to the distance from a light source, and second, the voltage drop over a fully charged discharging capacitor in an simple resistor-capacitor circuit. The MAA*s gave the students opportunities to use their models in different contexts (one having distance rather than time as the independent variable), and to work with phenomena with negative rates of change.

A model application activity – the light lab

In this section, we will briefly describe the Light Lab model application activity (MAA). The overall structure of the six tasks in this MAA is shown in Figure 2.

The first pre-lab task focused on the students' intuitive and initial models about how intensity varies depending on the distance from a point light source. In a one-dimensional scenario of an approaching car the students sketched graphs of how the intensity of the car's headlights varied depending on the distance to the car, and described how light disperses from a point source in terms of light rays.

In the second task, students used a point source of light to collect 15 measurements of light intensity data at one cm intervals from the source. In part one of the lab, students made scatter plots of their data and wrote descriptions of how the intensity of the light changed with respect to distance from the light source, and compared this relationship to their predictions from the first pre-lab. The students also calculated, described and plotted the average rate of change of the data in one cm intervals, and created rate graphs of the calculated average rates of change.

The second pre-lab introduced an inverse square model for how the light intensity varies with distance from a light source. Using four images representing light intensity indicated by number of dots per square inch at different distances, students determined the intensity at given distances from the light source.

In the second part of the lab, students determined a function fitting their collected data, explained their work, and analyzed the average rates of change of their function using the difference quotient; they calculated and graphed the average rates of change of the function, and described and interpreted the graphs of the average rates of change values. We will use these tasks from within this model application activity to examine our notions of connecting, coordinating and integrating models.

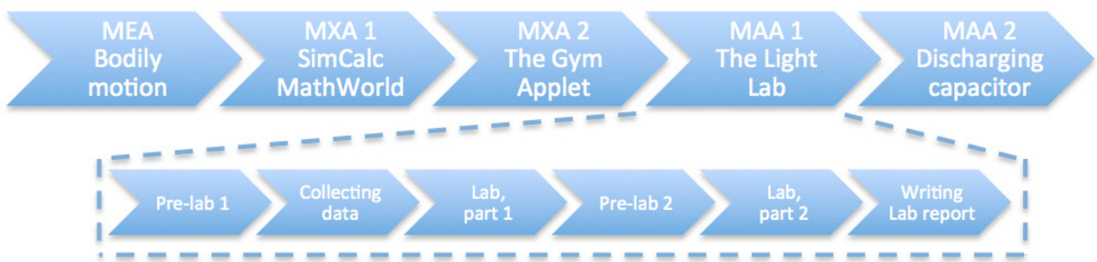

Figure 2: The model development sequence (top) and the six Light Lab tasks (bottom)

CONNECTING, COORDINATING AND INTEGRATING MODELS

We take *connecting models* to mean the establishing of a relationship between two or more previously unrelated models. As used here, connecting models captures the realization that previously isolated and unattached models, potentially from different disciplines or subject matters, partially overlap or have points of interest in common that in a given problem solving situation seem productive to explore. Connecting models also means taking the initial steps in identifying and delimiting the models being connected in the first place. Connecting models can thus be thought of as a united set of models together with some initial ideas and rationale for why these models might productively be considered together (see Figure 3). The reasons and rationale for connecting the models can be intuitive, tentative or speculative in nature, and to a large extent will depend on the modeller's previous experiences and knowledge. An example of an activity connecting models is the first pre-lab in the Light lab MAA*. Here, students' intuitive and initial models about how intensity varies depending on the distance from a point source of light in terms of previous experiences of car's headlights and how light disperses from a point source in terms of light rays (knowledge from previous courses in physics) are elicited. The juxtaposition of these questions implicitly suggests that it might be productive to consider these conceptual systems (or models) together. Another example of an activity connecting models from the Light lab MAA* comes from the second pre-lab which introduces a new representation (density of dots at varying distances) to be examined and considered along with the set of models the students are currently working with.

When a set of models has been connected, the *coordinating of the models* is the successively more systematic exploration and pursuit of the overlaps and points of interest in common across the models. The coordination of the models transforms the set containing the previously disjoint models into a set of more aligned models. This is a process entailing gradually mapping out where, and becoming clearer about how, the models partially overlap. The goal for moving beyond having a connected set of models and striving towards a coordinated sets of models is to facilitate the latter set of coordinated models as a whole to function in a more intertwined and concerted way when put into action and applied to the problem solving situation at hand. This is achieved by creating one or multiple bonds between the models, and successively making these clearer and stronger (see Figure 3). The coordinating of models is a multi-dialectic process where the specifics of all of the models in the set are important. The process of coordination results in the set of models becoming more aligned or (perhaps) more alienated. We note that the process of iterative refinement in a models and modelling perspective includes the sorting out and filtering of ideas, where some constructs (or models) are rejected as others become more aligned and subsequently integrated. A consequence of an unsuccessful coordination can give rise to the possible exclusion of the alienated model(s) or the rejection of the whole set altogether. An example of an activity facilitating students to coordinate models is the first part of the Light lab MAA* (Lab, part 1). Here the students are urged to keep thinking about their initial ideas and models elicited in the first pre-lab alongside representations (scatter plots, descriptions, rate graphs) of their collected real data and calculated values of the average rate of change over one centimeter intervals.

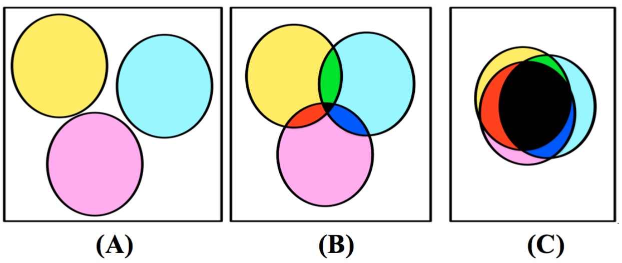

Figure 3: A conceptualization of connecting (A), coordinating (B), and integrating (C) models

Integrating models means merging the models so that the set now is conceived as one model in its own right (see Figure 3). Coordinated models are said to be *integrated* when the level of coordination is so high that further coordinating of the models in principle does not change the understanding and function of the newly merged models. A central feature of an integrated model is that it is self-contained. In the Light Lab MAA*, the students write a final lab report. The goal for the student is to present an integrated model of how intensity varies depending on the distance from a point light source. The purpose of the report is to reflect the students' integrated understanding of light dispersion on a qualitative and quantitative level using their collected data, average rate of change, rate of change graphs, the difference quotient, and a spherical light emission model.

Having introduced and exemplified the notions of connecting, coordinating and integrating models, we now turn to discuss how these constructs might be used and applied to current discussions about the nature of mathematical modelling, as well as the teaching of, and through, modelling.

MEAs, MXAs, and MAAs

Generally within a model development sequence, an MEA elicits the students' initial thinking about a problem situation, as that thinking is externally represented. This means that the students start to structure the problem solving situation by trying to identify and connect models that can work productively in the specific situation. An example of an MEA functioning to connect models is the MEA* where the students are working with motion detectors to make sense of bodily motion along a straight path. In this activity, the students are placed in a situation that exposes them to multiple representations through which to make sense of the situation. Centred on their own bodily motion, students are offered an opportunity to form and connect an initial set of models, consisting of their previous ideas and models together with the representations introduced in the MEA*, which then can be furthered explored and applied.

Generally within a model development sequence, the MXAs focus on supporting the students in developing the models elicited in the MEA by examining different representations: graphs, symbols and algebraic representations, tables, everyday language, manipulatives, embodied and animated motions as well as students' self-constructed representations. Regarding representations as models in their own right (Lesh, Post, & Behr, 1987), MXAs can then primarily be seen to be about the coordination of models with occasional elements of connecting models if new representations or models are introduced during the activity. Typically, this is done by either exploring communalities of the models connected in the MEA, but the emphasis of a MXA is really on connecting, coordinating and using representations. The two MXA*s in the model development sequence on average rate of change are good illustrations of this. In these two activities students use computer programs that provide access to digital environments and work on tasks that explore different representations of key ideas in their own right as well as the relationships among these.

The main purpose of MAAs is to provide students with new contexts and situations where they can apply their developing or previously developed models. However, to do this some sort of connection has to be established mapping the models of the students to the context of the problem situation at hand. In other words, the context of the problem situation and the models of the students first have to be connected. Then, in order to ensure the adequacy, legitimacy and the proficiency of this connection, it has to be coordinated, integrating the specifics of the new situation and context with the model being applied.

Applications, modelling, and the modelling cycle

Returning to Stillman's (2012) distinction between applications and modelling, it is now possible to argue analogously that connecting, coordinating and integrating models are necessary and fundamental processes both for applying models "already built and learned" (p. 903) and when "model has to be built through idealising, specifying and mathematising the real world situation (p. 903). The important difference between applications and modelling is not the point of departure (the mathematics vs. the real world) per se; rather, the difference manifests itself in the amount of effort and time spent on coordinating the context of problem situation and the models of the modeller before one ends up with an integrated model for adequately make sense of, and use for, the situation.

Regarding modelling ideally conceived as a cyclic process (e.g., Blum & Leiβ, 2007, and others), connecting, coordinating and integrating models provides a more dialectic and dynamic conceptualisation of the processes involved. For example, each of the transitions in cyclic perspectives on modelling, such as the modelling cycle used by Blum and Leiβ (2007) and Borromeo Ferri (2006), e.g., transitions between *real situation – mental representations of the situation – real model – mathematical model*, have to be subjected to sequential connecting, coordinating and finally developed into an integrated model to tackle the prevailing situation. In addition, the different transitions in terms of connecting, coordinating and integration should not be thought of as carried out sequentially, but rather as processes fundamentally evolving simultaneously, nested and organically. From this perspective, the typically one-way pointing arrows indicating the transitions in cyclic conceptualizations of modelling (e.g., Blum & Leiβ, 2007, and others) are misleading when trying to understand the complexity of, first, the modelling process in its own right, and second, and more importantly, the teaching and learning of modelling as well as teaching and learning mathematics through modelling.

THE SELF-SIMILAR NATURE OF TEACHING MATHEMATICS THROUGH MODELLING

Lesh and Doerr (2003b) discuss the connection between MMP and complexity theoretical ideas. One foundational idea of complexity theory is the principle of self-similarity, that structure and pattern repeat itself at different scales (Davis & Simmt, 2006). We wish to argue that this is also the case for the structure of model development sequences and the activities therein (at least for the MXAs and MAAs). The structure of the model development sequence at large and the activities that constitutes the sequence naturally varies from design to design, but using the notions of connecting, coordinating and integrating, the self-similarity of the two levels starts to stand out. In this paper we have tried to illustrate this point by providing examples from the model development sequence on average rate of change and the tasks in the Light Lab MAA*. We have argued that the two pre-labs in the Light Lab MAA* are activities connecting models, a characteristic of an MEA. In other words, Pre-lab 1, focusing on the students' initial ideas in the Light Lab MAA* (see Figure 3), has the function of an MEA. The elicited models and ideas are then subsequently coordinated in part one and part two of the lab under the support of an activity of data collection and a connecting activity (Pre-lab 2). However, the two parts of the lab (Lab, part 1&2) both function as MXAs with the primary goal of supporting the students in developing their model based on work on representations. The last task of the Lab, when students write a report, really aims at pulling the whole Light Lab MAA* together in an integrating sense. Looking at any MXA in a model development sequence, a similar argument applies: models need to be connected to set up the activity before the coordinating of the models can start. This self-similar aspect of model development sequences and the activities within occurs because when teaching mathematics through modelling, it is a necessity (by definition!) to bring in extra-mathematical contexts and situations.

DISCUSSION

One of the main points we have tried to emphasis in this paper is that regardless what theoretical stance on modelling is adapted, the three processes of connecting models, coordinating models, and integrating models are fundamental in all types of modelling situations. In our opinion, these three constructs capture and acknowledge the dialectic and complex nature of creating and developing models. Constructs like this might be the first steps towards a common conceptualization of modelling that bridges the research field so that we might better understand, coordinate and summarize research findings from different research traditions based on different perspectives.

By applying the three notions of connecting, coordinating and integrating models to the model development sequences, MXAs and MAA respectively, the self-similarity between the sequence and the MXAs and MAAs within the sequence came to the fore. The implication of this structural finding for teaching and the design of tasks might be profitably considered in future research.

While thinking about how models really develop and are formed in terms of connecting, coordinating and integrating models, we also found strong similarities to the principles of variation theory. The four types of variation within variation theory discussed by Marton, Runesson and Tsui (2004), *contrast*, *generalization*, *separation*, and *fusion* especially seems to resonate with the notions put forward in this paper: connecting models – contrast variation; coordinating models – generalization and variation of separation; integrating – fusion. To further investigate this, and what more variation theory has to offer, seems a promising way to continue the research initiated in this paper.

3 CICATA-IPN, Ciudad de México, Mexico

Considering the general problem of integrating mathematical modelling into current educational systems, this paper focuses on the ineluctable step of the professional development of teachers. Within the framework of the Anthropological Theory of the Didactic, the use of study and research paths for teacher education (SRP-TE) was recently proposed as a means to combine a constant practical and theoretical questioning of mathematical modelling school activities. After presenting the rationale of our proposal, we will illustrate the phases of the SRP-TE design and some preliminary results with the implementation of an on-line course for in-service secondary school teachers in CICATA-IPN (Mexico).

Keywords: Mathematical modelling, anthropological theory of the didactic, study and research paths, teacher education, on-line course.

INTRODUCTION

There exists an extended agreement about the necessity to foster the teaching of mathematics as a modelling tool and to enrich the study of contents at school through the development of inquiry processes. At the same time, many investigations highlight important objective difficulties that hinder any proposal of implementing modelling and inquiry as normalised activities in current educational systems (Burkhardt, 2008; Kaiser & Maaß, 2007; Doerr, 2007; among others). Many of these constraints are related to what has recently been called the 'monumentalistic' paradigm (Chevallard, 2012), which rules in many of our teaching systems, where mathematical contents tend to appear as 'works to visit' more than tools to provide answers to questions. To approach this far-reaching problem and help move towards the new paradigm of 'questioning the world', recent research carried out in the framework of the Anthropological Theory of the Didactic (ATD) proposes a new teaching device called *study and research paths* (SRP) based on the long-term inquiry of generating problematic questions (Barquero et al., 2008, 2013). However, designing and locally implementing new devices is not enough to ensure their long-term viability. Among many challenges, an important one is related to teachers' professional knowledge and competences, and furthermore to the mathematical and didactic infrastructures that need to be at their disposal to face this change.

The research project we are presenting starts from some particular cases of SRP that have been designed, locally implemented and analysed in previous research at preschool, primary, secondary and tertiary educational levels. Our purpose is to explore how these SRP could be used in professional development programmes for teachers. The aim is twofold: on the one hand, to identify teachers' professional problems in their day-to-day activities, and establish possible ways of approaching them; on the other hand, to enrich teachers' mathematical and didactic experiences with inquiry and modelling processes which will later be used as a source to introduce the didactic tools for the analysis and the questioning of any kind of teaching and learning processes. In this paper we will present the framework, principles and phases for the design of what we call SRP for Teachers Education (SRP-TE), together with some preliminary results of one of its first implementations.

STUDY AND RESEARCH PATHS FOR TEACHER EDUCATION

Previous research on the ATD concerning the problem of teacher education (Cirade, 2006) has made the following contributions (Bosch & Gascón, 2009). First of all, it is assumed that teacher education programmes should consider the difficulties and quandaries affecting the development of the professional activities of teachers and locate them at the core of the educational proposals. It is clear that the different tasks teachers should carry out are more or less specific to the content to be taught. However, an empirical study on more than 7000 questions posed by in-service teacher-students (Cirade, 2006) shows that many of these questions have an essential mathematical dimension. In other words, many of the problems teachers face are related to mathematics and, particularly, to the didactic transposition process and the specific mathematical knowledge to be taught (Chevallard, 1985). This issue has a clear connection with research on Pedagogical Mathematical Content (Ball & Bass, 2000), which we will not take into consideration here.

Secondly, starting from teachers' professional problems may help introduce didactic knowledge as a tool to approach them in a motivated way. Didactics of mathematics thus appears as a tool to solve problems instead of a set of (more or less dogmatic) theoretical developments to be known. At the same time, didactic knowledge should also appear as a tool to pose new problems and particularly to question the prevailing teaching proposals, including the curriculum and the pedagogical organisations.

Last but not least, it is important to note that many of the problems teachers face are still open problems for the mathematics education research community. Said problems need an important process of reformulation before they can be approached from a founded perspective. In fact, the more general question of what kind of knowledge has to be made available to teachers and how to help teachers develop it still is (and will always, to a certain extend, remain) an open question.

In order to take these considerations in teachers' development programmes into account, we propose to implement what we call 'study and research paths for teachers' education' (SRP-TE) as a way to provide teachers with pertinent (theoretical and practical) tools to nourish and sustain their professional development. They consist of the following five stages:

1) The starting point is an open question that comes from the teaching profession itself and is related to a given piece of knowledge to be taught: how to teach proportionality, algebra, integers, linear regression, etc.? This question is initially approached searching information and documentation available, including results from research, official curriculum guidelines and innovation proposals.

2) The second stage consists in presenting a *study and research path* (SRP) similar to what could exist in an ordinary classroom and is related to the professional question approached. The SRP can actually have been implemented in previous investigations or may simply have been designed by researchers for this purpose. Teacher-students have to follow the SRP as if they were students, under the supervision of educators.

3) The third stage is devoted to the analysis of the teaching process just followed. Three main phases are distinguished: (a) the *mathematical analysis* of the work done, including the elaboration of a reference epistemological model describing the modelling process involved (Bosch & Gascón, 2006); (b) a didactic analysis of the process, including a description of the differences between the contract established during the SRP to manage the modelling process, compared to the usual school didactic contract centred on the transmission of contents; (c) a more general study of the viability of SRP, including the identification of the institutional conditions and constraints affecting the development of modelling practices in school settings.

4) The fourth stage consists in *designing a SRP* based on the one previously followed and analysed, adapted to a given group of students. This design should be based on the analyses of the previous stage: sequence of mathematical questions to be posed to the students; sharing of responsibilities between teacher and students to pursue the questions; teaching devices to ensure the viability of the SRP.

5) The final stage of the SRP-TE, if possible, corresponds to the *implementation and a posteriori analysis* of the SRP designed. The same didactic tools made available at stages 3 and 4 are again supposed to play an important role: not only to provide some provisional answers to the question that was at the origin of the whole process ('How to teach ...?'), but also as a means to anal-

yse other possible alternative answers, as those found in stage 1.

The hypothesis of our research is that SRP-TE may contribute to the considerations previously presented in the following sense:

— *A tool to question mathematical contents to be taught.* The carrying out of a SRP (stage 2) provides a specific form of epistemological analysis of the content at stake (what we call a *reference epistemological model*) that helps approach the problematic mathematical dimension of the problem: what 'modelling' is, how the inquiry process can be described in terms of sequences of questions approached instead of contents used, how this sequence provides possible rationales to the contents at stake, etc. This reference epistemological model is a crucial tool to get rid of the transparency of school mathematical contents and to start questioning it.

— *Release teachers from the usual way of doing and teaching mathematics at school.* The mathematical activity developed in stage 2 is clearly different from (even if partially compatible with) current school activities and does not assume all the constraints of traditional teaching. This raises new questions during stages 3 and 4 to describe the mathematical and didactic activities carried out and to adapt them to real school settings. SRP-TE thus appears to be a good tool for detecting the institutional constraints hindering inquiry and modelling activities at school.

— *A fair contract between teachers and teacher educators.* Since in a SRP the teacher assumes the role of supervisor, there is no problem if the professional question taken as the starting point of the SRP-TE is an open question in research: teacher educators are not supposed to provide definitive answers (which do not exist) but help student-teachers approach the question by critically accessing the materials available.

Our research project wishes to explore to what extent these hypotheses can be confirmed and what changes or adaptations are suggested, using different implementations of SRP-TE as empirical basis. We are here presenting a single case of a SRP-TE for in-service secondary school mathematical teachers.

A SRP-TE ON SALES FORECASTING FOR IN-SERVICE TEACHERS

In Autumn 2013, a SRP-TE was experimented in an on-line course for in-service secondary school teachers coordinated by the CICATA-IPN centre (Legaria, Mexico) as part of a postgraduate programme in Mathematics Education. The course was led by a team of six teachers, three from CICATA-IPN and three from Spain, all of them researchers in mathematics education. The authors of this paper were all part of the team. In this case, the SRP-TE took the problem of teaching mathematical modelling at secondary school as the initial question. It was initially formulated as follows:

Q_0: How to analyse, adapt, develop and integrate a learning process related to mathematical modelling in our teaching practice? How to institutionally sustain a long-term learning processes based on modelling? What difficulties should be overcome? What teaching tools are needed? What new questions arise?

For four weeks, these issues were approached through a SRP on sales forecasting, considering four activities corresponding to the last four SRP-TE stages introduced in the previous section. There were 15 participants, all of them in-service secondary school teachers. They were supposed to spend 80 hours on the SRP-TE for five weeks: one week for each activity and one week for the final report.

The SRP on sales forecasts that was at the basis of the SRP-TE had previously been designed and implemented at university level and also at upper-secondary level (Serrano et al., 2010). In other words, we took an already experimented SRP, with a previous mathematical and didactic a priori design and some material concerning its implementation and a posteriori analysis. Students were informed of it and were invited to review some published works in the third phase of the SRP-TE. More concretely, the first activity (*Activity 1*) proposed the *Resolution and analysis of 'Forecast sales of Desigual'* with the main aim of letting participants experiment a SRP similar to the one experimented. Participants were asked to 'live' it like mathematical learners or apprentices. They had to act like a team of mathematical consultants and had to provide an answer to a request from Desigual (a Spanish fashion brand), which wanted to have an in-depth study on 'how to predict the evolution of several variables (see Figure 1): weekly sales in several of their shops, evolution of their benefits or of new national and international shop openings, etc.'

Participants were organised in five teams of three consultants each, combining individual work with group work (using the on-line forums of the CICATA virtual campus and Skype). They first had to act individually and propose their own answer to the question (phase 1). They later had to share and contrast their proposals with their partners (phase 2). Finally, in phase 3, they were asked to prepare and present a final report together, providing some answers to Desigual's request and defending it as the best proposal for the project. The final answer had to be accompanied by an analysis of the process followed by the team, including the difficulties encountered.

In *Activity 2*, the participants were asked to prepare a 'lesson plan' based on the mathematical work previously carried out in *Activity 1*. The situation proposed was that they were supposed secondary school teachers that had planned to implement the activity of 'Forecasting Desigual sales' in their classroom. Due to a cultural trip with other students, they had to ask another teacher to replace them. They were asked to write a brief and easy to read lesson plan including all the necessary elements for the substitute teacher to carry out the lesson/s. Like in the previous activity, participants first had to prepare and individual proposal, then share their proposal with the rest of their team and agree on a final common lesson plan. This activity was supposed to provide a first spontaneous answer of the teacher to the question: 'How to teach a modelling activity based on Activity 1?' in terms of a teaching proposal designed.

Activity 3 consisted in the experimentation of the participants' own design of the activity with a group of students. The participants had to individually assume the role of the teacher and implement the initial phases of the lesson plan proposed in Activity 2. With this purpose in mind, they had to elaborate a more detailed design, a more in-depth a priori analysis (phase 1), experiment their proposal (phase 2), finish with the a posteriori analysis (phase 3) and prepare a brief 'experimentation report' (phase 4).

Finally, *Activity 4* was devoted to a joint analysis and final revision of the lesson plan with the aim of proposing a new version taking into account both their own experience and the experience of their teammates. In particular, the difficulties found in the implementation of the modelling activity (a posteriori analysis) were supposed to highlight the constraints related to the normal implementation of this kind of teaching proposals and the possible ways to overcome them.

The supervision of the teacher educators during the SRP-TE consisted of the following. By way of feedback to the team discussions in the forum and to the activities (reports, lesson plans, etc.) submitted, the course staff progressively introduced some didactic tools to support the mathematical analysis of activity 1: notions of model and system, criteria and ways to characterise the models provided, ways of comparing them, etc. At the end of activity 2, as a means to carry out the didactic analysis of the spontaneous teaching proposals, some publications about SRP were provided: Serrano and colleagues (2010) and Chevallard (2012). Between activities 3 and 4, the educators prepared a guideline with the main sections of the a posteriori analysis of a SRP, including some examples of its mathematical description, some criteria to describe the didactic organisation and some elements of the conditions produced, the constraints faced and the global evaluation of the teaching process. They also provided an assessment grid for the final report and a questionnaire about the development of the course to be answered individually at the very end of the

course. All the material produced by the students was gathered during the course, especially the students' discussions in the forums (including the teacher educators' interventions), the students' questions raised (in the forums or by mail), the partial and final reports and their answers to the questionnaire.

THE 'LESSON PLAN' AS A CRUCIAL TOOL

Given the fact that this was the first on-line course based on SRP-TE, the results found are mainly related to the organisation of the course, the weaknesses encountered and the possible way to overcome them in further implementations. We will only present those concerning the function of the 'lesson plan', which appears to be a central element of the SRP-TE.

According to the design of this SRP-TE, activities 1, 2 and 3 were mainly based on the teachers' mathematical and professional knowledge. The function of the lesson plan is to provide shared teaching materials to support the analysis in a triple dimension: (1) as a description of the initial modelling-based activity on forecasting sales; (2) as a teaching proposal spontaneously designed by the teachers according to their professional knowledge and adapted to the usual institutional school conditions; (3) as the support of a real (partial) teaching and learning process. It is mainly in activity 4 where new types of didactic knowledge are needed to provide a critical analysis of the mathematical and teaching processes followed. In this section, we present how the lesson plan was used in the SRP-TE, its productivity and limitations.

In spite of some initial difficulties, the teacher-students quite easily dealt with activity 1 and experienced a specific mathematical 'unguided' work based on modelling and the inquiry of an open question close to the paradigm of questioning the world. In activity 2 (lesson plan), many teachers fell back on the usual didactic contract based on the learning of contents (as opposed to the study of open questions) and searched a school mathematical subject related to sales forecasting (such as 'linear regression' or 'function graphs') to teach it. They then prepared a list of mathematical techniques needed to answer the question previously provided to the students. For example in the lesson plan of teacher A, the teaching proposal was based on the presentation of different time-series forecast techniques, such as Gompertz (S-shape) curves.

In this lesson plan, the teacher is supposed to play the traditional role of teaching a repertoire of mathematical techniques the students should learn before proposing a forecast, as if the students could do nothing without it. However, other teachers respected the open character of the study process. For example, in the lesson plan proposed by teacher B, the students were asked to find an answer to the forecast question without any previously established strategy:

> In the next classes you will be employed by the company to make a short and long term forecast for each of the variables of the file 'Problem of Sales Desigual.pdf'.

Two tasks were proposed to guide the students through this new kind of work:

> Activity: Read the information provided by Desigual:
>
> 1) Which are the variables on which Desigual provided information? What types of variables are they? How does variation can be described for each of these variables?
>
> 2) Search for the following information: What articles do Desigual shops sell? Where in Spain are Desigual shops located? And outside Spain?

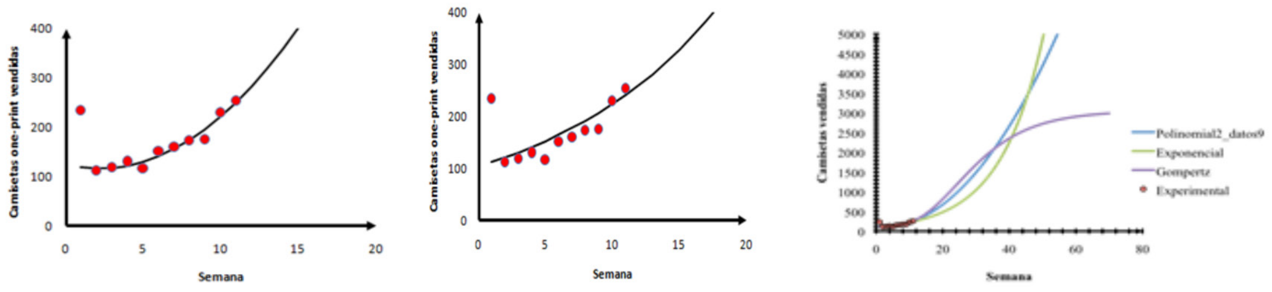

Figure 2: Mathematical models proposed by teacher A

Teachers A and B worked in the same team when preparing the first version of the joint lesson plan. In this case, the team ended up with a proposal similar to the proposal of teacher B (paradigm of questioning the world), but it could also have been the other way round. In any case, the reasons put forward and the discussions carried out in the forum appeared to be highly interesting material for the teachers' initial professional knowledge to be changed (especially the assumptions, reasons and criteria used to support their decisions). This knowledge was related to the school institutional constraints and was enriched with new didactic tools that enabled it to evolve. The a priori elements, progressively made accessible by the educators, consider the lesson plans as an initial empirical basis that was enriched during the teaching implementation in activity 3.

All this work eventually turned into a revision of the initial lesson plan now including the results of the experimentation. At this point, the supervisors proposed a guideline to organise the didactic tools provided in relation with the three previous activities. The mathematical analysis corresponded to activity 1. At this stage, the epistemological elements used to describe the modelling activity were completed with some examples of SRP descriptions in terms of sequences of questions and answers (see Figure 3).

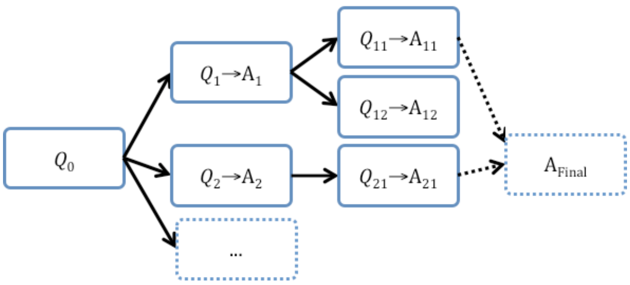

Figure 3: Sequence of questions and answers to describe a study and research path

This description starts with an open question (Q_0) and leads to different ways to formulate new sub-questions (Q_i) and obtain partial answers (A_i) until arriving at an acceptable final answer (A_{Final}) (also partial but provisionally considered as definitive). For instance, the team of teachers A and B proposed a description starting with the following sequence (the questions in italics being added by the authors):

Q_1: How to forecast the sales of the company, given some time-series real data?

A_1: Fit different functions to the real data, choose the best function and evaluate it in the future periods considered using appropriate software.

$Q_{1.1}$: What software to use: Excel, Geogebra, R?

$A_{1.1}$: Geogebra and Excel, which are the ones the participants know well.

$Q_{1.1.1}$: Do both tools provide the same results?

$A_{1.1.1}$: In the first calculations, the results obtained were different.

$Q_{1.1.2}$: How to explain the differences? [unapproached question]

$Q_{1.2}$: Which theoretical tools can be used? Where can they be found?

$A_{1.2}$: Document "Time-series. Least squares fit" provided by a participant.

$Q_{1.2.1}$: Should we use this sophisticated material to forecast the sales of an item that has increased from 100 to 500 units in ten weeks' time?

$A_{1.3}$: Elementary functions, 'trend line' option using Excel, 'fit line' using Geogebra.

$Q_{1.3.1}$: Which model fits the data best?

$A_{1.3.1}$: The best model is the one with the fewest errors.

$Q_{1.3.1.1}$: What types of errors are there? Do they lead to the same results?

$A_{1.3.2}$: The best model is the one with the highest R^2.

$Q_{1.3.2.1}$: What is R^2 and how is it related to the errors?

This schema of questions and answers, called the 'mathematical skeleton' by the educators, help the participants describe the elements of the teaching proposal designed, both those which effectively appeared in the process implemented and those left out. Based on this epistemological analysis, the guideline elaborated by the educators proposed certain elements to carry out a didactic analysis of the teaching and learning process (activities 2 and 3) experimented, using the notion of didactic organisation and focusing on the sharing of responsibilities between teacher and students during the development of the modelling process. We will not describe the SRP-TE any further. To this short description, we will simply add that the documents given to the participants as complementary reading were of crucial importance.

CONCLUSIONS

To sum up, let us stress what we consider at this very initial moment of our research, to be the main contributions of the theoretical framework used, ATD. An important characteristic of a SRP-TE is to locate the questioning of the mathematics content to be taught (here, a modelling activity) and of the traditional didactic organisations prevailing in our current schools at the heart of the teachers education programme. In the case here presented, the first stage of the SRP-TE (searching information and documentation available) was not developed. This clearly appears as a weakness, since it would most certainly give rise to interesting discussions about different ways of interpreting modelling as a school content, the ambiguity of the official guidelines regarding this matter and the variety of proposals existing in different countries and even within the same country. Another characteristic of a SRP-TE is to nourish the questioning of the mathematical content to be taught through the 'in vivo' performance of a mathematical activity based on a previously designed SRP. The role-playing technique used was a good choice and it worked well, in spite of some logical difficulties at the beginning for the participants to enter the new contract: they all initially hesitated between acting as secondary school students or as real mathematicians, but ended up playing their role. Of course, another main contribution of the ATD is the kind of methodological tools provided by the educators to help participants describe the content to be taught and the didactic organisation of the teaching and learning process, an aspect of our research that has just been outlined here, especially with respect to what concerns the description of the knowledge to be taught, the new responsibilities assumed by both teachers and students, and the institutional constraints found.

Mathematical modelling, problem solving, project and ethnomathematics: Confluent points

Maria Salett Biembengut

Pontifícia Universidade Católica do Rio Grande do Sul, Porto Alegre, Brazil, maria.salett@pucrs.br

This paper presents a documental study about the confluent points among mathematical modelling, problem solving, project and ethnomathematics as methods of research and mathematics teaching. As a result, the study has shown that there are elements that bind these methods structurally together as research methods. Starting from the fact that education should promote knowledge this study provides evidence for these methods. Thus in each one of them, it is required knowledge from the student about the topic of the problem-situation; method to delineate the phases to go through; technological instruments to support the solution; aesthetics for the expression; and ethics in the communication of the resulting ideas.

Keywords: Mathematical modelling, problem solving, project, ethnomathematics.

INTRODUCTION

The concepts of modelling, problem solving and project permeate the most varied contexts. It is known that concepts arise from the human mind and are developed by necessity. According to Boutinet (1990), this ability to model the 'imagined thing' is what drives people to conceive projects. As concepts guide people's daily actions, they have been at the core of educational curriculum reforms in mathematics and have nourished several thematic developments, among them three topics that are confluent with Mathematical Modelling (MM): Problem Solving, Project and Ethnomathematics. Despite being independent topics, they instigate us to identify confluent procedures in research and teaching. Two questions steered this study: (1) what are the confluences among Modelling, Problem Solving, Project and Ethnomathematics? and (2) in what circumstances can the involved phases be integrated into pedagogical practices of MM in Education?

METHODOLOGICAL PROCEDURES

In order to answer the research questions, I collected data in the literature about Modelling, Problem Solving, Project & Ethnomathematics. I sought to gather a deep understanding of the authors' propositions as well as attempted to identify the commonalities among the topics. I also subdivided the expression about each topic into two parts: scientific research method and teaching method. This study may be considered documental, since the data comes from publications of authors who are referenced in academic literature. In this context, it is essential to highlight that in the process of identifying confluences among the topics, different identifications may coexist. Additionally, it is crucial to bear in mind that the expression in this article is not neutral, since it carries along the conceptions implicit in the works analyzed.

MODELLING, PROBLEM SOLVING, PROJECT AND ETHNOMATHEMATICS

Most of the problem situations people experience require them to make use of representations to solve them. These situations are inserted in a sociocultural context and sometimes exceed the needs of subsistence. As a result, such situations prompt people to design ways to solve problems and to learn new knowledge in order to solve them. When one of such designs involves the 'desire to know' about something, a research method is required to accomplish the goal. If this 'knowledge' aims to solve a problem situation for which the available data are not sufficient for the person to use an existing model, there is the need for Modelling. However, if this 'knowledge' aims at constructing knowledge, at explaining how a person or a group from a social culture elaborates a mathematical model or makes use of this model in their activities, the method is called Ethnomathematics.

Mathematical modelling

Modelling is the process involved in the development of a model in any field of knowledge. The essence of this process emerges in a person's mind when a genuine doubt/circumstance instigates her to find the best way to solve, understand, create or improve something. The route of scientific research is delineated when someone models a problem situation using mathematical concepts. According to Biembengut (2014), this research happens through three connected phases: (F1) understand and grasp – recognize and become familiar with the subject; (F2) understand and explain – formulate the model and solve the problem situation; (F3) articulate meaning – interpret the solution, validate, explain the process and results.

As MM is in essence a research process, it has been advocated as a process for mathematics teaching. The goal of MM in Education is to teach students the contents of the curriculum departing from a topic, formulating a project with a proper design and guiding students to conduct research within the limits of the school structure. The teacher organizes the project following the modelling steps by promoting (E1) understanding and grasping (topic presentation, provoking questions, selection of adequate issues to develop the content); (E2) understanding and explaining (presentation of the data, suggestion of hypotheses, presentation of the content and examples); (E3) expressing meaning (model formulation, requiring students to solve the problem, result evaluation). The purpose consists in providing students with opportunities to research about topics of their interest while they learn the curricular contents.

Problem solving

A problem emerges when the person realizes that there is a gap between the situation she does not know how to solve and her desire to solve it. The solution may come from an idea, in a heuristic approach: a set of rules and methods that leads users to solutions and discoveries. A person may solve problems using different heuristics, and each heuristic may be more appropriate or less for each kind of problem. Authors such as Wallas (1921), Dewey (1922) and Polya (1981) are recurrently cited as references in heuristics for Mathematical Education.

Dewey (1922) proposed five phases: identification, definition, plan, execution and survey; Wallas (1921), four stages: preparation, incubation, illumination and verification; Polya (1981), four: understanding, plan, execution and retrospection. As these heuristics are related, four non-linear phases may be proposed: (F1) identify the problem situation: become familiar, collect data, identify relationships – preparation; (F2) establish procedures: look for similar problem situations, map, identify the knowledge required; (F3) solve the problem: implement strategies for a plausible solution – illumination; (F4) evaluate results and validate them: check the validity of the result – retrospection.

As these procedures are requirements for any type of activity, they are part of the pedagogical proposals in Mathematical Education. Researchers such as Schoenfeld (1985), Gage and Berliner (1992) consider that helping students to solve problem situations is the reason why we should teach Mathematics. Problem situations should require students to review basic facts, identify unknowns, look for meanings in the unknowns, (re)learn math operations, understand relationships between operations and their implications, formulate, solve and argue whether solutions are compatible.

In light of the exposed, it is possible to prescribe a three-step method for Problem Solving in pedagogical practices: (E1) proposition – proposing a problem situation to students that require them to decompose the data, identify the unknowns; (E2) ideation – guiding them to perceive mathematical relationships and formulate a plan; (E3) synthesis – guiding them to apply and evaluate the resulting data. These steps allow students to combine their ideas to the extent that they are encouraged to learn about issues of their interest.

Project

A large number of people have needs that exceed the solution of practical problems. Anything may inspire people to know, do or have something, an impulse that leads one to design ways to achieve solutions. People may delineate a project to solve a problem related to physical survival as well as when they are interested in learning about something. Boutinet (1990) suggested essential steps in this process: (F1) diagnosis – setting the purpose and learning about the available resources; (F2) outline – describing means to obtain data and evaluating; (F3) strategy – identifying how to organize and classify the data; (F4) execution – performing actions and evaluations; (F5) analysis – judging the results and evaluating the situation.

Similarly, the project heuristics is a proposal for Education. Izard (1997) states that school projects encourage active participation from students; provide them with motivation and challenges; encourage them to ask questions, to learn about some topic, to observe their context. Projects also reveal students' interests in the formulation and description of the data as well as their skills in interpreting and evaluating the results. Three steps are proposed as a method to include projects in pedagogical practices: (E1) preparation – instigating students to know about a topic/issue, look for data and learn about the topic; (E2) development – guiding students to ask questions about the topic/issue, describe the data encountered, identify concepts, formulate and understand the circumstances; (E3) projection – guiding students to interpret results, analyze them and identify other facts. I believe that one of the purposes of education is achieved when students are offered with projects that enable them to expand their knowledge, to learn about their surroundings, making them feel valued.

Ethnomathematics

D'Ambrosio (2001) sustains that all social cultures have a legacy of knowledge, behavior and rules that they seek to convey to generations, making it possible to perpetuate cultures. Many social cultures have created and developed instruments to explain, understand, and learn about things. Each culture has developed unique mathematical techniques arising from their needs. D'Ambrosio calls Ethnomathematics the art or technique to explain, know or understand how a person or a group generates mathematical knowledge, makes use of it in their business, and organizes and transmits knowledge to others. It is the study of concepts, traditions and mathematical practices of a person or a sociocultural group. The researcher goes deep into the person/community's culture by observing, asking questions, among other means.

Research on Ethnomathematics, for D'Ambrosio (2001), consists of three phases: (1) develop methods from practices and solutions; (2) develop theories from methods; (3) innovate from theories. Ethnomathematics procedures involve the need to: (F1) explicit the fact – recognize the fact, become familiar with the practices and the solutions presented by a person/group; (F2) present the explanatory assumption – analyze facts, methods, practices and solutions, establish conceptual principles and formulate explanations; (F3) indicate other facts – interpret, validate the pragmatic model from the perspective of the person/group, describe and check whether theory resulted from the method; (F4) complement the fact – identify whether innovation resulted from theory ↔ method ↔ practices and solutions.

In Ethnomathematics, the focus lies on recognizing the mathematical actions and knowledge of people, resultant from the needs and experiences these people have. Using people's activities and knowledge in pedagogical practices may best contribute to the students' learning process, since they may interact with problems and solutions, and experience the culture. The Ethnomathematics method for pedagogical practices consists of three stages: (E1) interaction – help students to get acquainted with the facts from the activities, to interact with the person/group and to recognize practices and solutions; (E2) explanation – encourage students to understand practices and solutions, to identify mathematical concepts, to stipulate phases, to learn and make explanatory assumptions; (E3) indication – guide students to interpret the assumptions, to describe or verify whether the method or theory used resulted in innovation.

Ethnomathematics has as its source the activities that a person/group performs and the knowledge they have resulting from the needs of their daily lives. It assumes dynamic sharing between activities and knowledge; values popular knowledge as a means of contributing to knowledge production; and proposes education as a process in which knowledge is transmitted across generations.

CONFLUENT POINTS

Modelling has elements that converge with Problem Solving, Project and Ethnomathematics, depending on the desire to know. As Education should promote knowledge, instigate the desire to know, I believe one of these methods should relate to the desire to teach.

Confluent points in the 'desire to know' as a research method

Modelling is used when we need to solve a problem situation for which the available data are not sufficient to apply an existing model to obtain the solution, or when we need to (re)create, improve something. To confront the MM procedures with those of Problem Solving, Project and Ethnomathematics, for research purposes, the similar points consist of: delimitation of the problem situation, theoretical framework, hypotheses/assumptions, development, implementation, interpretation and evaluation of the solution.

MM is the area of research for the development/creation of a model for the solution of a particular problem situation or to support other applications and theories. Ethnomathematics is the area of research that seeks to understand a person/group's knowledge related to their activities. When someone intends to conduct research, a project with a proper design is required to accomplish such a goal. In light of these definitions about the desire to know, I may conclude that in all these areas, the researcher is guided by the scientific methodology following common steps to produce knowledge; be it something original, be it a complement to what already exists.

It can be stated that a research design, be it in Modelling or Ethnomathematics, has as its source a problem situation, a desire to know. To solve a problem, we direct our steps through other areas of knowledge, fact that allows the researcher to expose events, enunciate models of relationships between things and facts. As they are part of the scientific research pathway, they cannot be denied in the school context as methods of teaching and research, since they give students the chance to design projects, be them in Modelling, Problem Solving or Ethnomathematics.

Confluent points in the 'desire to teach' – teaching method

Modelling in Education is a method for teaching research in Basic Education. To confront the procedures of Modelling with those of Problem Solving, Project and Ethnomathematics, for teaching purposes, the 'desire to teach' point is similar: proposition of a topic or problem situation, review or presentation of data, procedures for resolution and evaluation of results. For instance, the teacher may use the context of an apple plantation to teach modelling. She may begin the class by talking about the context in the Brazilian state of Santa Catarina. She may present some data, such as the fact that apple trees are planted in line and that for that reason, there is a particular spacing among them. She may ask students: what is the ideal distance between one tree and the next one if we aim at producing more apples? To help them answer the question, the teacher models the data by teaching the students the required mathematical contents. At the same time, the students study the ethno-mathematic aspect of the problem and start a project. They seek to understand how the producer uses farming "models" (his knowledge might possibly have been acquired through experience, or inherited from his ancestors). Students can research about the topic by talking directly to the producer and observing his work. Drawing on the data collected, students can attempt to verify whether or not the producer received technical orientation (help from specialists), whether he modified his practice, and hence, his mathematical conceptions.

I conclude that the essence of the four themes resides primarily in involving each student in the interaction among real elements present in the environment in relation to the topic in question. Be it in Modelling for Education, be it in Ethnomathematics, students will have a problem situation as a starting point, and to solve the problem they will delineate a project to guide them. Moreover, to outline a project, they ought to have knowledge beyond the traditional school topics. I believe that when students feel themselves capable of solving a problem situation that requires going through the steps of Modeling or Ethnomathematics they learn the curricular contents along the process, and teachers will feel encouraged in their desire to teach.

FINAL REMARKS

As a researcher, I hope I have not committed any kind of improbity by articulating the principles of each of the themes. I hope this work can be improved and contribute to teaching and research in education. This study had as its main guiding question the confluent points among Modelling, Problem Solving, Project, Ethnomathematics and the desire to know research method and the desire to teach teaching method. The art of these themes lies in guiding students to understand the environment in which they live as well as in the potential to put these topics into practice: by translating results into suitable language for general comprehension. The procedures, even when implemented as extracurricular activity and only by a few group of teachers and students, can contribute to improve the knowledge of those who are involved in the process. Taking the real value of Education into account, it is worth considering one of the themes, or all combined in the classroom, since they offer students the opportunity to ask questions, identify and learn about facts, accumulate experiences, become more attentive to events, become enchanted with solutions to problems, and feel free to express their knowledge.

Taxonomy of modelling tasks

Wolfgang Bock, Martin Bracke and Jana Kreckler

University of Kaiserslautern, Kaiserslautern, Germany,
bock@mathematik.uni-kl.de, bracke@mathematik.uni-kl.de, kreckler@mathematik.uni-kl.de

When teaching mathematical modelling it becomes essential to be able to construct modelling tasks of a similar difficulty for projects and exams. In order to be able to compare these tasks, an evaluation scheme concerning the difficulty becomes necessary. In this paper, we introduce an extension of a model developed by Bock, W., Bracke, M., Götz, T. & Siller, H.-S. (2014) which is based on a model from Eyerer & Krause (2012) for comparing difficulties of projects between industry and school. This is used to evaluate the difficulty of a modelling task. The theoretical model of Bock and colleagues (2014) is made applicable by means of a software tool: Taking into account all relevant dimensions of modelling, a measure of difficulty is calculated based on the normalized covered area in the constructed multi-dimensional model. This allows a comparison of the difficulty of several modelling tasks.

Keywords: Taxonomy, authentic problem, modelling.

THEORETICAL BACKGROUND

Mathematical modelling is part of the educational standards in many different countries; moreover it is named by the German Education minister Conference (KMK, 2012) as one of the general mathematical competencies that need to be taught and learnt. “By mathematical modelling competence we mean being able to autonomously and insightfully carry through all aspects of a mathematical modelling process in a certain context” (Blomhøj & Jensen, 2003). A modelling process can be described as a modelling cycle, see, for example, (Blum & Leiß, 2007) or (Kaiser, 1995); compare also (Ackoff, Arnoff, & Churchman, 1957) for similar cycles in Operations Research. In order to teach mathematical modelling, both concepts as well as good modelling tasks need to be developed. Following a definition of Blomhøj & Kjeldsen (2006), a good modelling task must fulfill the following seven criteria. A good modelling task should

… be understandable and reasonable,

… give an appropriate challenge for an independent work,

… be authentic and include authentic data,

… be open for interesting modelling results,

… be open for critics to the model,

… lead to representative modelling activities and

… challenge the students appropriately to work with concepts and methods that are relevant for their mathematical learning.

In most cases mathematical modelling in school, at university or in industry is group work. To be able to compare student results regarding different modelling tasks during class or in exams, an evaluation scheme for their level of difficulty becomes necessary.

Cohors-Fresenborg, Sjuts, and Sommer (2004) have developed a model to determine the level of difficulty of PISA-tasks. The focus of their model lay on the cognitive processes necessary when solving the tasks. The four criteria *linguistic complexity*, *cognitive complexity*, *formalization of knowledge* and the *handling of formulas* were defined to be the criteria affecting the difficulty of tasks. Each criterion was divided into three levels of difficulty 0, 1 and 2. The complexity of a task was then defined to be the sum over those levels achieved in the four criteria.

The difficulty of modelling tasks is much harder to determine as many different dimensions play a decisive role. Reit (2014) has developed a model determining the difficulty of modelling tasks based on thought structures of different solution approaches. The model is based on the assumption that different mathematical models and solutions to the same task require different knowledge and mental activities. Based on cognitive load theory, the approach acts on the assumption that parallel thought structures are more difficult than sequential thoughts. The level of difficulty is then described as the sum of the factorial of the single levels.

The problem of the above model is that student solutions have to be available a priori. In many problem settings this is not the case. Especially for authentic or real world problems (see, e.g., Bock & Bracke, 2013) possible student solutions are hardly predictable. These problems are classified by a client structure and are of full generality.

Definition: An authentic problem is a problem posed by a client, who wants to obtain a solution, which is applicable in the issues of the client. The problem is not filtered or reduced and has the full generality without any manipulations, i.e. it is posed as it is seen. A real-world or realistic problem, is an authentic problem, which involves ingredients, which can be accessed by the students in real life.

With these problem settings another aspect makes a taxonomy of the tasks hard. The problem can be posed to students from primary school as well as to students from university, since every learning group is using their individual methods. This makes a general classification dependent on competences and the respective pre-knowledge. Since general industrial projects for mathematical modelling are of a high dimensionality concerning the use of competencies, Eyerer and Krause (2012) developed the spider web method to illustrate difficulty of tasks in the TheoPrax method. TheoPrax is a method which focusses on project teaching with real industrial projects. Here, industrial partners give tasks to students who then have to write an offer to the industry to obtain the job. The project is then worked out by the students. The industrial partner is obliged to cover the costs and also to finance workshops for the students if the offer of the project is acceptable for them. The financing part also has to be planned by the students.

The idea of the Eyerer model is to use a spider web diagram, comparable to Figure 1, to grade a project. This model was adapted by Bock, Bracke, Götz, & Siller (2014) to measure how teachers rate the difficulty of certain modelling tasks. For this purpose eight dimensions and corresponding levels of complexity for each of the dimensions were chosen. Using this system teachers and supervisors rated several modelling problems and their ratings were illustrated by spider web diagrams. If we want to compare the difficulty of two modelling tasks we have to compare two spider web diagrams: Let us assume that we get diagrams *A* and *B* as in Figure 1 (the diagrams are for the modified nine-dimensional spider webs introduced later in this paper).

We would now like to compare the two tasks *A* and *B* regarding their difficulty – of course relative to our special situation (time frame, learning group, ...) and needs. This seems to be nontrivial because of the multidimensional nature of the data and different weights we may have for each of the dimensions. In the following paragraph we first extend the model developed by Bock and colleagues (2014) by one dimension which is relevant when dealing with authentic modelling tasks. In order to compare the difficulty of modelling tasks we propose a *measure of difficulty* which can be easily calculated using a software tool. Moreover, the rating of modelling tasks as well as the computation of the

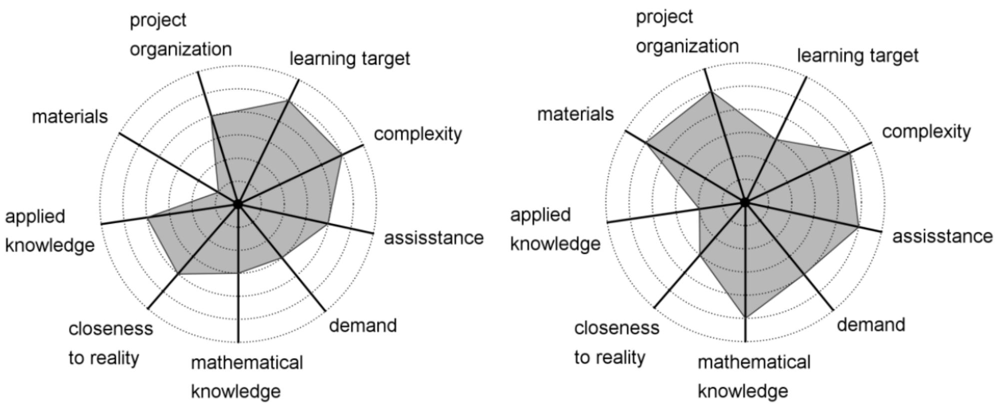

Figure 1: Comparison of two star diagrams for modelling tasks *A* and *B*

new measure are made easily applicable by a newly implemented tool.

THE MODEL

The aim of the following model is to describe and compare the difficulty of modelling tasks from the viewpoint of one individual teacher or supervisor. Note that the measure of difficulty for different teachers using the model to evaluate the difficulty may vary. This is due to the different background and experience teachers have. Also with growing experience and competencies the value may vary in time. However on a small time scale, in the opinion of the authors, the score value is stable.

Assume that the difficulty of a modelling task depends on many different dimensions. These dimensions also could be adapted, extended or reduced according to which aspects the score will focus on. *To be able to apply the model it is essential that the person using it can account for practical experiences with mathematical modelling tasks.* This is at first necessary to be able to estimate the different scales of the dimensions and secondly to obtain an intuition for their interplay. In a small pilot study a group of teachers participating in a modelling week was asked to rate different modelling tasks using the following model. For some teachers this turned out to be quiet difficult as they were missing some essential knowledge and experience concerning modelling.

Bock, Bracke, Götz, and Siller (2014) identified the following eight dimensions affecting the complexity of modelling tasks:

1) Project organization
2) Learning target
3) Complexity
4) Assistance
5) Demand
6) Mathematical knowledge
7) Closeness to reality
8) Applied knowledge

Each of these dimensions was divided into six levels of complexity, where 1 describes the easiest and 6 the most difficult level. For each dimension the possible answers are categorized, where the numbers are assigned to the respective competence levels. An example is given for the dimension *complexity:*

1) solution approach is clear
2) one-sided methods (e.g. only programming, geometry…)
3) alternative solution approaches possible
4) data set is too big or insufficient
5) solution requires variety of methods
6) alternative solution approaches in combination with many methods necessary

All eight dimensions, each consisting of six complexity levels, are illustrated in a diagram in the shape of a star (compare Figure 2). Each dimension is pictured as a ray emitted from the centre of the star. The length of each ray is divided into six equal parts. The first ring defines the easiest complexity level 1, the most complex level 6 is reached at the end of each ray.

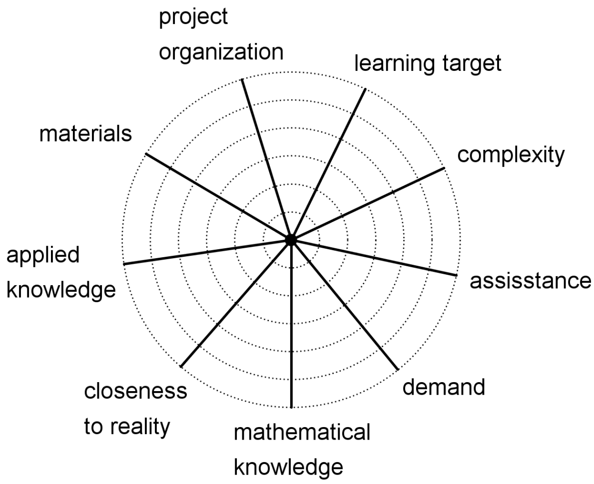

Figure 2: Extended model: nine-dimensional star

Considering a given modelling task, its complexity is rated for each dimension separately and marked on the correspondent ray. The marks of all rays can then be connected and the enclosed area calculated (compare Figure 3). The size of the enclosed area symbolizes the difficulty of the task and therefore gives a possibility to compare the difficulty of modelling tasks. The larger the area, the more difficult the task. Note that the diagram shows also the directional weights of the individual dimensions, which can be used to test the tasks according to the pre-knowledge and competencies of the students.

Due to the authors experiences the model has been developed further by incorporating the dimension "*materials*" to the model with the following score levels:

1) Computer/Laptops with internet connection are available for research the whole time

2) Computer/Laptops with internet connection are available for research temporarily only
3) A subject-specific library is available for research
4) Selected books and journals are available for research
5) Some information selected by the teacher is available for research
6) There is no possibility for research

This dimension takes into account that the complexity of a modelling task does also depend on the amount of research that is possible during the process of finding a solution. An extra ray for the dimension *materials* was added to the model (see Figure 2). The model was then implemented in a new software tool such that ratings of modelling tasks can easily be evaluated and compared. Of course, rating a modelling task according to the named dimensions always depends on the specific target group and the individual project settings.

With the help of the implemented tool the area which is formed by connecting the neighboring score levels is computed and normalized by the maximal area, i.e., if all dimensions have maximal score. Thus the output can be interpreted as the percentage of the task compared to a task of maximal difficulty and delivers a number between 0 and 1 indicating the difficulty of the investigated task. We will call this number the *measure of difficulty (MOD)*. The closer MOD is to 1, the more difficult the task.

Definition: (i) Let M be the area of the convex hull spanned by the complexity ranking of 6 in each dimension. Let I be the measured area of the enclosed area of a rated modelling task. The measure of difficulty (MOD) of the modelling task is then equal to: MOD = I/M and takes values in the interval (0,1].

(ii) Two modelling tasks T1 and T2 are said to be of equal complexity of fineness e if

$$|MOD(T1)-MOD(T2)|<e.$$

A difficulty that arises when calculating the MOD is the fact, that the area differs for the same rating with different arrangements in the sequence of the dimensions. This problem was solved by calculating not only the area but the mean value of the areas over all permutations of arrangements.

EXAMPLE

As an example consider the following setting: A group of students from 11th grade of a German secondary school is supposed to work in small groups on the authentic *Airline Problem*. During the time of the modelling activity (4 h) the students have access to computers and internet.

Airline Problem: The time a plane is on the ground is time in which the airline is making no money! Therefore the airline is interested in a system for the boarding of a plane such that the time the plane is on the ground is minimized.

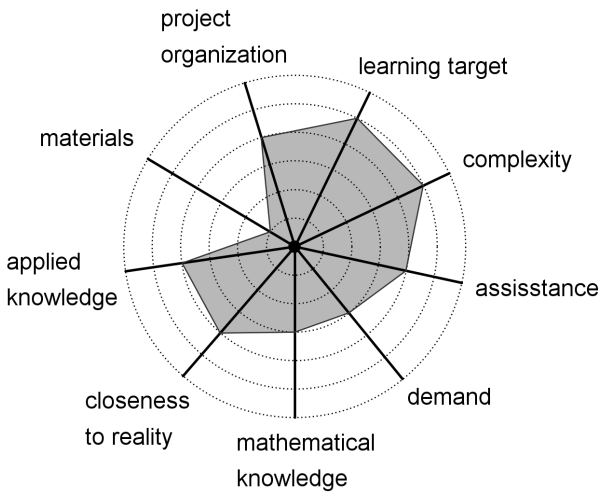

Figure 3: Example: Rating a modelling task to calculate the MOD

The authors would rate this problem according to the model as in Figure 3. This rating was developed by taking the average value of the individual ratings of the authors. The precise categories apart from the material dimension can be found in Bock and colleagues (2014). For the *Airline Problem* the MOD is calculated to be 0.3688. This rating can be retraced in the following way.

The dimension *materials* is rated depending on the individual setting set for the project work planned. In our example, level 1*"computers/laptops with internet connection are available for research the whole time"* describes the situation planned by the teacher.

Project organization is rated with complexity level 4 *"with great difficulties, risk to fail is controllable."* This is justified by the fact, that the Airline Problem has a very open formulation which leaves several decisions and estimations to the students. Still, these difficulties can be overcome and a solution can be obtained by a simple simulation with chairs and a stopwatch.

The *learning target* is described in level 5, *"new combinations of different techniques"*, which is set as the desired outcome while working on the problem. Hence, the dimension *complexity* is rated with 5,*"solution requires variety of methods"*.

The *assistance* given in the above setting can be described within the meaning of level 4 *"teacher or external tutor supporting in wide steps"*. The rating of this dimension is depended on the individual support teachers are planning to give their students and can be varied for each realization of a modelling project.

The *demand* on the Airline Problem can be rated by level 3, saying that the *"demand (is) alternatingly increasing"*. This marks a medium level of difficulty to the task. The *mathematical knowledge* in this example is based on the *"recognizing (of) missing knowledge in detail"* (level 3) while the *applied knowledge* requires the *"researching and arranging (of) missing information and correlations"* (level 4).

Finally, the Airline Problem has a *"high correspondence to reality"* which leads to complexity level 4 in dimension *closeness to reality*.

POSSIBLE EXTENSIONS

If one wants to lay more focus to certain dimensions, the model can be extended to a weighted model. This can be dependent on the background and formulation of an individual task. Depending on the situation, some of the nine dimensions carry a greater weight than others and therefore influence the complexity of a modelling task more than others.

For example, in the described setting of the *Airline Problem* computers and internet are accessible but play a minor role for the finding of a good solution. In practice, the authors noted that students for example simulated themselves the time to sit down on a seat while blocked with the help of chairs in the room. With a very limited time horizon there is no gain of having access to computers or internet. Therefore, the dimension of material can be weighted less than the other dimensions in this case.

Of course, also the model of maximal difficulty has to be adapted. This can be implemented by modifying the length of the individual rays. A dimension which is considered to be less important in its effect on the difficulty of a modelling task is assigned a shorter ray than more important dimensions. For this, an exact assignment of weights and the proportional change in the length of the corresponding rays still needs to be formulated.

Possible modifications are also the adding and deleting of certain dimensions from the diagram. But this has to be done carefully since too few dimensions are not reflecting the whole difficulty of the modelling task while also too many dimensions make the tool inconvenient and unclear.

SUMMARY AND OUTLOOK

In this paper, we presented the extension of a model developed by Bock, Bracke, Götz, & Siller (2014) based on (Eyerer & Krause, 2012) evaluating the difficulty of modelling tasks. The extended model considers nine dimensions with six complexity levels each affecting the difficulty and is illustrated as a star with nine rays (see Figure 2). To calculate the newly defined measure of difficulty (MOD) of a modelling task, the task is rated with respect to its complexity level in each of the nine dimensions. The ratings are marked in the nine-dimensional star and connected to calculate the enclosed surface area which leads to the definition of the MOD (see Figure 3). A new tool was implemented such that ratings of various modelling tasks can easily be compared by their value of MOD. The closer the value of MOD is to 1, the more difficult the modelling task. In further research the validity of the model should be analyzed and an exact ranking for the values of MOD defined. This could be done by comparing the MOD values with student solutions and the correlation between those. Up to now, this model represents a subjective rating. It is therefore necessary to undertake an empirical study to validate the model by comparing theoretical ratings with the feedback given by students working on the respective modelling projects.

The model of a multi-dimensional star with rays of equal or weighted length can also be used to evaluate self-assessments of participating students or to assess the expectations of students regarding modelling or other activities. For this, different dimensions and items need to be defined. Bock and colleagues (2014) developed a questionnaire to investigate the self-assessment of students. In the context of modelling days at the University of Kaiserslautern, Germany, Kreckler developed item formulations to compare expectations and conclusions of students concerning the project days. A small sample of students was tested and evaluated. The answers for expectations and conclusions were marked on the rays and compared for each student. With this an evaluation regarding the categories *exceeded expectations*, *fulfilled expectations* and *expectations not fulfilled* for the single dimensions was made possible.

Of course, it may not be correct to assume that every dimension is of equal weight. To overcome this, practical empirical studies are planned, in which the weights of the individual dimensions are obtained via a fitting. For this, also a survey for the students is in preparation. The aim is to find a benchmark model for the measure of difficulty.

Conceptions in France about mathematical modelling: Exploratory research with design of semi-structured interviews

Richard Cabassut[1] and Irene Ferrando[2]

1 Strasbourg University, LISEC-EA 2310, Strasbourg, Paris 7 University, LDAR, Paris, France, richard.cabassut@unistra.fr

2 Universitat de València, Dpto. de Didáctica de las Matemáticas, València, Spain

From ongoing research, we present the design of interviews on conceptions about modelling in order to better know the relations between students, teachers, researchers, authors of resources and decision makers in the field of mathematical education in France. The theoretical framework combines theories on conceptions, on modelling and on anthropological approach. The methodology uses bibliography, exploratory data analysis, comparative approach and interviews. We describe how a review of the literature, an exploratory data analysis of existing questionnaires and interviews are used to design these semi-structured interviews.

Keywords: Modelling, interview, France, teacher, conception.

DESIGN OF INTERVIEWS ON CONCEPTION ABOUT MODELLING

Philipp (2007) points that teachers' conceptions play a key role in the teaching and learning of mathematics. Kaiser (2006) remarks that German "teachers and their beliefs concerning mathematics must be regarded as essential reasons for the low realisation of applications and modelling in mathematics teaching". CERME has reported several research on teachers' conceptions about modelling as we will show later in the review of the literature. We found only one research, (Cabassut & Villette, 2011), dealing with French teachers' conceptions: it was limited to French primary school teachers attending a teacher training course on modelling. *The problematic of our ongoing research* is the following: What are conceptions about modelling in France? What are their relations with the practice of modelling? The answers to these questions will help to understand differences and similarities with conceptions in other countries and to produce resources taking into account French conceptions: for example to produce resources considering difficulties or obstacles expressed in French conceptions. The *focus of this paper* is at the beginning of the exploratory phase of this ongoing research. We describe the design of interviews and we expose how Chevallard's levels of didactic codetermination will help us to analyse the French conceptions. Hypotheses and results about French conceptions are not the focus of this present paper and will be produced in another paper. *The results of this exploratory phase proposed in this paper* are the theoretical framework, the review of literature and the design of interviews. Let us now describe our theoretical framework.

CONCEPTIONS ABOUT MODELLING

In many researches, different terms such as beliefs, emotions, attitude... are used to refer to similar concepts. We will adopt the definitions given by Philipp (2007), particularly: "Knowledge – beliefs held with certainty or justified true belief [...]. Conception – a general notion or mental structure encompassing beliefs, meanings, concepts, propositions, rules, mental images, and preferences". The general term "conception" allows us to avoid the debate on the differences between "beliefs" and "knowledge" and to concentrate on the interaction between teachers' conceptions and teachers' practice.

Maaβ (2006, p. 115) expresses: "Modelling problems are authentic, complex and open problems which relate to reality. Problem-solving and divergent thinking is required in solving them". This conception and other ones collected in the review of the literature are considered in the questionnaire but it is not the focus of this paper to discuss them. The extract of the interviews in part 6 shows how these conceptions are taken into account and how the future answers could express them.

ANTHROPOLOGICAL APPROACH

To help analysing these conceptions, we use Chevallard's levels of didactic codetermination as suggested in Barquero, Bosch & Gascón (2011, p. 1938). At the *level of mathematic discipline*, we ask questions about mathematic conceptions and practices in order to observe relations with modelling conceptions and practices, and to point what is specific to modelling and what is general to mathematics. For example in the interview, some open questions are: "What are mathematics for you? What is mathematic teaching for you? How do you teach mathematics? How easy is it?" Examples of question with Likert scale: "from my point of view, in my mathematic lessons, school mathematics is the memorizing and application of definitions, formulas, mathematical facts and procedures." About practice with a Likert scale: "In my mathematic practice it is important to do open problem solving". At the *level of domain*, we can consider modelling as a transversal domain, covering different mathematical domains. We ask questions about modelling conceptions (already mentioned in part 2) and its practice. At the *level of pedagogy* for example we ask "In my mathematic teaching practice is it important to do small group work?" At the *level of school*, in the biography part, we ask in what type of teaching institution (primary school, general, technical or vocational secondary school, tertiary education) the teacher works. To consider the *level of society* the semi-structured interviews will be adapted to different types of members of French mathematical educational sphere, in order to conjecture how teaching, training, resource and decision making contribute to the conceptions and practices of modelling. The *French mathematical educational sphere* gathers students to become mathematics teachers from different types of school, researchers, authors of resources and decision makers (mathematical supervisor, curriculum adviser, etc.) in the field of mathematical education. At the *level of civilization,* Cabassut and Ferrando (2013) show how PISA and European parliament recommendations are explicitly mentioned in French common base of knowledge and skills that encourage modelling. We adopt a comparative approach involving others countries (Switzerland, Spain and Germany) to conjecture variations between different cultures.

The role of the different levels of didactic codetermination resulting of the semi-structured interviews will be interpreted with help of other studies on modelling. At this point of our research we just prepare the way to collect all the interviews and are waiting for their results to be analysed through the grid of levels of determination.

METHODOLOGY OF EXPLORATORY RESEARCH

We will describe now the four components of our exploratory methodology, method of interviewing, review of literature, exploratory analysis of existing data and comparative approach, which will all help us to design the interviews.

Semi-structured interview

Among the different ways of collecting conceptions about modelling, we choose semi-structured interviews proposed by Bernard (2006, p. 212). For every topic within the interview, we ask at first some open questions without directive contents to enable the interviewed person to express freely his or her mind without direction given by interviewer. The topics are selected from a review of modelling research literature. In a second part, the answers are completed with directive closed questions in order to cover entirely the topics. This second part will be the base of a future written questionnaire that will be produced for confirmatory research. The questions are selected from a review of modelling research literature: LEMA project (Maaβ & Gurlith, 2009), Schmidt (2011), Borromeo and Blum (2013). Some questions are adapted from inquiry based research: Dorier and Garcia (2013), Engeln and colleagues (2013). They often use the 5 levels Likert scale.

The semi-structured interviews are particularly adapted to researchers, authors of resource and decision makers because they are not so numerous in comparison with students or teachers, sometimes it is difficult to contact, and they have often time constraints that make harder to get a written answer to a questionnaire from them. Finally, after the exploratory research, we will produce a questionnaire to test the hypotheses. A cluster analysis of people answering the questionnaires could be produced, delivering for every cluster a representative paragon of the cluster. An additional clarifying semi-structured interviews could be made with clusters paragons in order to make the results of the analysis of the questionnaires answers clearer. This shows how interesting semi-structured interviews are.

Review of literature

The review of literature concerns the two last CERME proceedings, the last three years of Educational Studies in Mathematics review, and of Zentralblatt für Didaktik der Mathematik, the proceedings of ICTMA 14 and other papers found on the internet or known by the authors. These review deals with research papers on conceptions about modelling in the mathematical educational sphere. We would like to remind the reader that we did not find research on conceptions of modelling specific to France, and that every collected research studied a specific population (for example primary school teacher or prospective secondary teacher) and none studied the conceptions of researchers, authors of resources and decision makers.

Exploratory analysis of existing data

The LEMA project described in Cabassut and Mousoulides (2009) has developed a teacher training course on modelling. During the project, two different kinds of data were produced. First, 83 teachers attended a LEMA pilot training course and have answered a questionnaire before and after the training in order to evaluate the training course. The questionnaire is well described in Maaß and Gurlitt (2009). Secondly, 3 French teachers have been interviewed after the LEMA training course to evaluate the impact of the training course. We propose an exploratory analysis of these data to explore these teachers' conception about modelling in the way suggested by Tukey (1977): we use descriptive statistic to observe existing data without preconceptions and without formulating hypotheses in advance. We do not use inferential statistics to test, in a deductive way, hypotheses formulated in advance on data to be collected for the research: that will be the job of confirmatory analysis.

For the 83 teachers, the questionnaire is composed of questions (variables) with multiple-choice qualitative answers and questions with quantitative answers. We split the variables in two parts: the biographical variables (country, age, gender, type of school…) and the active variables on conceptions about mathematical modelling. We will process a cluster analysis (as described in Cabassut & Villette, 2011). For every cluster we will consider the splitting active variables. A *splitting active variable* is an answer for which the percentage of the answer in the cluster is very different than in the whole population. Every cluster will be described through these splitting variables. The biographical variables are also split by clusters. Some of them are *split variables* when the percentage of the answer to this question in the cluster is very different than in the whole population. The splitting and split variables are essential because they enable to explain heterogeneity and differences that are not shown by aggregated statistic indicators.

From the previous cluster analysis, three French primary school teachers belonging to different clusters were interviewed at the time of the LEMA project. This interview will be mentioned in this paper as *LEMA interview*. The LEMA interview is analysed as suggested in Creswell (2007, pp. 156–157) for grounded theory approach: transcription and reading, reduction to different categories and development of relations between categories.

It is not the focus of this paper to explain how the answers to the questionnaire will be analysed. But we can mention that a cluster analysis similar to the previous one will enable the description of every cluster with biographical variables (country, age, experience, job and education), mathematic conception variables, modelling conception variables, and variables about difficulties by modelling teaching. Interpretation of these clusters through levels of determination and additional clarifying interviews with clusters paragons will complete this analysis.

Comparative approach

We will also adopt a comparative approach as suggested in Cabassut (2007) to observe the levels of determination of modelling conceptions in different countries. The levels of determination can appear explicitly (in the questions or in the interview) and implicitly in the possibility to compare the answers between countries. The interview guide has to be formulated clearly for each country of the project: we will be aware about countries cultural references and translation issues. For example the expression "inquiry based approach" is not translated word by word: we use "démarche d'investigation" in French and "problema de investigación" in Spanish.

In the chronology of designing the semi-structured interview, we started from an existing questionnaire of LEMA project that was modified in a dialectic process with every new review of papers, results of exploratory analysis of existing answers to LEMA questionnaire, results of LEMA interview, and discussions between the two authors of this paper. As resulting process, the different parts of semi-structured interviews are defined. Then, the general questions introducing each part for the non-directive part of the interview are formulated and completed. Thus, for the directive part, the corresponding questionnaire is completed. The guide is adapted for every category of *mathematical educational sphere*. We choose to present now every part by illustrating it with questions and their justifications from literature and existing analysis.

DESIGN OF SEMI-STRUCTURED INTERVIEW

Research shows that biographical questions, within the first part of interview, play an important role in the teaching of modelling. Cabassut and Villette (2011) show that country, age and type of school are split variables. Borromeo and Blum (2013) show differences between teachers who studied mathematics as a subject or not; Borromeo and Blum (2013) and Kuntze (2011) identify the influence of experience in teaching mathematical modelling, what Cabassut and Villette (2011) identify as split variable. Dorier and Garcia (2013) point the importance of initial training.

The second part deals with the conceptions and practice about mathematics and can be introduced by the following questions "What are mathematics for you? What is mathematic teaching for you? How do you teach mathematics? How easy is it?". As pointed by Maaβ and Gurlitt (2009) "teacher's knowledge and beliefs about the nature of mathematics [...] influence how they design or select tasks, plan, implement and evaluate their lessons". Also Lee (2012) pointed "the significant impact of teachers' knowledge and beliefs on their interpretation and implementation of curricula and daily teaching practices". We keep the splitting questions of LEMA dealing with mathematical beliefs (Cabassut & Villette, 2011).

An interviewee from LEMA interview mentions that the difficulty related to heterogeneity is not specific to modelling problem but general to every mathematical problem. Another interviewee asserts that there are no more difficulties in modelling situations than in ordinary ones. Another one mentions group management difficulties. For this reason we ask questions about difficulties in mathematic, to be compared with the difficulties about modelling.

The third part of the interview deals with conceptions and practice about modelling. If the interviewed person does not understand the word "modelling" and to enable him to go on with the interview, we suggest a possible definition based on Maaβ definition mentioned on previous part on modelling conception. Borromeo and Blum (2013) are also defining modelling and LEMA questionnaire suggests an example of modelling task. About practice, Borromeo and Blum (2013) show the influence of experiences in teaching mathematical modelling concerning barriers and motivations. They point also the importance of training on modelling, which can only be learned effectively if there are teachers that have competencies in this field. An interviewee from LEMA interview expresses needs to create a lot of modelling situations to be used during teaching. In following part 6, the extract of interview guide is related to conceptions and practice about modelling.

The last part deals with difficulties about modelling collected from international research to observe how these are perceived in the French *educational sphere*. We selected six topics: time, assessment, lesson organisation, context, students' involvement and resources. This selection is explained by the following reasons. Schmidt (2011) and Borromeo and Blum (2013) find time, assessment and resources as the three main difficulties by German teachers. An interviewee from LEMA interview mentions he needs time to keep the modelling process in class. Additionally, Borromeo and Blum show that "for 50% of the teachers, "time" is seen as a barrier". But when it is a barrier for inexperienced teachers, it is not the case for experienced teachers; they observe the same difference about material. From the questionnaire of Engeln and colleagues (2013) on inquiry-based learning, we adapted some items to modelling: for example "to find modelling problems for the class I use textbook?". Concerning assessments, Borromeo and Blum point that "teachers who did not study mathematics see here a barrier to teach modelling and for the other teachers "assessment" is a strong motivator". About lesson organisation, Borromeo and Blum show that lesson-planning is relevant for the teacher but it is not necessarily seen as an obstacle; for several teachers it is a motivation. Cabassut and Villette (2011) find splitting variables about lesson organisation (for example, to design the lesson or to help student). An interviewee needs to prepare a lot for a modelling lesson. About the context, Borromeo and Blum point "systemic obstacles (such as expectations of parents, scientific associations and other pressure groups, regulation examinations)". An interviewee from LEMA interview mentions that the syllabus is not an obstacle and can be interpreted in his mind. Sometimes "the resistance does not only come from teachers but also from students or maybe even parents or the society as a whole" (Dorier & García, 2013). The topic about students' involvement is based on Borromeo and Blum's questionnaire. This part about difficulties is illustrated in the following extract of the interview guide.

EXTRACT OF THE INTERVIEW GUIDE

This extract is from parts 3 and 4 of the interview guide for teachers.

Part 3 Conceptions on modelling

Do you know what means "modelling problem"? (Yes/No)

If yes go on. If no go to item « A possible definition of a modelling problem »

Open question

For you what is a modelling problem at school?

Complementary questions

For each of the following statements mark how much you agree (agree, rather agree, neutral, rather disagree, disagree):

- a modelling problem at school is related to real world
- a modelling problem at school deals with authentic data
- for a modelling problem at school, there is only one solution
- a modelling problem at school is an open problem
- a modelling problem at school requires an inquiry based approach
- pupils have to be familiar with the context of the modelling problem

A possible definition of modelling problem

We consider a possible definition of modelling problem and other terms.
A modelling problem is:

- a problem (no immediate answer),
- open (it could be necessary to make some parts clearer: questions, data, hypotheses, mathematical solution, way to find a solution...)
- complex (many steps to solve the problem, some data have to be searched, discovery of a new type of solution...)
- related to real world (the context of the problem is related to reality on the contrary of some abstract mathematical problems)
- using mathematics and inquiry based approach to find a solution. How much do you agree this definition? (agree, rather agree, neutral, rather disagree, disagree)

Modelling practice

Open question

Do you use, in your teaching, problems that are open, complex, related to real world, and solved with mathematics and inquiry based approach? How? What resources do you use?

Complementary questions

How often do you use the following types of problems in class? (often, rather often, rather not often, often)

- Modelling problems
- Problems to be solved with inquiry based approach
- Authentic problems from reality.
- Problems with data interpretation
- Open problems
- Complex problems
- Problems with more than one solution

Resources

To find modelling problems for the class I use: (often, rather often, rather not often, not applicable because I don't use modelling)"

- textbooks
- internet
- exchanges with colleagues
- exchanges with pupils or students
- other resources

Mention the other resources

Part 4 Facilities and difficulties of modelling
Open question
Is teaching of modelling easy or difficult? Why?

Complementary questions
How much do you agree (agree, rather agree, neutral, rather disagree, disagree)?

Time
It takes too much time to prepare modelling task for teaching.
The work on modelling tasks in the classroom is very time consuming.
It takes too much time to assess modelling tasks.
When I teach modelling, I have not enough time left for other learning content.
It is difficult to estimate how long it takes to solve a modelling task.

PERSPECTIVE OF CONFIRMATORY RESEARCH

With the interview guide, several interviews will be addressed to different members of *educational sphere*. In a next step of research, the results of these interviews will help to formulate research hypotheses and to adjust the final questionnaire. Then, a large-scale questionnaire will be processed to confirm hypotheses. It is difficult to get answers to a questionnaire from some members of *mathematical education sphere*. In this case the questionnaire will be replaced by an interview. “Finally, the question of how culture-dependent task-specific convictions of mathematics teachers related to modelling are merits attention in corresponding comparative research” (Kuntze, 2011). It is why all this research includes a comparative component to study the role of the different levels of determination when the context varies. This confirmatory research and its analysis will be the last step of our study.

ACKNOWLEDGEMENT

This research is funded by Strasbourg University and the Mission of IDEX and also by the Spanish Ministerio de Economía y Competitividad under research EDU2012-35638 project.

Assessing the best staircase: Students’ modelling based on experimentation with real objects

Susana Carreira[1] *and Ana Margarida Baioa*[2]

2 Group of Schools D. Manuel I – Tavira and Centro Ciência Viva de Tavira, Faro, Portugal, ambaioa@gmail.com

In this study, we look at the use of experimental activities for developing mathematical modelling, considering those as consistent with the Models and Modelling Perspective and Realistic Mathematics Education. The experimentation with several staircases elicited a central model based on linearization. Such model stems from the key idea of average step and constant slope and allows mathematical generalization.

Keywords: Mathematical models, realistic mathematics education, models and modelling perspective, experimental activities.

INTRODUCTION

The use of experimental activities in mathematics is a way of providing students a practical approach to real world problems with a particular emphasis on mathematical modelling. It encourages students to collect data, to interpret them and to develop reasoning and mathematical communication through discussion and presentation of findings. Experimentation with real and material daily objects in mathematics learning puts the real phenomenon as a central part of students’ work, pushing them to understand how it works, to address it from a mathematical point of view, and to look for ways in which it can be “driven” mathematically, while incorporating real experience and everyday-life knowledge.

Unlike what happens in experimental sciences, it is far from common the inclusion of activities in mathematics classes where students are invited to examine and study material objects and artefacts from the real world in search for mathematical ways of interpreting the surrounding everyday reality. However, this may represent an interesting possibility to address mathematical modelling from a distinctive perspective, namely by representing an opportunity to investigate the role of experimentation in the development of mathematical models in school learning (Bonotto, 2003; Halverscheid, 2008).

It is possible to explore the mathematics involved in everyday life by asking about the appropriate size of the steps of a staircase. In the image beside (Figure 1), one can see a diagram of a staircase profile retrieved from a website on housing and accessibility where the ‘step geometry’ for best preventing falls, especially from elderly people, is suggested.

The activity of studying a number of different staircases in the surrounding environment was seen a good context to engage 9th graders in significant mathematical modelling, namely entailing mathematical ideas such as gradient, slope, similarity of triangles, trigonometric ratios and others. Our research aim is to understand the effects of experimental work with artefacts on students’ development of mathematical ideas and concepts through modelling tasks. In particular, we intend to see how the idea of slope is con-

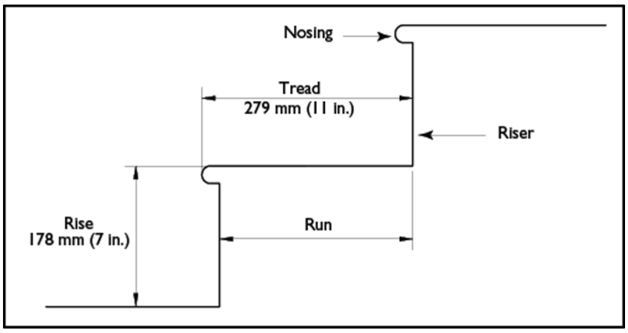

Figure 1: Suggested dimensions for the steps
(Source: http://www.cmhc-schl.gc.ca/en/co/acho/acho_012.cfm)

ceptualised throughout the activity of examining and assessing staircases.

THEORETICAL FRAMEWORK

The theoretical framework draws on both the theory of Realistic Mathematics Education and the Models and Modelling Perspective, by taking experimentation with real artefacts as a hinge which connects and articulates the two theories. This is carried out under the perspective of networking theories that bear significant intersecting concepts in spite of their different roots and foundations: in particular, both theories conceptualize learning in mathematics in terms of constructing and developing mathematical models of the real world.

The model development perspective

In the Models and Modelling Perspective (MMP), the term *model* is the key to explain students' learning of mathematics. A model is conceived as a system of elements, relationships between elements, and operations that describe or explain how the elements interact (Lesh & Doerr, 2003; Lesh & Harel, 2003; Lesh & Zawojewski, 2007). To become a model, the system has to be useful for describing, representing, interpreting, explaining or making predictions about a phenomenon and its behaviour.

In this perspective, modelling activities are important for students to reveal their various modes of reasoning, as well as for the development of conceptual systems and for creating efficient ways of representing structural aspects of the situation.

> The focus of model exploration activities is on the underlying structure of the elicited model and especially on the strengths of various representations as well as on how to productively use these different representations (Ärlebäck, Doerr, & O'Neil, 2013, p. 941).

An essential aspect of MMP is the recognition that solutions to problems usually involve several modelling cycles where the descriptions, explanations and predictions are gradually refined while solutions are being revised or rejected based on their interpretation in the real context.

Model eliciting activities are the kind of activities that provide students with real-life situations where mathematical thinking is necessary for successfully dealing with problems and achieving solutions (Lesh & Lehrer, 2003). The kind of problems proposed is meant to engage students in bringing forth their personal experience and informal knowledge. It is expected that more than one adequate solution is proposed and the use of tools, resources and collaboration are highly endorsed.

Students are presented a real situation from which a problem is originated. For solving it, they usually start to simulate the real situation through experimentation, then they have to model the situation (mathematizing it through diagrams, tables, symbols, relationships between variables, equations...), and finally they generate mathematical results and obtain one or more solutions to the initial problem. Throughout this process students perform micro-cycles of mathematization, i.e., within the modelling cycle, the steps are not all sequentially performed but rather there are forward and backward movements within the cycle itself.

The problem of finding a real model of a convenient staircase seems to comply with this perspective. The real situation of going up and down a ladder is something very common in daily life and it incorporates empirical knowledge and personal experience. There are staircases in many places, both indoors and outdoors, which makes experimentation, simulation, and actual experience with the artefact easy to accomplish. In addition, there is a clear purpose in electing a convenient staircase: everyone has felt, at some point, that there are stairs which aren't easy to climb or descend. Finally, a staircase is an object intended to join by successive steps different levels of a site and the mathematical concept of slope is immediately present in the relationship between the run and the rise of a step. Deciding on the best staircase involves forms of representing and expressing the real world situation, it comprises problem solving (or decision making), brings a specific purpose to modelling, and the resulting model can be developed, modified, and generalised.

The realistic mathematics education theory

Two main ideas that are central to the theory of Realistic Mathematics Education are *mathematization* and *guided reinvention*. Contextualized situations aim to generate meaningful experiences for students that will bring forth the implicit mathematics through a mathematization process. By working on contextualized situations to achieve contextualized solutions, students gradually develop mathematical tools that progressively lead to higher levels of mathematical thinking.

The principle of guided reinvention requires contextualized problems to be well chosen, in order to engage students in the development of strategies that generate informal solutions. The informal way to get solutions is a starting point for formalization and generalization, which is referred to as progressive mathematization (Gravemeijer, 1994; 1999). The process of reinvention is set in motion when students use everyday language (informal description of phenomena) to develop informal or formal mathematical ways of conceptualizing solutions to real problems.

In RME, the starting point of mathematics teaching should be experientially real to the student. The mathematization process will lead to: explore the situation; locate and identify relevant mathematical elements; schematize and visualize patterns, and develop a model that integrates mathematical concepts. It is expected that students subsequently apply these to other realistic situations, and in doing so, reinforce and strengthen their mathematical knowledge.

The models allow students to work at different levels of abstraction, making possible that even those who have difficulty with more formal notions make progresses and create strategies for solving problems (Gravemeijer & Stephan, 2002). The term model refers to models of situations and to mathematical models that are developed by the students at different abstraction levels.

Four levels of models are described in the design of experiences based on the RME theory. At the situational level, domain-specific knowledge and situational strategies are used within the context of the situation, taking into account the knowledge and experience often obtained out of school; at the referential level or in the production of *models of*, the models are closely related to the situation described in the problem; at the general level or in the production of *models for*, mathematical strategies dominate over the reference to the context; and at the formal level, one works with conventional procedures and notations (formal mathematical language) without the support of the context of the situation (initial model).

One of the features that stands out from activities grounded on the RME theory is the mathematical concept(s) that the student is expected to develop. This is usually apparent when reading and interpreting the situations presented, which sometimes include a request to find a generalization. This generalization is not the only goal but it is surely a goal to be reached throughout continued work on this type of activities.

From the point of view of RME, the situation of deciding on a convenient staircase motivates students to work actively on the context. The mathematization process is expected to start with realistically considering the actual situation of climbing and descending staircases. A referential model would probably start to grow from sketches of different staircases, leading to the idea of step as a covariation between horizontal and vertical distance. A model of the covariation might be developed in close relationship with the particular features of a staircase and in terms of how it fits human body (the size of the foot and the range of a person's step). Ultimately a general model of a staircase may be developed in terms of relevant dimensions and this entails a mathematical model for the slope of a straight line.

Experimentation and artefacts use in mathematics

In this study, we have in mind the rationale offered by Bonotto (2003, 2010, 2013) and by other researchers (e.g., Alsina, 2007; Halverscheid, 2008) for the use of experiments in school mathematics. The main idea is that handling and manipulating objects and cultural artefacts existing in students' daily lives is an important way to connect mathematics with reality.

> ... an extensive use of suitable artifacts could be a useful instrument in creating a new link between school mathematics and everyday-life with its incorporated mathematics, by bringing students' everyday-life experiences and reasoning into play (Bonotto, 2010, p. 21).

It can be argued that mathematical modelling involves a comprehensive cycle that stands on its own as a mathematical approach to solving real problems. However, both MMP and RME are theories that seek to connect modelling and mathematizing with the learning of mathematical ideas and the development of mathematical meaning. They both promote activities where realistic situations require some kind of informal knowledge and the unfolding of some mathematics by acting upon and representing real phenomena. They both place mathematics as the ultimate target of the modelling activity but they both acknowledge that models have to be evaluated as to their agreement with the real world and revised if needed.

Experiences with cultural artefacts are more than a context for the formulation of problems; they are the realistic contexts in which data, informal constructions, conjectures and testing occurs, that is, they become the real world.

> Experiments related to mathematics find their natural place in the framework of mathematical modelling because they represent the 'rest of the world' for which mathematical models are built (Halverscheid, 2008, p. 226).

Experimental activities with real objects as the basis for mathematical modelling are grounded on the following facts: (1) students have the opportunity to "learn by doing" as they manipulate and experiment, conjecture and validate; (2) working with concrete materials is a form of questioning mathematically the properties of objects; and (3) inquiry through experimentation is reflected in thinking and mental models and becomes a means to develop an understanding of mathematical models.

Quite often the argument that manipulatives are only useful in elementary schooling is set forth. In contrast, we claim that mathematical modelling with experiments and artefacts may synthesize the connection between two relevant theories – RME and MMP – for the inclusion of mathematical modelling in mathematics learning.

METHODOLOGY

Our study concerns a classroom activity implemented in two classes of 9th grade students (14–15 year-olds), one with 20 students and the other with 23 students. Throughout the teaching intervention several other activities that involved experimentation with cultural and everyday objects were proposed. The activities were performed in groups of 4 to 5 students in each class, totalling ten groups. The groups were video-recorded during the classes; the transcribed dialogues and the written reports of the groups were collected and analysed.

Qualitative content analysis of the data was developed and episodes were selected to document students' models and the conceptual structures underlying such models.

The task

The real problem consists of establishing the convenient dimensions of a staircase for a house building. To initiate the activity, the examination of particular cases was proposed as a means to define the convenience criteria; measuring, recording and sketching were also conducted, which entailed the identification of variables and relationships between them (Figure 2). Therefore, students went out of the school and walked in the city to experience many of the stairs that are part of the outdoor architecture, from the oldest to the newest ones.

The activity was divided into four parts. The first is the introduction to the topic under study. The second, called "From experience…" is a hands-on experimental phase performed with everyday objects (staircases) aiming at developing informal models and collecting data. The third, called "… to the model" consists of a mathematical study of the data obtained in the experimental stage, and one of its goals is the creation of a local mathematical model and possibly a more general model that can apply to wide-ranging situations. Finally, a written report is required to document the experimental situation, the assumptions made, the strategy used, the results obtained, and the evaluation of the proposed solution.

Figure 2: Staircases in the city and students collecting data

DATA AND RESULTS

The model of the average step and constant slope

During the fieldwork, all students experienced up and down five staircases with different characteristics, in order to classify them from 1 to 5, corresponding to a scale from less convenient (1) to more convenient (5). They also measured the run and the rise of several steps in each of the staircases and recorded them on their worksheets. The five staircases were proposed by the teacher within a relatively limited area around the school and fitting the time available for working on the outside.

One observation made by several groups was that the steps in certain staircases did not maintain the same dimensions, with variations of a few centimetres on the treads and on the mirrors. The subsequent discussion was on the possibility of standardizing the sizes of the steps on each staircase considered. The idea of taking the average of the lengths of the treads and the lengths of the mirrors was one of the suggestions. One group realised that the sum of the treads corresponded to the total run the same way as the sum of the mirrors was equal to the total rise. Then, dividing by the number of steps they got the average step dimensions and started to analyse the ratio between them. Another group preferred to measure the pitch line (the hypotenuse) for a sequence of k steps and found the total rise by adding up the mirrors of the k steps. Then using Pythagoras obtained the total run and finally divided the run and the rise by k to get the average step dimensions.

Therefore the model used by most of the groups for the staircase was a model of constant slope regardless the variability of the steps. By considering homogenous steps, students were making the assumption that each step corresponds to a unit of change. No matter the steps were irregular, the inclination was consistent in every step. Based on the ideas that students proposed, which evolved around the steepness of the staircase, the notion of constant slope was being developed as schematized in Figure 3. Even though they have not mentioned this ratio as the slope of the pitch line, their reasoning involved the idea of inclination of a straight line.

In their reports, students showed their representations of the staircases and their evaluations in terms of convenience for climbing and descending. To their qualitative evaluation they associated the ratio of the vertical change (mirror) to the horizontal change (tread), even though they did not define this ratio as the slope of the pitch line. In their discussions it became consensual that there was a distinctive ratio for the most convenient stairs, as in the following dialogue:

> (After reviewing the classification made and the relations found)
>
> Student M: So the conclusion is that the tread should be twice the mirror so that the stairs are convenient!
>
> Teacher: But can the tread be of any length as long as it's twice the mirror?
>
> Student D: A bit larger than the size of the foot.
>
> Student M: About 30 cm.

An extract of this group's report shows how they assessed a few staircases (Figure 4).

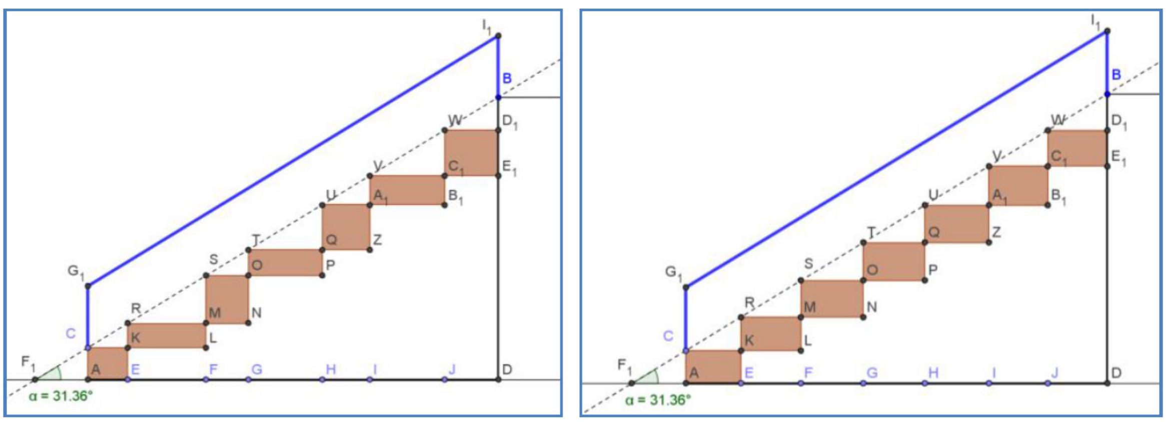

Figure 3: The variation of the steps doesn't change the slope of the staircase

Escadinhas do Castelo: O espelho é aproximadamente metade do cobertor, por isso as escadas são cómodas.

Escadas da Praça da República: O cobertor é aproximadamente 2,5 vezes maior que o espelho.

Escadas das Portas do Castelo: O cobertor é aproximadamente 4 vezes maior que o espelho, mas como é exagerado, as escadas não se adaptam ao nosso andar.

Stairs of the Castle: The mirror is approximately half the tread, therefore the stairs are convenient.

Stairs of the Republic Square: The tread is approximately 2,5 times longer than the mirror.

Stairs of the Castle Doors: The tread is approximately 4 times longer than the mirror but this is too extreme and therefore the stairs are not convenient for our climbing.

Figure 4: Excerpt of a report with the slope as a criterion for convenience

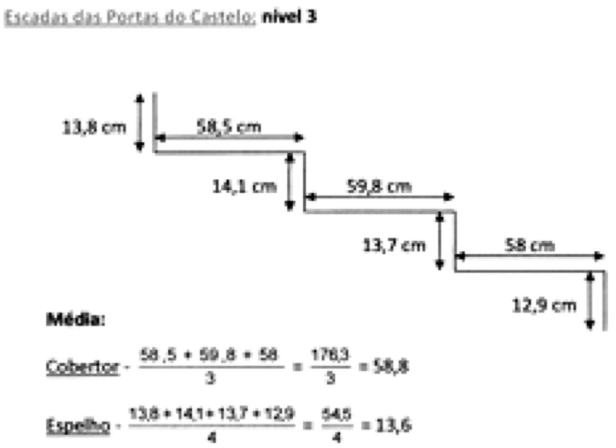

Figure 5: Model of the stairs of the Castle Doors (level 3) and the average step

Another piece of the report shows the idea of using the mean of the dimensions of a sample of steps to find out the dimensions of the average step by assuming a constant slope for the staircase (Figure 5). This was a common strategy in other groups, as a way of dealing with the irregular steps.

The conclusion of this particular group about a convenient staircase was summarised as follows: "We have found that the tread should be approximately twice the mirror so that the stairs are convenient, and the tread would have the approximate length of the foot of most people, therefore measuring between 30 and 40 cm, depending on being indoors or outdoors stairs. As to the mirror, it should measure between 15 and 25 cm".

DISCUSSION AND CONCLUSIONS

The mathematics curriculum for grades 7–9 covers the study of the linear function and stresses the meaning of the parameters in the equation $y = ax + b$, in particular through its graphical representation. The meaning of the parameter a is handled qualitatively in terms of the slope of the line. The linear function is also related to the idea of constant rate of change. However, this conceptual model brings the difficulty of associating a rate between quantities to a geometric notion.

The task of finding a convenient staircase led to the observation that real stairs in the existing surroundings are not perfectly regular stairs. It also showed several facts clearly important to the concept of linear variation and to its translation into a geometric model. In fact, a plausible real model of a staircase is coherent with the notion of regularity, that is, all the steps having the same dimensions. However, it is not necessarily so in real life. Yet, the idea of a constant slope is a good initial model of a staircase. In other words, the average slope of the steps corresponds to the slope of the staircase, and both are consistent with the rate between the rise and the run.

From the point of view of the MMP, the activity of choosing a convenient staircase elicited a relevant mathematical model. The profile of a staircase is consistent with the constant ratio between the length of the tread and the length of the mirror thus suggesting how steep the staircase is. It is a robust and mathematizable idea which makes the basis of the mathematical model of linear variation (or slope):

$$\frac{(\Delta y)_1}{(\Delta y)_1} = \frac{(\Delta y)_2}{(\Delta y)_2} = \dots = \frac{(\Delta y)_i}{(\Delta y)_i}$$

for any number of steps i, and

$$\frac{\sum_i (\Delta y)_i}{\sum_i (\Delta y)_i} = \frac{(\Delta y)_i}{(\Delta y)_i}$$

Its translation into the geometric constant rate of change is well represented by the variable but proportional dimensions of the steps as in the following graphs, showing different changes in run and rise (Figure 6).

Regarding the theory of RME, the mathematization of the idea of a regular staircase matches an informal model of linearization, leading to calculating the mean of the dimensions of the different steps. Then,

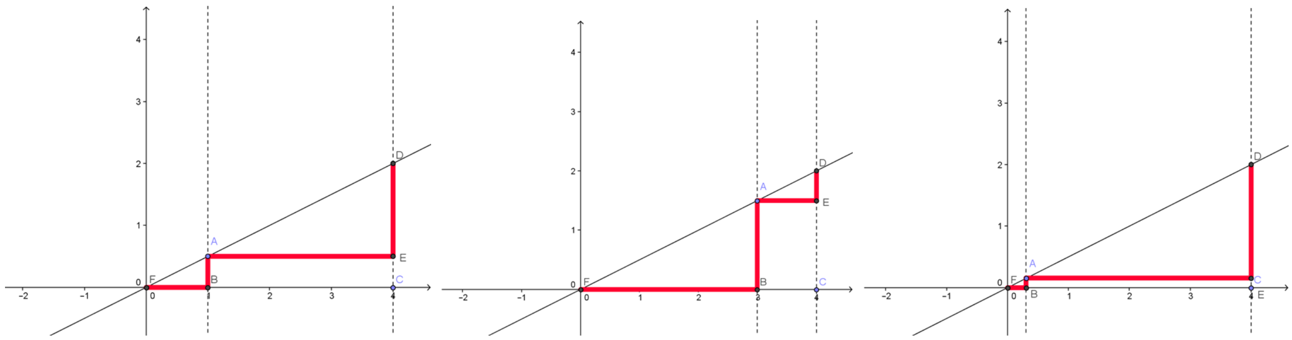

Figure 6: Variable but proportional dimensions of the steps (equal slope)

the relationship between the average rise and the average run develops into a gradient: the constant rate at which the value of the rise changes with respect to the change of the run, or the 'slope of the staircase'. Therefore the slope has a connection to the steepness of the stairs as expressed by the ratio of the mirror to the tread. A model of a convenient staircase (referential model) was characterized by the students as having a ratio of 2:1 for tread to mirror. This is a *model of* a convenient staircase but it is also a model that can be easily transformed into a *model for* any staircase and likewise for the formal constant rate of change.

Both theories allow seeing mathematical modelling as a process that simultaneously creates a simplification of reality, introduces a mathematical point of view and leads to interpreting reality through mathematics and interpreting mathematics through reality.

The experimental, practical and direct way to address the problem through examination of several outdoors real stairs proved to be of vital importance. In the real world stairs are uneven and linearization emerged as a sensible mathematization tool.

Competing conceptual systems and their impact on generating mathematical models

Jennifer A. Czocher

Texas State University, San Marcos, USA, czocher.1@txstate.edu

Using a models and modelling perspective, this paper examines instances of competing conceptual systems within a problem situation for an engineering undergraduate. The goal is to explore how conflict impacts the framing of a mathematical model and to present evidence that the assumptions the modeller makes are influenced by his mathematical framing of the problem context.

Keywords: Mathematical modelling, tertiary education.

Research on mathematical thinking often focuses on pointing out or classifying student misconceptions. Fewer studies have examined how an individual makes sense of the problem context, though the student's interpretation may differ from what the task writer intends (Stillman, 2000). Sense making in modelling tasks is worth examining explicitly because student work leading to errors or incorrect models may be attributed to mathematical misconceptions rather than to the student's interpretation of the task.

It is unclear how an individual's framing of a modelling task is tied to the generation of a conventional mathematical representation, especially in a case where there are multiple possible framings. Each framing comes with its own set of assumptions, variables, parameters, and even constraints against which the model and its predictions must be checked. In a group work setting, Lesh & Doerr (2003) identified the production and resolution of "competing conceptual systems" as part of model creation and Lesh, Doerr, Carmona, & Hjalmarson (2003) classified the cognitive conflicts that accompany competing conceptual systems. But what is the interplay between mathematical framing and conceptual systems?

Drawing on a models and modelling perspective, this paper closely examines instances of competing conceptual systems for a problem situation within a single individual in order to explore how the mathematical framing impacts the creation of the mathematical model. I argue that model construction is influenced by the mathematical framing adapted or derived from the individual's interactions with the problem context and that additional sources of knowledge, beyond mathematical and contextual, are necessary for resolving the conflicts that arise from competing conceptual systems.

THEORETICAL PERSPECTIVE AND DEFINITIONS

The theoretical perspective adopted here draws on the models and modelling perspective (MMP) (Lesh et al., 2003) and a characterization of modelling as a process (the mathematical modelling cycle or MMC) (Blum & Leiß, 2007). The theories are taken together in order to operationalize *mathematical framing* (defined below) and examine its connection to the conventional mathematical representation constructed to represent the real life situation being modelled.

In the most general terms, a *model* is a simplified representation of a system. A *mathematical model* has three components: a situation in the real world, a mathematical representation, and an invertible relationship between the two constructed by the modeller (Blum & Niss, 1991) that preserves structural characteristics as mathematical properties. A key component is identifying appropriate structural characteristics that can be put into correspondence with appropriate mathematical structures and concepts.

The MMP emphasizes the usefulness of mathematical concepts, that models (and not solutions) are the important products of modelling tasks, and that an individual approaches a task with an initial interpretation of the task. The process of formulating a well-posed mathematical problem can be summarized as *framing* – how an individual renders a problem setting, giving it context, determining which facts and relationships are relevant, and which rules are usable for reasoning (Schwarzkopf, 2007). The framing process can be operationalized in terms of the MMC, which is briefly introduced below.

Blum & Leiß (2007) decomposed the mathematical modelling process into six stages of modelling construction supported by six transitional activities. The first three stages of model construction are: the situation model (an understanding of the problem; a conceptual model of the problem), the real model (an idealized version of the problem with simplifications and assumptions), and the mathematical representation (in conventional mathematical terms). The stages are connected by activities. The situation model is brought about by an individual forming an *understanding* of the problem. During *simplifying/structuring* the modeller identifies assumptions, variables, parameters, and conditions that reduce the potentially messy problem to an idealized real model. For example, an object falling from a height might be thought of as an object in free fall and a freebody diagram could be drawn where the relevant forces from Newtonian mechanics are identified. Next, *mathematizing* occurs where the individual represents the real model (in essence, a collection of assumptions and constraints) in conventional mathematical terms. This is the mathematical representation from Blum & Niss's (1991) definition.

Cognitive conflicts, in the Piagetian sense, often arise as the modeller attempts to frame the problem. Lesh, Doerr, Carmona, & Hjalmarson (2003) described three kinds of cognitive conflicts that arise as conceptual models develop: within-model mismatches (incongruence among aspects of representational media), model-reality mismatches (when predictions do not match reality), and between-model mismatches (incongruence between ways of thinking about a problem). For example an object falling from a great height could be modelled using the algebraically based kinematics equations. We know from mechanics that these equations hold only when air resistance is negligible. In a situation where an extended body is falling a great distance the effect of air resistance is not negligible. If we used kinematics equations to predict the velocity of the body at time , the prediction might differ significantly from an actual measurement. This is an example of a model-reality mismatch. Debating whether to use kinematics equations or more accurate differential equations to model the situation would be an example of a between-model mismatch.

The three mismatches are not mutually exclusive but are evidence of competing conceptual systems and highlight where the individual is considering alternative framings of the task. In this paper, I refer to the mismatches with regard to local mathematical model construction rather than global mathematical knowledge construction. The results are presented as a set of illustrative vignettes purposefully selected for their ability to demonstrate and explain the impact of framing on model construction.

METHODOLOGY

This study followed a case study logic found in social sciences (Walton, 1992) where the guiding principle was to provide evidence that challenged dominant ideas about the modelling process. Specifically, the goal was to provide insight into how competing conceptual models in order to argue that framing is idiosyncratically tied to the modeller's experiences. The phenomenon to be illustrated, *competing conceptual systems* "coalesced in the course of the research through a systematic dialogue of ideas and evidence" (Ragin, 2004, p. 127). The case is presented through a set of illustrative vignettes purposefully selected for their ability to demonstrate and explain the impact of framing on model construction.

Data were collected from a series of seven task-based interviews with four undergraduate engineering students enrolled in differential equations. Tasks were designed in order to evoke the mathematical modelling cycle (Blum & Leiß, 2007) and in accordance with guiding principles on openness of the problem statements (Lesh & Zawojewski, 2007; Maaß, 2010). The participants were selected in order to maximize variety in their approaches to modelling tasks and so they had a range of mathematical strength. The participant whose work is reported in this paper, Trystane, did not score top marks in his mathematics or engineering classes. His work on the Falling Body Problem (described below) was selected to share because within one task he exhibited all three kinds of cognitive conflict.

The interviews were video recorded and transcribed. Cognitive conflicts were identified in two ways. First, the transcripts were coded according to the transitions in the MMC and the occurrences of the first three transitions were examined to be sure that framing was taking place. Second, transcripts were summarized as thick descriptions (Geertz, 1973) of the mathematics used by each student during each task. Introduction, changes, or adjustments in mathematical framings were tracked. Throughout the reduction, my focus was on the student's mathematics and on its structural ties to the real world situation presented by the problem statement. This analysis through writing produced a second-order model (Steffe, 2013) of the student's mathematics during modelling. Instances were interpreted as competing conceptual frameworks when the student was debating among mathematical framings or among assumptions that would simplify the problem but would require different mathematical framings.

The Falling Body Problem, for which Trystane's work is presented below, is a first-year physics or calculus problem solvable by kinematics if one assumes that there is no wind resistance. Otherwise, a differential equation is necessary to model the falling body's velocity.

On November 20, 2011, Willie Harris, 42, a man living on the west side of Austin, TX died from injuries sustained after jumping from a second floor window to escape a fire at his home. What was his impact speed?

ANALYSIS AND RESULTS

The vignettes presented below are based on the thick descriptions but reference the transcripts from a problem common to a first year kinematics course, *The Falling Body Problem*. Trystane's work on this task was selected to illustrate cognitive conflict and competing conceptual models within a single individual because it offers a sense of tension as he debated the merits of each. The ongoing tension is not conveyed when examining model revision among multiple individuals.

Trystane explicitly considers three different mathematical framings of the task that eventually lead to model revision. The framings were identified because he returned to understanding and simplifying/structuring the problem, according to the MMC. He first considers using algebraic kinematics equations, which wouldn't account for air resistance. He then considers algebraic energy equations, until he realizes he doesn't have information about the man's weight. He then tries to derive a differential equation in order to account for air resistance. These distinct framings account for different variables, require different sets of assumptions, and rely on different mathematical concepts and structures.

Within-model mismatch

Trystane began by reading the task silently to himself and then stated that he would need to know how big the man was in order to account for air resistance. He indicated that mass was not an important factor and that his approach would be to use a "bunch of kinematics formulas." The kinematics formulas would not account for air resistance. He then indicated that he would like to use energy equations but that he'd need to know the man's weight. Since that information was unavailable, he'd have to "do it a different way and [he'd] have to know how high he fell from." Trystane's conflict arose due to a between-model mismatch. He was considering the merits of adopting different mathematical framings. Note that this is distinct from adopting different mathematical representations because both framings would be expressed in terms of an algebraic formula. There was a mismatch between the information perceived as available (note that he could have used m for mass) and his preferred mathematical framing (energy equations) leading him to adopt the kinematics equations. This framing subsequently influenced the variables and assumptions that could be made, prompting him to seek the height the body fell from.

Model-reality mismatch

Next, Trystane estimated that the window was 16 feet above ground. He attempted to use kinematics equations to calculate the impact velocity but encountered difficulty since "it's [the equation] got time in it and I don't know how long he fell." He resolved this issue and obtained an impact velocity of 32 ft/sec. He validated his answer: "At 32 feet, is actually the height of my house, is how I would think of it. He would fall, he would go that distance in 1 second. I'd say that's reasonably fast for a human to go." The interviewer then asked whether the size of the man mattered. Trystane responded, "Technically, yeah. If he's a really big guy, he's gonna have more wind resistance falling down. Other than that it wouldn't." Trystane indicated that he wanted to take wind resistance into account, but didn't know how to. This suggests a model-reality mismatch because he knows that the extended body will experience air resistance but his model does not account for it.. The competing conceptual systems were acknowledged (desire to include wind resistance and the fact that the kinematics equations did not incorporate it) and led to Trystane rejecting the kinematics equations and seeking to use a differential equation to describe the body's velocity throughout the fall.

Trystane began speaking about changing rate-of-descent and the interviewer responded by challenging his choice of model.

> Trystane: Air resistance is more the faster you go, rather than the slower you go. So in [the man's] case, the higher up he fell from, the more wind resistance until he reached his terminal velocity. Which is when wind resistance is pushing up as much as gravity is pulling down.

> Interviewer: What I'm hearing you say is that in very few cases wind resistance is actually negligible. You have to have a very short fall or be in a vacuum. Does it bother you at all that you don't learn how to take that into account or that the models you use all assume no air resistance?

Trystane responded that he felt that including air resistance in the models early in his physics studies would have been "needlessly complicated." He explained that wind resistance is negligible for most applications and offered an empirical demonstration by dropping a pencil and stated that "the pencil falling this high [placed pencil lower, near the desk surface] and this high [placed pencil higher, further from the desk surface] is so close to the same that it's not worth taking the effort to figure out what it is." This explanation demonstrates that negligibility of wind resistance has to do with height rather than other factors he had mentioned previously such as mass or the value or change in value of the force due to wind, or size of the object. In general, negligibility of a variable is an assumption that is related to the estimated sensitivity of predictions to that variable and also to available information.

Between-model mismatch

Trystane's treatment of wind resistance demonstrates that he weighed expended effort against improvement of results when determining which variables to include and therefore which mathematical model to adopt. Though not in competition, Trystane entertained two conceptual models of the problem situation, one with wind resistance and one without. The source of the dispute was a between-model mismatch. The resolution was to choose the less-complex model because the extra effort necessary to build a more accurate model was not worthwhile.

Later, the interviewer suggested that Trystane use a differential equation to model the velocity of the falling body. He concurred and then began by indentifying the man's movement rate as a function of time as an important variable. He then wrote the equation (in Figure 1), which is a first-order, linear, homogeneous equation in standard form. He then wrote the generic solution where Q represents position and dQ/dt represents velocity. He wrote the solution with the intention of determining the value of . Assuming the initial positions and velocity were both zero, he substituted the general solution into the equation and obtained the expression and thus the result

Within-model mismatch

Trystane pondered the correctness of the model:

> I'm not sure that that's right because I'm not sure if there should be some sort of constant increase

$$Q(t) = Ce^{\lambda t} \qquad Q(t) = 0$$
$$Q(0) = 0$$
$$\frac{dQ(t)}{dt} + \beta Q(t) = 0 \qquad \lambda Ce^{\lambda t} + Ce^{\lambda t} = 0$$
$$\lambda Ce^{0} + \beta Ce^{0} = 0$$
$$Q(t) = Ce^{-\beta t} \qquad \lambda = -\beta$$

Figure 1: First order linear differential equation with initial conditions

> as you get faster, um, I guess that just stems from fluid mechanics. For instance, I don't know if it's a linear graph [draws left graph in Figure 2] or if as you're going faster it gets [traces figure on the right].

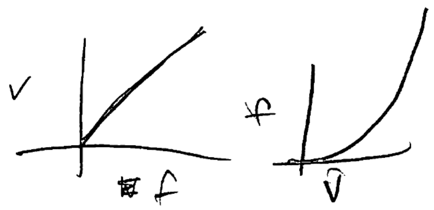

Figure 2: Exponential and linear relationships between air resistance and velocity

The graphs represented force due to wind vs velocity. Trystane knew that there should be an increasing relationship between the two quantities, but didn't know what the relationship would look like and he was debating which representation best matched the situation. He concluded that the model was incorrect because velocity should not increase exponentially with position as but that it was the best he could do without a fluid dynamics book.

Here, Trystane struggled to validate the model he selected because his conceptual model of the rate of change of the body's velocity was not well defined. The within-model mismatch surfaced as he tried to use the two distinct graphical representations of force versus velocity. The consequence was that he rejected the differential equations model because it was incompatible with his conceptual interpretation of ever-increasing velocity described by an exponential solution.

Next, Trystane noted that wind resistance was

> sort of like friction where it's an opposing force. Actually, that kinda sparks an idea. If the wind is always just an opposing force, it could be treated like the force of friction. I dunno. Maybe in a certain density wind you would multiply the coefficient of wind friction or air friction times the surface area of the body moving.

Here Trystane reintroduced the size of the man as an important variable and spent the remainder of the session attempting to include it in his differential equations representation. His final mathematical model (after he "waive[d] the white flag") is the nonlinear differential equation shown in Figure 3.

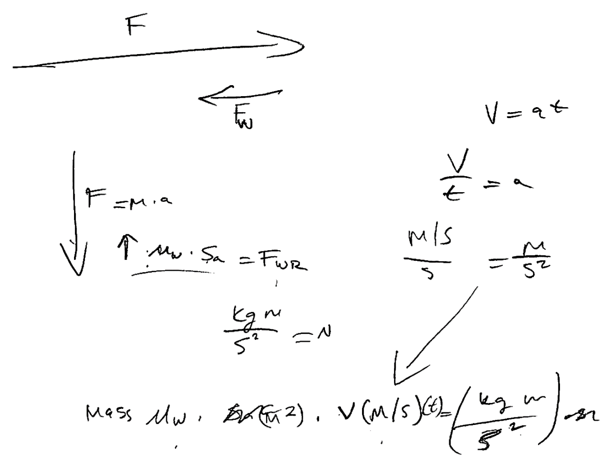

Figure 3: Nonlinear differential equation including wind resistance and surface area

Between-model mismatch

The transition from a first order linear equation with an incorrect solution to the final version of Trystane's model was provoked by competing conceptual systems that had been acknowledged at the start of the modelling task. One conceptualization of the physical system included wind resistance, which depended on the man's size, as a variable. The other conceptualizations ignored wind resistance in favour of algebraic equations with either known or easily-estimated parameters. This ongoing conflict, which was set aside while Trystane explored other possible models, was a between-model mismatch. Trystane's insistence on including wind resistance is a testament to how competing conceptual systems can provoke model development. Moreover, this look at competing conceptual systems suggests that the conceptual system determined the framing of the problem. That is, his selection of which mathematics to use was interactively determined by the data he had available.

DISCUSSION AND CONCLUSIONS

Analysis illustrated three kinds of mismatches that arise as cognitive conflict during mathematical model construction. The mismatches were symptoms of competing conceptual systems each of which came with their own sets of assumptions, variables, and expectations. The conflicts were identified during validating activity when the modeller noted mismatches between expectations of how the mathematical model should be constructed and its congruence with his idealized conceptualization of the situation to be modelled. Thus, expectations were based on both real world experiences, such as Trystane's claim that mass does not affect the velocity of a falling body, and the mathematical structure selected underlying the model, such as when Trystane rejected an exponential growth model for velocity.

Both mathematical and nonmathematical knowledge have been identified as important to model construction. Indeed, modelling is often characterized as bringing together both bodies of knowledge. In the vignettes above, Trystane generated and referred to ideas not explicitly in the problem statement. He relied on additional resources beyond mathematical and contextual knowledge. His spontaneous demonstration with the falling pencils and his resolution of the within-model mismatch between the two graphs of force against velocity suggest that he appeals to common sense and to thought experiments as resources for generating missing information. At times, Trystane had to abandon a particular framing because of a conflict where he did not have the relevant information to use the framing. In another case he was able to generate the missing information via a thought experiment. For example, the task did not give the height the body fell from but he was able to validate his answer (32 feet per second) by using the corresponding length of time it would take to fall 32 feet. In such a case, Trystane used a thought experiment to obtain and validate an appropriate estimate of the height.

Conflict resolution may depend certainly depends on student knowledge about the context and student characteristics (such as persistence). It may also depend on the modeler's values in model construction, and these values may be discipline specific. For example, Trystane demonstrated that he valued economy of effort. He valued avoiding "needlessly complicated" problem idealizations. He also valued avoiding revisions that made the model overly complex for only a marginal gain in accuracy or predictive power.

Trystane used knowledge both of plausible alternative mathematical representations and structures as well as sufficient knowledge of the problem context in order to resolve the conflict product productively. Trystane demonstrated reasoning based on a blend of mathematical and nonmathematical knowledge: his value judgments about effort and worthwhileness and his ability to willingness missing information. This suggests that mathematical and contextual knowledge alone do not account for how the conceptual model or subsequent mathematical model are revised. Future research should investigate criteria or factors students use to decide how to resolve competing conceptual systems.

Two related aspects that merit further examination are *how* the conflict resolution is executed and how conflict recognition can be promoted. When cognitive conflicts arose, at times Trystane rejected the initial model (such as his rejection of the energy equations) or to the revision of a model (such as his decision to include air resistance in the differential equation). One resolution required an additional assumption (neglect air resistance) while another required a change in mathematical structure (regarding net force as a function of time).

Mismatches between the individual's expectations and the model produce the cognitive conflict and the mismatches point to the presence of competing conceptual systems. When conflict is absent, the task may be too easy or familiar or the student may not recognize a particular kind of incongruence that is noticeable to the teacher or researcher. It should be noted that Trystane, as an engineering student was trained to look for such mismatches.

The conflicts arose when Trystane tried to fit available data to selected framings, such as setting initial velocity to zero in the differential equation. He changed representation and structure as information became available rather than undertaking derivations. He made progress when he had a mathematical frame that fit his personal (or scientific) experiences. This suggests that at least in some cases, framing precedes (or even determines) the relevant assumptions and variables sets.

Aside from theoretical consequences to perceptions of mathematical modelling as a cyclic, linear process, these observations have practical consequences. First, tasks should be selected that are amenable to multiple possible framings. Second, if a goal of using modelling tasks is to help students learn to make simplifying assumptions, it may be beneficial to use modelling tasks where potential framings are not obvious.

Mathematical modelling cycles have been long offered as descriptions of the mathematical modelling process, but the community still does not have an adequate explanation for how mathematical and non-mathematical knowledge are blended to render a real world problem as a mathematical one. The models and modelling perspective adopted here, along with the cognitive conflict framework (Lesh et al., 2003) revealed that competing conceptual systems play an important role in the selection of appropriate mathematical structure, mathematical representation and the subsequent fitting of available data into the selected model. The cognitive conflicts framework is a promising avenue to reveal how validation of the mathematical model leads to resolution (or lack of resolution) of the competing conceptual systems.

Exploring grade 9 students' assumption making when mathematizing

Brikena Djepaxhija, Pauline Vos and Anne Berit Fuglestad

University of Agder, Kristiansand, Norway, brikena.djepaxhija@uia.no

Making assumptions is a key activity in modelling. The present study aims to explore the variety of assumptions that lower secondary students make in this process. As theoretical basis for the data analysis, we used the modelling cycle by Blum and Leiss (2007) and framed a definition of assumptions. The study was carried out with grade 9 students. The results show three categories of assumptions: (1) parameter assumptions, (2) assumptions for the choice of the mathematical model, and (3) assumptions about task expectations. Assumptions from the first two categories assist students to use extra-mathematical knowledge to construct a mathematical model, while the third category of assumptions can assist but also hinder them. Our study shows, that students were well aware of their assumption making.

Keywords: Assumption making, task expectations, modelling, mathematizing, lower secondary students.

INTRODUCTION

In mathematics education there is an increasing emphasis on applications and mathematical modelling (Vorhölter, Kaiser, & Borromeo Ferri, 2014). This international development is also reflected in the intended curriculum of Albania, the country in which the current study is based. In the curriculum framework for primary and lower secondary schools (grades 1–9), the Ministry of Education and Sports highlights that students need to understand the role of mathematics in everyday life and use mathematics adequately to solve problems from everyday life (IED, 2013).

However, Albanian students have displayed a rather poor performance on modelling problems as used in the Programme for International Student Assessment (PISA), in which Albania now has participated three times (Harizaj, 2011; OECD, 2014). The Albanian results on PISA urge for a closer investigation of the process when students deal with modelling problems. Therefore, we have started a study on the first phases of this process, when students are facing a problem situation and have to make a translation to a mathematical model in order to reach a solution of the problem. In particular, we aim to explore the various assumptions that students make in this start-up phase of the modelling process.

THEORETICAL FRAMEWORK

Blum and Leiss (2007) have framed mathematical modelling as a process, which consists of subsequent activities. See Figure 1. The process begins with understanding 'the real situation' given in the task, which leads to the construction of a 'situation model' (e.g., a rough drawing of the problem situation). Then, this 'situation model' is idealised into a 'real model' through relevant structuring, and by making assumptions and simplifications (e.g., the drawing is made more specific).

In the next step this 'real model' is translated into a 'mathematical model' (e.g., an algebraic formula). The 'mathematical model' is then used to obtain 'mathematical results'. These results are interpreted into 'real results' and then validated in light of the given problem. In the case the results are considered inadequate for the real situation the entire modelling process is run through again.

The above description of the mathematical modelling process is an idealized one, because in practice the modelling process is more complex and often non-linear (Borromeo Ferri, 2006; Galbraith & Stillman, 2001). Moreover, Borromeo Ferri (2006) empirically showed that some phases in the modelling process can overlap and that the problem structure affects the process.

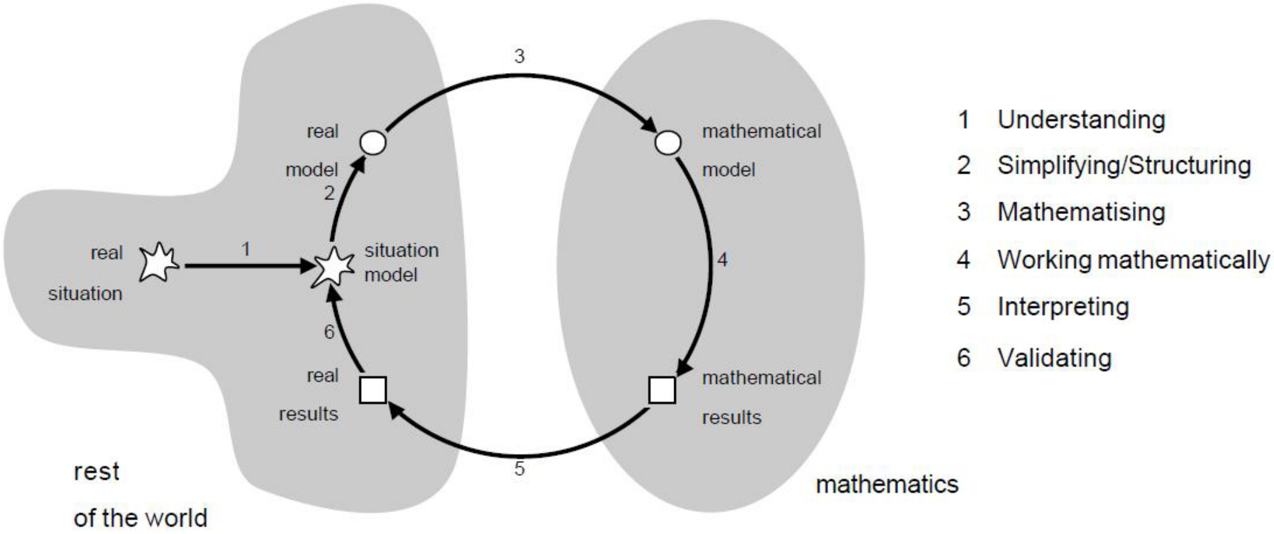

Figure 1: Modelling cycle from Blum and Leiss (2007)

An important term in the modelling process is *mathematizing*. Blum and Leiss (2007) use this term to describe the translation activity from the 'real model' to the 'mathematical model'. However, Borromeo Ferri (2006) has argued that it can be difficult to distinguish between 'situation model', 'real model', and 'mathematical model', because these differ between students and tasks. For example, many tasks with problems from the real world are already structured and de-authenticated by the task authors, to communicate the problem situation unambiguously to the students (Vos, 2011). Therefore, in the present paper the term mathematizing will be used to describe holistically all activities from 'problem situation' to 'mathematical model'. In this frame, mathematizing comprises all activities before a student starts on the purely mathematical work, such as: understanding; simplifying; scouting the problem (Schaap, Vos, & Goedhart, 2011); assuming; structuring; idealising; and finally translating into mathematics. Results of several studies in the field of mathematical modelling (Schaap et al., 2011; Stillman & Brown, 2012; Stillman, Brown, & Galbraith, 2010) display that the mathematization process is complex and that students face various obstacles within this process.

Making assumptions is one of the activities in the mathematization process (Edwards, 1989; Galbraith & Stillman, 2001). Maaß (2006) empirically showed that inadequate assumptions (unrealistic or over-simplified) lead to an inadequate real model, which further leads to an inadequate mathematical model for the problem situation.

Goldin (2002) defines assumptions as being:

> [...] often propositionally encoded, taken as a basis for exploration or discussion but (at least temporarily or provisionally) without attribution of truth, validity or applicability. (p. 65)

This definition converges with the definition in the Oxford English dictionary (www.oed.com), which says that an assumption is:

> The taking of anything for granted as the basis of argument or action.

An assumption can be formulated as *"let's take <statement A>"*, proposing statement A to temporally be true without further argumentation, but statement A offers a productive opening towards subsequent activities. Assumptions made during the mathematization process "provide building materials from the real world to bridge the divide between a descriptive problem statement and its representation in mathematical terms" (Galbraith & Stillman, 2001, p. 304). Assumptions are practical, enabling students to continue their work; assumptions may even assist in overcoming cognitive blockages. The present study aims to explore the variation of assumptions during the mathematization process. The research question is: what assumptions do students at lower secondary school level make while mathematizing?

METHODS

The study was operationalized by studying Albanian students while working on modelling items. The participants in the study were four grade 9 students from a lower secondary school in Albania. The four students were average achievers in mathematics and they were selected by their teacher. They had no particular experience in modelling. The students participated voluntarily and they will be identified by pseudonyms.

A three step design was used to capture a holistic view about students' mathematization process, consisting of (1) observation, (2) stimulated recall and (3) interview (Busse & Borromeo Ferri, 2003). The combination of these three methods draws on strengths of each and makes it possible to capture the connection between internal and external processes which occurred when mathematizing. The first author was the interviewer, being able to communicate with the students in their language. The present paper will report only on the data associated with the assumptions that students made while mathematizing.

In the first phase (observation), students worked in pairs on solving three modelling items collaboratively. To enhance their thinking aloud, just one pen was made available to both students. In this way they could not write both at the same time. The second and third phases (stimulated recall and interview) took place in another session (later on the same day or on the next day), whereby each student was individually invited to watch excerpts of the video recordings from the first session. The students were asked to comment and reflect on their activities in the video. In this way stimulated recall helped students to be "close to the process of working on the task without interfering [with] the process itself" (Busse & Borromeo Ferri, 2003, p. 257). In the third phase (interview), the interviewer cited some statements made during the solution process and asked them to comment on these statements. By using statements of the students, the risk of making students speak with the interviewer's words was avoided.

All the three phases of data collection were video recorded and then transcribed. First, transcriptions were used to identify all assumptions students made in the complete modelling process. Then, based on Blum and Leiss (2007) modelling cycle, we identified assumptions that the students made in the mathematization process. Assumptions associated with the mathematization process were investigated for their purpose (why), their emergence (when), and the awareness that the students displayed on the making of these assumptions.

The modelling items for the present study were taken from PISA. The PISA items for mathematics are designed as problems with a real world origin and they have been designed in a careful process (OECD, 2013). Moreover, their globally widespread use should enable us to compare, validate and generalize research results internationally. We selected PISA items on several criteria: (1) they should require students to integrate the offered task information with extra-mathematical knowledge in order to construct a mathematical model; (2) the cognitive demand should match with students' abilities and therefore the mathematical content was taken from the curriculum of at least one year below the students' level; (3) the real-life situations presented in the tasks should align with Albanian students preferences on the relevance of mathematics, as studied by Kacerja (2012).

FINDINGS

Because of the page limitations of this paper, we report only on the data from one pair of students, the girls Joni and Megi, on two of the PISA items used in the study. The first item is named Rock Concert.

> For a rock concert, a rectangular field of size 100 m by 50 m was reserved for the audience. The concert was completely sold out and the field was full with all the fans standing. Which one of the following is likely to be the best estimate of the total number of people attending the concert?
>
> a) 2000 c) 20000 e) 100000
> b) 5000 d) 50000

Joni and Megi started to calculate the area of the field (100x50) and then started a discussion on how to connect this to the other information in the problem statement.

Megi: Since the concert was completely sold out then there will be 5000 fans because the field was full.
Joni: But one fan per one square meter will be...here it says that all fans are stand-

ing, therefore they are more than 5000... there will not stand one fan per square meter because it has no meaning for a concert...how many fans can stand in one square meter?

Megi: But since nothing else is given, it will be 5000 fans... Just option b) has to do with it. Because we have the numbers 50 and 100 in the problem statement, we do not have any other numbers... The total number of fans according to me is 5000 because we cannot solve a problem by supposing.

In the above episode Megi equals the area with the number of fans, and then Joni translates this into the assumption: *one fan per* m^2. However, she thinks that this is not realistic for a rock concert, considering the information that all the fans are standing, so she implies the assumption that *there are more than one fan per* m^2, and she asks explicitly the clarifying question on the density of fans standing in a concert: *"how many fans can stand in one square meter?"*

Her partner, Megi hesitates to connect the problem statement to the real world. She bases her argumentation on two other assumptions that we reformulate as: *only given numbers should be used to build a mathematical model* and *one cannot make assumptions in these kinds of tasks*. However, these assumptions are not accepted and they continue the discussion on the density of fans. This leads to another assumption:

Megi: The rock concert is attended only by adults, because rock concerts cannot be attended by children... It is attended only by adults and adults use more space.

Here, Megi has changed her perception of what the task is asking her, namely that she can use extra-mathematical knowledge. So, she makes the assumption *only adults attend rock concerts*, which is relevant to define the density of fans.

Thereafter, Joni and Megi are carried away by the context of the task, talking about whether the rock players are popular, or not and there may not be too many fans coming. They also talk about whether there can be chairs in the field. In these discussions we did not identify assumptions, until the next utterance:

Megi: It depends on how fans stand...but we can divide the field in rows and columns... it depends on how fans stand because in a rock concert the audience tries to be as near as possible to the stage, but we can consider the same everywhere.

This utterance shows that Megi recognizes the complexity of defining the density of fans, and that one needs the assumption: *fans are uniformly distributed in the field*.

The above findings from the students' work on the Rock Concert item show that they made different assumptions in the mathematization process. Some of these assumptions can help students to incorporate new information into the mathematical model that is missing in the problem statement, while other assumptions are about their perception of task expectations. Also, we observe that students display an awareness of their assumption making.

The other PISA item, on which we report here, is the Pizza item:

> A pizzeria serves two round pizzas of the same thickness in different sizes. The small one has a diameter of 30 cm and costs 300 ALL. The larger one has a diameter of 40 cm and costs 400 ALL. Which pizza is better value for money? Show your reasoning.

After reading the problem, Joni and Megi make a straightforward mathematization of the situation by taking the ratio between the diameter of the circle and the price. Implicitly, they take for granted that *the size of the pizza is linear to its diameter,* which fits the definition of an assumption. After calculating these ratios they conclude: *"both pizzas have the same value for money"*. However, they do not find this result satisfying – they validate the obtained answer. To do this, they return to the mathematization process and start to ask clarifying questions on the meaning of "better value for money":

Megi: In this case, it means which one is bigger, which one makes you full.

Joni: But it also can be: which one is cheaper, which makes you save money...or which one is smaller, which helps to keep your body in a nice shape.

In this short episode the students make both a dietary assumption ("*makes you full*" and "*keep your body in a nice shape*") and a financial assumption ("*makes you save money*"), which both give a basis for further calculations. After some discussion, the students select one assumption: *better value for money means it makes you full,* because, according to Megi, *"this is what we do in our everyday life"*. Then she uses this assumption to carry on:

Megi: Since they have same ratio, the same thickness, but different size, it is the big pizza because it is bigger…therefore it has more calories …offers more opportunities to make you full.

So, the mathematical model consists of selecting the maximum. However, Joni is uncertain about this approach/choice:

Joni: It is a mathematical problem and we cannot solve it supposing what we do in our everyday life… We involved our individual opinions from our life into the solution and the solution was not a fixed one, we got it by supposing, while in the problems of our mathematical textbook…there are given more numbers and information and the solutions are fixed.

In this utterance Joni expresses uncertainty about the use of familiar, everyday assumptions into the mathematization process. This 'assumption on the making of assumptions' was also expressed in the Rock Concert item: *one cannot make assumptions in these kinds of tasks*. Interestingly, in that case it was expressed by the other student, Megi.

The above findings from the students' work on the Pizzas item show again that they purposefully made different kinds of assumptions. With this Pizza item the assumptions are made either during the mathematizing or the validating process. Some assumptions are made by using extra-mathematical knowledge to choose a mathematical model. Other assumptions limit the students to focus only on the given information in the task.

To summarize, we have categorised the assumptions identified in the above episodes into three broad categories:

Parameter assumptions

Parameter assumptions are assumptions that students make to refine a mathematical model, such as refining the formula in the Rock Concert item: *density of fans x area*. These assumptions incorporate extra-mathematical knowledge into a parameter of the mathematical model, such as in *density of fans*. These assumptions emerge when students understand that the given information in the problem statement is not enough for mathematizing.

Assumption for the choice of the mathematical model

Assumptions for the choice of the mathematical model are assumptions made to select a mathematical model, such as taking either the ratio of diameter and price, or taking the maximum of the size. These assumptions are made in the mathematizing process (for creating a model) or validating process (for critiquing the model and refining it).

Assumptions about task expectations

Assumptions about task expectations emerge from the learning environment of mathematics education, for example when students have been trained on so-called *word problems*. These word problems consist of short texts, generally describing inauthentic situations and irrelevant questions, and students have to deduct some numbers and an operation from the text to find a number answer. Word problems are part of a school culture with unwritten rules, also known as 'didactical contract' (Brousseau, 1997). Assumptions such as *only given numbers should be used* and *making assumptions is not allowed* make students hesitate to consider the situation context and to generate assumptions based on their extra mathematical knowledge. When students' perceptions do not align with the task, their assumptions about task expectations may hinder them. However, not all assumptions about task expectations will be counter-productive. For example, an assumption such as *we should use our extra-mathematical knowledge* is also about task expectations, but it is a productive opening in modelling.

Assumptions about task expectations can be statements on whether or not extra-mathematical knowledge can be used, and these assumptions can assist or hinder students to make modelling assumptions. Assumptions about task expectations emerge in the mathematizing or validating process.

CONCLUSION AND DISCUSSION

In the present study, we explored the various assumptions that grade 9 Albanian students make while mathematizing, that is while constructing a mathematical model from a problem situation. From the data analysis we identified three categories of assumptions:

- *parameter assumptions,*
- *assumptions for the choice of the mathematical model*, and
- *assumptions about task expectations.*

The first category, *parameter assumptions* are assumptions made to refine a mathematical model by using an additional parameter. The second category, *assumptions for the choice of the mathematical model* are assumptions made to choose, or even justify the mathematical model. These two types of assumptions emerged in different phases of the modelling process, such as during mathematizing or validating activities. Their need arose, when the students were constructing or criticising the mathematical model and they used extra-mathematical knowledge for choosing operations, and as such they used these assumptions for creating or refining the mathematical model.

We observed that the students were well aware of their assumptions. This is evident in the words they used: "we can consider", "we can suppose". Moreover, students were explicitly commenting on whether it was allowed to make assumptions based on extra-mathematical knowledge. This lead to the third category of assumptions: *assumptions about task expectations*, such as *only given numbers should be used* and *making assumptions is not allowed*. These are assumptions made by students to deal with the norms and values of a mathematical culture. These assumptions derive from students' beliefs on how they should work, in particular in relation to work on inauthentic word problems. Beliefs "are abstracted from one's experiences and from the culture in which one is embedded" (Schoenfeld, 1992, p. 74). Other researchers have termed the educational culture, in which students behave according to certain norms as a 'didactical contract' (Brousseau, 1997).

The above three categories also were observed in other episodes of our study, but space does not allow us to report this here. We do not claim that the three above named assumption categories are the only assumptions that students make while mathematizing. Our study was a pilot study done with only a few participants (sample of convenience) and a limited number of problems. Empirical findings from other studies (e.g., see Borromeo Ferri, 2006) show that mathematization activities differ between tasks. Therefore, further research with the same focus on assumptions is recommended. If items are used that require students to define variables or constants, it is possible that they will make assumptions on those variables and constants.

Our study revealed that *assumptions about task expectations* increased students' insecurity in the mathematization process. Therefore, we suggest as teaching implication, that assumption making should receive emphasis in mathematics lessons, as also said by Seino (2005). By discussing assumptions on the parameters or on the choice of the model, both teachers and students can learn about their *assumptions about task expectations*. They can then better understand the role of extra-mathematical knowledge in the mathematization process and in the entire modelling process. Moreover, such a focus can advance their awareness on validating their assumptions.

Our study displays that students make assumptions, which can assist in the mathematizing process. Some authors have described assumptions as "building materials" (Galbraith & Stillman, 2001, p. 304) or "the cement" (Edwards, 1989, p. 95). We support these metaphors, but at the same time we observed some assumption being made, which held back students from the situation context. Thus, some assumptions can be metaphorically described as "*blocked doors*". Our study shows that if students can open these doors, they can make meaningful assumptions in mathematizing, which will then lead to successful modelling.

Fostering students' independence in modelling activities

Helen M. Doerr[1] and Jonas B. Ärlebäck[2]

1 Syracuse University, Syracuse, USA, hmdoerr@syr.edu

2 Linköping University, Linköping, Sweden

Over the last twenty years, research on the teaching of mathematical modelling has recognized the difficulties that students encounter in becoming independent modellers. In this paper, we put forward the notion that supporting and preserving student independence should be a central principle in guiding teaching practices that support students' modelling activities. This potentially provides new ways to address the tensions, dilemmas and in the moment decision making that occurs when teaching mathematical modelling. We provide empirical evidence of teaching practices that encourage students' self-evaluation of their modelling activities in ways that foster their independence as learners and modellers.

Keywords: Modelling, teaching practices, student independence, self-evaluation.

If we want students to be productive independent individuals and problem solvers with the abilities to apply mathematical reasoning in various situations, they need to have a range of possibilities for acting mathematically readily available when faced with a problem. Mason and Davis (2013) argue that this readiness is not fostered by pedagogies that keep students dependent on their teachers. Rather, teachers need to support students to act in ways that can become part of their own repertoire of mathematical ways of thinking. Students' mathematical learning needs include developing productive dispositions, flexible strategies, persistence and independent thinking (National Research Council, 2001). Mathematical modelling problems would appear to be a particularly rich site for developing these dispositions while learning mathematics in realistic problem situations. However, this poses many challenges for the teacher, especially how to: tackle classroom discussions, structure group interactions, and provide effective feedback to students (Brodie, 2011; Lobato, Clarke, & Ellis, 2005; Magiera & Zawojewski, 2011). In this paper, we provide empirical evidence of teaching practices that appear to support and encourage students' independence in their modelling activities and we identify dilemmas that present challenges for teachers in their pedagogical decision making.

THEORETICAL BACKGROUND

Adequately describing and theorizing about what teachers actually do in and around their classrooms is a complex task – one in which research has been slow and sometimes elusive in providing a holistic and comprehensive picture of teaching practices (Even & Ball, 2009). One important strand of research has emphasized and seriously acknowledged the important role of giving voice to and using students' own work and ideas in the teaching and learning of mathematics. Recently, Stein and colleagues (2008) proposed a model of five practices (*anticipating*, *monitoring*, *selecting*, *sequencing*, and *making connections between student responses)* that can be taken up by novice K-12 teachers, as they learn to orchestrate productive mathematical discussions by simultaneously building on students' ideas and important mathematics. Stein et al. argue that this model gives guidance to teachers so that "the teacher remains in control of which students will present their strategies, and therefore what the mathematical content of the discussion will likely be" (p. 328). However, by centering the control of the mathematical discussion with the teacher, these novice teaching strategies may not help students become more independent learners and, as such, offer little guidance for experienced teachers in managing more complex learning situations, such as modelling tasks. Such situations occur when the teacher has to respond to unanticipated student ideas and manage the emergence of student interactions that cannot be fully anticipated ahead of time. Mason and Davis (2013) refer to these situations as requiring teachers to make "in the moment" pedagogical decisions, something that presents a dilemma and tension for experienced teachers.

A common response to this dilemma is for the teacher to engage in telling or explaining to the students the intended content. Lobato, Clark and Ellis (2005) suggest a reconceptualization of the telling or not-telling dilemma by distinguishing between the teacher action of *telling as initiating* and the action of *eliciting*. According to Lobato et al., *telling as initiating* refers to teacher actions "that serve the function of stimulating students' mathematical constructions via the introduction of new mathematical ideas into a classroom conversation" (p. 110). The teacher's intention is to promote student sense making and is often followed by eliciting students' ideas. Brodie (2010; 2011) elaborates the dilemmas faced by experienced teachers when, having elicited students' ideas, they must make in the moment decisions about when and how long to press individual students for making meaning and giving justifications. As teachers engage with model eliciting activities (Lesh & Doerr, 2003), they are faced with pedagogical dilemmas and in the moment decision making about how to move students' mathematical learning forward. In this paper, we want to put forward the notion that student independence should be one of the most central principles in teaching practices, guiding both planning and in the moment pedagogical decisions and actions. The focus of this paper is on elaborating teaching practices that foster student independence.

Our research is situated in the models and modelling perspective on teaching and learning mathematics (Lesh & Doerr, 2003). Within this framework the notions of eliciting student thinking and developing their emerging models are central to learning mathematics. In this work, we take models to be externally represented conceptual systems that consist of objects, operations, relations, and interaction-governing rules used to predict, explain, describe, or understand some other system (Lesh & Doerr, 2003). By engaging in a sequence of model development activities, students' models are repeatedly developed, modified, extended and revised through "multiple cycles of interpretations, descriptions, conjectures, explanations and justifications that are iteratively refined and reconstructed by the learner" (Doerr & English, 2003, p. 112). From this perspective, learning is equated with model development. The ability to develop, apply, and adapt a generalized model to be used in a range of contexts is the essence of what it means for students to be independent learners and problem solvers.

METHODOLOGY AND SETTING

This study took place in a six week summer mathematics course for beginning engineering students, designed around a model development sequence centred on the concept of average rate of change (Ärlebäck, Doerr, & O'Neil, 2013). Model development sequences are sequences of structurally related activities that are intended to engage students in multiple opportunities to describe, interpret, make conjectures, explain, develop and iteratively refine their models while interacting with other students (Lesh, Cramer, Doerr, Post, & Zawojewski, 2003). A model development sequence begins with a model eliciting activity where students' ideas about a problem situation are elicited and made explicit in forms that can be tested, revised and refined. Following the model eliciting activity are one or more model exploration activities and model application activities. In the model exploration activities, the underlying mathematical structure and representations (such as tables, interactive graphics, diagrams, or animations) of the elicited model are further investigated and developed. In the model application activities, the students apply and adapt their previously elicited and explored models in new contexts and situations.

The model development sequence in this study consisted of a model eliciting activity (MEA) using the context of bodily motion along a straight path; a model exploration activity (MXA) using a computer simulated walking-world (cf., Kaput & Roschelle, 1996); and, two model application activities (MAA). In the first model application activity the students developed a model for how light intensity varies with the distance from a light source, and in the second model application activity, the students modelled how the voltage changes over a fully charged discharging capacitor in a simple circuit (Ärlebäck et al., 2013). In this paper, we report on our analysis of the video recordings of the lessons focusing on the teacher moves (or actions) identified in the data as either *independence preserving* or *neutral* or *non-independence preserving* moves. We also analysed debriefing interviews with the teachers to understand her intentions. The data presented in this paper are from the MEA and the first MAA.

An *independence preserving move*, is a teacher move whose intention and consequence is that it preserves students' independent on-going work. A teacher move that provides students with a tool or strategy to facilitate the students' independence in a future activity/situation would be considered independence preserving. Encouraging student persistence ("keep thinking", "keep talking", "keep working") and collaborative work ("talk to your partner") is considered to be independence preserving. As well as being independence preserving, a teacher move can be *neutral* or *non-independence preserving*. A non-independence preserving move typically implicitly suggests that meeting external expectations ("label your columns") is valued rather than independent thinking and work. A neutral teacher move would be the teacher's observations as the students are working on a task.

We identified one particular sub-category of independence preserving moves that occurred regularly within our data set: *encouraging self-evaluation moves*. Teacher moves that either implicitly or explicitly encouraged students to be evaluators of the correctness, appropriateness, usefulness or goodness of their work are called *encouraging self-evaluation moves*. Examples of encouraging self-evaluation include moves that support students in having confidence in their solutions, in validating solutions with a partner, and in giving reasons or justifications about why their solution has to be correct. Encouraging self-evaluation also occurs when the teacher simply responds to the student "think more" about a particular result, representation, relationship, object or idea. We take encouraging self-evaluation to be a particular category within the more general category of independence preserving moves.

RESULTS

We give examples that occurred in two parts of the model development sequence: during the model eliciting activity and during a model application activity. In these examples, the teacher encouraged students' self-evaluation within the larger goal of fostering students' independence in their modelling activities. In the first example, over three days of the MEA, the teacher engaged in a range of moves (described below) that fostered aspects of student independence at the individual, small group and whole class level. In the second example, the teacher engaged students in an extended argument among the students and led by the students about the rate at which light intensity changes with respect to distance. Rather than resolve the argument for the students, the teacher preserved student independence by engaging them in collecting empirical data that they could use to resolve the question.

Examples from a model eliciting activity

The MEA was designed to elicit students' ideas about constant rates, about the distinction between velocity and speed, and about position graphs for which the motion was not physically possible. The students began the task by working in small groups to create a line with negative slope, using their graphing calculators, motions detectors and graphing software on a computer. The design of the task required them to transfer data from their calculators to other group members' calculators and to a computer. Thus, this MEA was comprised of a mathematical task (using bodily motion to create a line with negative slope) and the learning of technology skills. The teacher assumed that many of the students had limited background with the technology from high school and knew that their fluency with the technology would be needed throughout the model development sequence. Throughout the MEA, the teacher made numerous moves that were intended to set expectations for student independent work at both the individual and the group level and expectations for students to self-evaluate the goodness of their work and that of their peers. We will briefly illustrate five teacher moves: establishing the utility of a reference tool; turning back questions; gathering data; encouraging persistence; establishing criteria for self-evaluation.

At the beginning of the MEA, the teacher distributed a "data management reference sheet." Since one goal of this particular MEA included developing fluency with technology that would be needed throughout the model development sequence, the teacher had created a reference sheet that contained technical details for using the technology. Nearly all of the teacher's interactions with the students were brief as she answered their technology related questions with "do you have your data management reference sheet?" or "look at the data management reference sheet." She consistently referred to the need for each individual to acquire the necessary technology skills. In referring to the computer data transfer, she commented, "your whole group should go because everyone should know how to do that." We take this as the teacher's intentional moves to support the independence of each individual in gaining fluency with the technology that would be needed throughout the modelling activities.

In a segment that occurred after the students had worked on finding and interpreting equations for a linear position versus time graph with negative slope, the students initially incorrectly referred to speed as the slope of the line. As a discussion of this was about to conclude, a student asked, "what does the motion detector measure?" Rather than answer this question directly, the teacher turned this question back to the students. We take this as a move to engage students in self-evaluation, that is, in answering other students' questions. Eventually, there was an answer from the students that what the detector measured was distance in feet, recorded every tenth of a second. The segment ended with the teacher inserting the units for speed as feet/second.

One part of this modelling task focused students' attention on the possibility of creating a U-shaped graph with the motion detector by walking at the same speed the whole time. The students were sharply divided on this issue. The segment ended as one student suggested "why don't we just try it?" We take this as an example of students suggesting self-evaluation and of the students taking up the teacher's encouragement of their independence by gathering data and evidence to support their claims.

One aspect of student independence would seem to be persistence in working on tasks and solving problems. An example of this occurred at the end of the first lesson where one student had worked on finding an equation for the line with negative slope that the group had created. The student asked the teacher if his solution was correct and the teacher responded by asking him how he could evaluate the correctness of his answer for himself ("how do you check it?" "figure it out"). Later, when he determined that there was an error in his work, the student again approached the teacher, who responded with "find your mistake. I'm sure you can find it." Finally, at the end of class, when the student came to her again, she again reassured him that he can find his mistake. We take this as both encouraging student persistence and as a form of encouraging student self evaluation.

In the third lesson, the teacher displayed examples of students' descriptions of motion from work done in an earlier lesson. The teacher asked the students to choose a good description and provide a reason why the description was good. The students worked on this individually. We take this as an example of students evaluating descriptions created by other students. However, it was unclear what criteria the students had for deciding what constitutes a "good" or "best" description? This dilemma became clearer as the teacher asked the students to discuss in groups which description was the best. The students had difficulty in coming to consensus in their groups. The teacher had a whole class discussion where students gave their reasons for choosing various alternatives. The teacher shifted the goal of the task when she suggested that they consider how to improve a description as some students claimed "none of them are really good." As this task ended, the teacher asked the students, "could you create the graph if you were given this description?" This final statement by the teacher appears to be a form of establishing the criteria by which one could decide if a description were "good" enough. However, this criteria was not clear to the students from the beginning of the task.

Examples from a model application activity

This example is from a model application activity, where students investigate how the rate at which light intensity changes with the distance to a light source. At the beginning of the activity, the students are asked the following question as part of their homework prior to the lesson to elicit their thinking about changing light intensity:

> Imagine the tail light of a car moving at a constant speed away from you. Is the light intensity:
>
> 1) fading at a constant rate
> 2) fading slowly at first then quickly
> 3) **fading quickly at first and then slowly**
> 4) unsure

Although all of the students had taken a prior course in physics in secondary school, where the relationship between light intensity and distance is studied, only one of the students correctly identified the rate at which the light intensity fades: quickly at first and then slowly. The majority of students concluded that either the light faded at a constant rate (60% of the responses) or slowly at first and then quickly (27% of the responses). One student was unsure.

These responses were displayed for the students via a student response system. The teacher commented that there was "lots and lots to talk about" and that she wanted to know from them "why did you choose the answer you chose?" To accomplish this, she arranged the students in groups and asked them to discuss their answers. After a few minutes, while the teacher was walking around listening to students' reasoning, the teacher pulled the class together for discussion. Each of these teacher moves – eliciting their ideas with the initial question, asking them to engage in peer discussion, and listening to their reasoning – served to encourage the students to self-evaluate their responses to the question on changing light intensity.

The ensuing whole class discussion began as the teacher asked S1, a member of one group, to start the discussion:

S1: My other group members, they voted for number two, but I voted for number one because I explained that the car is going away at constant speed, so I thought like the light would go away at a constant speed too. But then I don't know if that's the same thing. It would be like how you see the light and the intensity of the light, if they drop in the same way.

The teacher re-stated S1's comment and invited students to consider S1's argument or offer their own:

Teacher: Are you guys thinking similarly to S1 or why did you think it was at a constant rate? [several students mumble] S2, what did you say?
S2: The car is moving away at a constant speed so I think the intensity decreases at a constant speed.
Teacher: S3
S3: The light travels at a different speed...
S4: ...than the car...
S3: ...than the car...
S4: So, it would actually be different.
S5: Isn't the speed of light constant?
S6: If the speed of light is constant, why...
S4: ...why is the car moving? – because it creates a variable!
All: [Laughter and many students talking at the same time]
S7: But yeah [inaudible] the speed of light and speed of...
S3: ...S7, what do you think the answer is?

The students were actively engaged in arguing whether or not the light was fading at a constant rate. Many of those who thought the rate was constant were arguing that it had to be constant because the speed of light was constant. However, the intensity of light with respect to distance is not related to the speed of light with respect to time, as S1 had suggested in her initial argument. What is striking about the conversation above is that the teacher is not mediating, restating, or directing the discussion. She is listening, off to the side. The argument takes a turn in a new direction as S3 asked S7 what she thought:

S7: Me?
S3: Yeah!
S7: I put two [slowly then quickly], but I'm not sure that, but I don't know what the ratio is between light intensity and [S7 starts gesturing]...
S2: I mean for instance, if the speed of light's constant, and the cars' constant...
S7: ...Yes, but the speed of light is the travelling speed of light. We're talking light intensity which is what you see
S2: Right...

In this segment, S7 has made the critical distinction (which was foreshadowed in S1's initial argument) between the speed of light and the intensity of the light. S2 seemed to acknowledge this, with his comment "right." But it is not entirely clear what he meant by this. But the next response to S7 is from S3, who had asked S7 for her answer in the first place. S3 claimed to have an example, which was then immediately followed by another student's (S4) example. From the teacher's perspective, it was not possible to fully anticipate what these examples might be, what they would mean, and how they would relate to the central question about the rate of change of intensity of light.

S3: Yes, so in 7th grade we were studying the change of motion and stuff and whatever. And so, we found out, like if you're in, okay, I'm from New York City, we're doing that, like, if you're walking in a train, like running inside of a train, at, you know let's say your running like, 20 feet per second or whatever, whatever, that's unrealistic, but just say you're doing that, right. And the train is going at, like 100 feet per second, then the total would be 120 feet per second. That's how fast it would seem you're running, because the train is like moving, and then you're moving...

S4: ...I think I have a better example, of how you know that light is not travelling at a constant rate. Why do they put the eenie-teenie-tiny [very tiny] lights on the top of buildings that planes aren't gonna be able to see from 50 yards away? [inaudible] explain that to me – why are runway lights so small, you see the guy [starts gesturing as if he was taxiing a plane to its gate]

All: [many students talking at the same time]

The discussion was ended by the teacher, but not by drawing a conclusion for the students. Instead, the teacher continued to engage the students in evaluating their emerging models of light intensity by initiating the next task of collecting real data that would enable them to resolve the question based on empirical evidence.

The results elicited from the initial question showed that 60% of the students thought that the relationship between light intensity and distance from the car was linear. To address this, the teacher encouraged the students to self-evaluate their emerging models of rates of change and of light intensity. As the episode unfolded, the students unpacked their models by themselves, first in small group discussion and then in a student-led and student-driven whole class discussion. S1 raised the core question about the relationship between the constant speed of the car and the rate of change of the light intensity. The discussion then revolved around the speed of light and its constancy, prompting many students to express their ideas on this matter. When S7 tried to focus the discussion back on S1's core question, S3 and S4 both drew on personal experience in trying to understand the situation. S3 remained focused on the role of the constancy of the speed of light, whereas S4 argued about the rate of change of the light intensity. The teacher functioned as a listener throughout the discussion. The teacher ended the discussion by initiating the next activity where students were to collect real data to resolve the issue. This shift was a key move in encouraging further student self-evaluation of their emerging models for how the light intensity varies with the distance from the light source and in preserving student independence.

DISCUSSION AND CONCLUSION

In this paper, we wanted to further the research on using students' thinking in mathematics lessons and the dilemmas connected with this practice, as reported in the literature, to forefront an argument and empirical evidence of teaching practices that encourage students' self-evaluation of their modelling activities in ways that preserve their independence as learners and problem solvers. This focus presents a shift in emphasis on students' and teachers' roles and responsibilities. For example, the essence of *sequencing* in the Stein and colleagues' (2008) model is for the teacher to be in control of the form and content in a whole class discussion. An independence preserving stance would instead advocate sharing with students the responsibility for the sequencing of contributions in the discussion in order to engage them in the self-evaluation of their ideas and their emerging models. The first example illustrates the role of the teacher in setting expectations for students to use tools such as a data management reference sheet to solve technology related problems, to answer questions from peers, to gather data to support arguments, to persist in finding mistakes, and to collectively establish criteria for evaluating the goodness of written descriptions. Taken together, these moves by the teacher appear to support the students in becoming more independent learners and problem solvers. The second example suggests the benefits of engaging students in peer-discussion and encouraging students' self-evaluation by having them collect data that can be used to self-evaluate the goodness of their emerging models. This practice seemingly resolved the teaching dilemma that would otherwise have confronted the teacher as to how to resolve students' conflicting ideas about changes in light intensity, while at the same time providing the students with peer-discussion as a self-evaluation tool for them to use in modelling activities. We offer these examples as ways of thinking about the notions of *students' independence* and *stu-*

dents' self-evaluation, with the hopes of contributing to the on going discussion of effective teaching practices.

One-sided limits of a function at a point in a drug metabolism context as explained by non-compulsory secondary students

José Antonio Fernández-Plaza, Luis Rico and Juan Francisco Ruiz-Hidalgo

University of Granada, Granada, Spain, joseanfplaza@ugr.es, lrico@ugr.es, jfruiz@ugr.es

We present the results of an exploratory and descriptive study performed with Spanish students in Non-Compulsory Secondary Education focusing on how they explain the meaning of both one-sided limits within a temporal phenomenon (drug metabolism) given by a graphical non-authentic model. We organised the given explanations according to the following options: Only calculation; interpretation in a neighbourhood (locally); meaning of the value (pointwise); direction of approaching in time with regard to right-sided limit. We also highlight a particular attention to other elements of the model apart from limiting notions and some difficulty to give sense to right-sided limit, possibly because the direction of approximation is contrary to the natural progression of time.

Keywords: Partial modelling activity, one-sided limits, non-authentic drug metabolism model, spontaneous extension of a model, graphics.

PROBLEM

Mathematical modelling has been integrated in international programmes of students' assessment (e.g., PISA) and it has been a fundamental part of the mathematics education curricula for students aged 6–15 years old for several years (OECD, 2013). In some countries, such as Spain, mathematics teaching in Non-Compulsory Secondary Education (16–17 years old) is intended as a preparation for tertiary studies. However it seems not to keep this trend but rather emphasizes abstract concepts and procedures from advanced mathematical activity (Crouch & Haines, 2004). Successful teachers' training programmes in design and assessment of modelling classroom proposals (Ortiz, Rico, & Castro, 2006) make possible to transfer such proposals to pre-university education. Mathematical modelling is a field of mathematics education widely explored (Fischbein, 1987; De Lange, 1987; Niss, Blum, & Galbraith, 2007; Swetz, 1991).

This study aimed to explore how students perform a pre-modelled task related to the concept of limit of a function at a point. Concretely, we choose a task contextualised in how a human body removes a drug in two days period, focusing on both one-sided limits of the amount of drug at the moment at which a new dose of drug is introduced.

Since we had previously characterised a misconception about the limit of a function related to the continuity (Fernández-Plaza, Rico, & Ruiz-Hidalgo, 2013a, 2013b), we considered for this study a function with a discontinuity at the limit point.

The outcomes of this study provide a better understanding of students' learning of the concept of finite limit of a function at a point, specifically jump discontinuities where there is an instantaneous change to the function at a point in the domain. We examined students' learning of advanced mathematical content, but also their understanding of continuity as a tool to model real phenomena.

The specific aim we propose for this study is:

"To describe student meanings of one-sided limits of a function at a point as they explore a given graphical model describing a temporal phenomena, and the possible influence of variable time on left-sided and right-sided limits interpretations."

THEORETICAL FRAMEWORK

We provide a brief description of what we understand by a model and how to model. We then establish a relevant distinction between modelling and application, with particular reference to the concept of limit of a function at a point.

Notion of model, applications and modelling procedure

We consider a mathematical model as a mathematical structure that approaches or describes certain relationships within a phenomenon in order to explore, understand, explain and eventually control it (Swetz, 1989). As Fischbein (1987, p. 21) notes, not only physical facts can be modelled but also concepts can be associated with a model and properties of the abstract concept may be better understood from the corresponding model.

Niss and colleagues (2007, pp. 10–11) stress a significant distinction between an application and a modelization. Modelling focuses on finding mathematical knowledge from a certain part of the real world, for example, the cycloid is the model related to the motion of a point in a wheel as it rolls along a straight line without slippage. In contrast, application focuses on the opposite direction. Given a model the problem is finding what parts of the real world are susceptible of being modelled by such a model. For example, the inverted cycloid provides a solution to the Brachistochrone and Tautochrone Problems.

The modelling ability as considered by PISA 2015 draft framework (OECD, 2013) (called *mathematising*) involves capabilities such as:

> To structure the field or situation to be modelled,
>
> To make assumptions
>
> To translate the reality into a mathematical structure
>
> To work on the mathematical model to obtain findings
>
> To reinterpret these findings in terms of the real situation, and
>
> To establish limited or generalized conditions to validate or modify the model.

Greefrath and Riess (2013) summarise the modelling procedure into five steps, Understanding of the problem; approach selection; performing; explanation of results; checking results, calculations and approach. They developed and implemented a solution plan (it consists of these five steps with questions and clarifying points) with 6th grade students. In spite of some students engaged appropriately with this aid, other of them had some difficulties.

We pay special attention to the last two aforementioned capabilities: Interpreting, criticizing and modifying a given model. To sum up, modelling is the process to find a mathematical structure which approaches relationships within a phenomenon, which consists of an understanding of the problem, approach selection (assumptions), performing (translation of the reality to the mathematical structure and work on it to obtain findings), explanation of results (to reinterpret the findings in terms of the real situation) and checking results (to establish limited or generalized conditions to validate or modify the model).

Applications and Modelling related to the concept of limit of a function at a point

Classical problems, which were modelled using the concept of the limit of a function at a point, dealt with movement of an object and variations in magnitudes with respect to time.

According to the distinction between application and modelling, other phenomena may involve relationships between variables and time and the limit concept could be applied. The basic question to which the concept of limit of a function at a point tries to give an answer is the following:

> Given a flow of amount of a magnitude along an interval of time, $y = f(t)$ and an instant $t = t0$, obtain the best approximation L of the amount of magnitude near $t = t0$, providing that $t = t0$ is an accumulation point of the interval of time. If it does not exist, explore the reasons why not. L is the best approximation of $f(t)$ near $t = t0$, if for any K approximation, there exists an instant tK, such that $|t - t0| < |t0 - tK|$ implies $|f(t) - L| < |f(t) - K|$.

This question leads us to four different models related to the concept of finite limit of a function at a point depending on the properties of the function:

Instantaneous invariance model, related to the existence of limit. If the image of the point is the same as the limit, we referred to a *continuous model*, otherwise, it is a *hole model*.

The non-existence of the limit leads to the other models:

Jump or instantaneous change, when there are both one-sided best approximations, but they are different, so there is not a best approximation of the function at any neighbourhood centered at $t = t_0$.

Asymptotic change model, when one or both of the one-sided best approximations do not exist but there is a tendency to plus or minus infinity.

Oscillating change model, when none of one-sided best approximations exist, either finite or infinite.

For this study we are going to consider students' work on a jump model, because the asymptotic one involves infinity and oscillating one is not usually taught at their educational level.

METHOD

This is an exploratory and descriptive study based on a survey method. We designed and implemented a questionnaire including open-ended and closed-ended questions. This paper is focused on the following one:

> A patient is given a 0.05 mg injection of a drug daily, and each day 40% of the drug in the body is eliminated. The following graph (Figure 1) corresponds to the function $y = f(t)$ that relates time to the amount of the drug in the body during the first two days of treatment. Interpret $\lim_{t\to 1^-} f(t)$ (from now on *Lim_Left*) and $\lim_{t\to 1^+} f(t)$ (*Lim_Right*)

The sample was composed of 36 Spanish students in the first year of Non-Compulsory Secondary Education (grade 11th), 16–17 years of age, who were taking Mathematics for the Science and Technology track. The students were chosen deliberately based on their availability.

The survey was administered to the sample described above in the middle of the academic year 2010/2011 during a regular session of the math class (1 hour) counting on the collaboration of the teacher. Subjects had received prior instruction on the concept of limit by their teacher.

The analysis of students' answers (interpretations of left-sided limit and right-sided limit) is based on a *content analysis methodology*. Firstly, characterization of students' interpretation of left and right-sided limits. Secondly, detection of different approaches used to the interpretations of one-sided limits. Finally, detection of spontaneous attempts related to a further analysis of the model.

According to limit models framework, the task describes a phenomenon with a jump instantaneous change. However, the real phenomenon is continuous. According to Andresen (2007, p. 2044) is a non-authentic model. We discarded the time taken to inject the drug which is very small in comparison with the unit of the variable t (days), otherwise the function would seem to have a vertical line at $t = 1$.

It is important to note that the task does not consider the whole modelling procedure, because a model is given beforehand and students only have to interpret the value of the one-sided limits according to the provided model. However, our results show that some students spontaneously focused on other aspects of the model and tried to develop or modify it. So we argue that in part they were doing modelling activity and therefore bringing into play the two last capabilities according to PISA 2015 framework.

RESULTS

We describe the interpretations provided by the students of left-sided and right-sided limits, also different

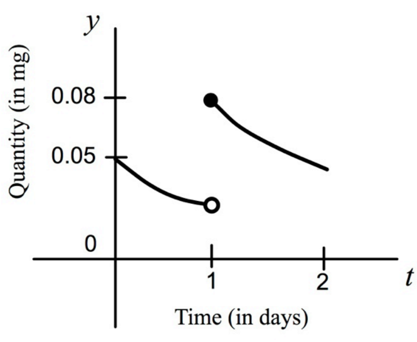

Figure 1: Graphical model of the situation described on the text

approaches to conceive them, as well as the modelling actions of students apart from the requirements of the task.

Students' interpretations of left-sided limit from the model

The different interpretations of the left-sided limit can be organised into these main categories, developed from answers, considering two dimensions: Information included from the graph and Contextualization. Answers in "Other Category" related to each dimension are incomplete or vague.

Dimension 1. *How much information from the graph is included*

Only the value of the left-sided limit. Some answers only provide the specific value of the left-sided limit (Example 1).

Example 1. " = 60% of 0.05 which is 0.03"

Local / pointwise interpretation. Some answers describe the behaviour of the function around the point t=1 (locally) (Example 2), particularly using specific terms such as, "to approach," "to tend," or "to get closer and closer," or focusing on the possibility of the limit to be reached, while other ones focus exclusively on the "left side" of the point t=1 making explicit the meaning of the left-sided limit value (pointwise) (Example 3).

Example 2. "The limit as t tends to 1 from the left represents how the amount of drug is decreasing along the day and at the end of the day increases by 0.05 mg due to the injection"

Example 3. "To know the remaining amount of drug in the body after the first dose"

Dimension 2. *Contextualization*

Contextualized. Students interpret the meaning of left-sided limit in terms of the real situation. The clearest interpretations used infinitesimal expressions such as "just before" or "before" (Example 4), or "at the moment drug has been removed" (Example 5).

Example 4. "To know amount of drug that patient has before 40% is removed"

Example 5. "As time goes on, body is removing drug until the moment in which a 40% has already been removed"

Decontextualized. Students interpret the meaning of left-sided limit in a purely mathematical context, not in the real situation (Example 1).

Table 1 shows the frequencies of each interpretation category. These categories are mutually exclusive.

Dimension 1	Frequencies (N=36)
Only value	2
Local	19
Pointwise	10
No answer/Other	5

Table 1: Frequencies of interpretations of Lim_left related to Dimension 1

Table 2 shows the frequencies of contextualized and decontextualized interpretations of left-sided limit.

Dimension 2	Frequencies (N=36)
Contextualized	29
Decontextualized	4
No answer/Other	3

Table 2: Frequencies of interpretations of Lim_left related to Dimension 2

Students' interpretations of right-sided limit from the model

The different interpretations of the right-sided limit can be organised into the aforementioned categories, but there is a new singular category:

To relate the tendency of t to 1 from the right to stepping back in time. Some students become aware that tending to 1 from the right implies "counting" backwards in time (Example 4). However, we note the contrary fact in the example 5.

Example 4. "As we get close to 1 from the right, we see that the drug has just been injected and the patient has not eliminated any amount of drug"

Example 5. "If we take limit from the right, the approximate amount of drug will tend to 0 mg"

Table 3 shows the frequencies of each interpretation category. These categories also are mutually exclusive:

Dimension 1	Frequencies (N=36)
Only value	1
Local / Tendency as stepping back in time	7
Pointwise	11
Tendency as stepping forward in time	13
No answer/Other	4

Table 3: Frequencies of interpretations of Lim_Right related to Dimension 1

An example of contextualized interpretation of right-sided limit is Example 6.

> Example 6. "As t approaches 1 from the right we see drug has just been injected and the patient has not removed any amount of drug"

Table 4 shows the frequencies of contextualized and decontextualized interpretations of right-sided limit.

Dimension 2	Frequencies (N=36)
Contextualized	28
Decontextualized	6
No answer/Other	2

Table 4: Frequencies of interpretations of Lim_Right related to Dimension 2

Different approaches of left-sided and right-sided limit interpretations

Even though students clearly identified the value of the left-sided limit, we consider that there are two different approaches when the right-sided limit is interpreted: (a) *formal*, according to the formal notion of right-sided limit, and (b) *contextual*, according to the natural development of the phenomenon along the time, as expressed in Figure 2 and Example 5.

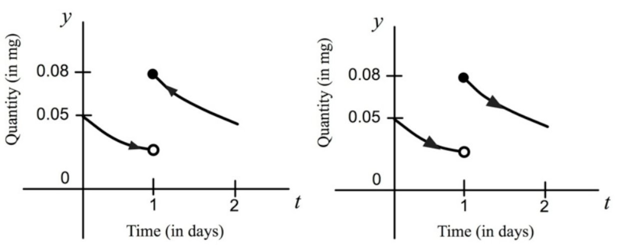

Figure 2: Formal (left) and contextual (right) direction of approximation

Table 5 shows the frequencies of formal and contextual approaches related to students' pairs of interpretations (N= number of formal left-sided limit direction of approximation).

Approach	Frequencies (N=30)
Formal	19
Contextual	11

Table 5: Frequencies of formal or contextual pairs of interpretations

Unexpected students' attempts of further analysis of the model

Students spontaneously focused on other aspects of the provided model (8 out of 36), such as:

To set an absolute start-end of the day. 2 out 8 students arbitrarily do not consider the day as a measure of time between two instants of time, but like a day in the calendar (from 00:00 a.m. today to 00:00 a.m. next day) (Example 8).

To consider that the total amount eliminated during a day is constant for every day. 2 out of 8 students do not consider that the 40% is taken out of the current amount of drug in the body, but of 0.05 mg dose, so the eliminated amount of drug is constant just like the length of the jump (Example 9 and Figure 3).

To extend the model to other days. 7 out of 8 students generalised the model to next days (inductive reasoning, Example 9). Some of them (3 out of 7) consider as well that the velocity of elimination is increasing day to day, because the amount of drug to remove in the same interval of time (1 day) is higher (Example 10), but in fact the phenomenon reaches a stationary behaviour around 0.05 mg of drug eliminated per day.

Discussion on the arbitrary setting of the hole in the graph. Only one student discussed the arbitrary place of the hole in the graph, i.e., the image of the function at t =1, because the limit is independent of what happens at the point t =1. He stressed the finite jump (Example 11).

> Example 8. " [Lim_Left] For example, let us suppose that the injection is administered at 0:00 a.m. As the time goes the amount of drug in the

body is decreasing. 24 hours later the amount has reached 0.03 mg...”

Example 9. “[Lim_Left] The patient eliminates 0.02 mg per day. [Figure 3 provided]”

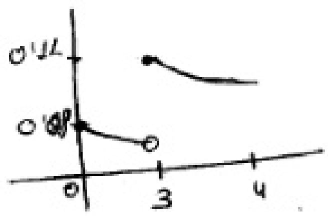

Figure 3: Inductive reasoning from the model (Example 9)

Example 10. “[Lim_Right] After 24 hours on the next day amount has increased by 0.05 from the remaining 0.03, that is 0.08. So, each day 1, 2, 3... there would be a jump and step by step the patient will have a higher amount of drug in his body”

Example 11. “[Lim_Right]...it has been set the hole at the end of the first day and the image at the beginning of the second one, but it could be done anyway. There is a finite jump because the one-sided limits are different”

Finally, given the similarity between right-sided limit at $t = 2$ (0.048 mg) and the amount of drug at $t = 0$ (0.05 mg), Example 12 could be interpreted as establishing by the student the equality between both values graphically rather than by calculation.

Example 12. “We observe that the patient takes the drug and so the amount in the body increases, along the day, the amount of drug is reducing until the same level when the first dose was administered.”

DISCUSSION AND CONCLUSIONS

According to the aim we draw the following conclusions:

The pointwise interpretations of both one-sided limits have been slightly frequent (10 and 11 out of 36), so we can tell that some students have a routine procedural conception of both one-sided limits. On the other hand, the local interpretations are more frequent for the limit from the left (19 out of 36) than are those from the right (7 out of 36), possibly due to the natural progression of time that produced some conflicts of interpretations as is shown by the answers (11 out of 36). Such a kind of conflicts was reported by other studies, such as Blázquez (2000). For further research, new examples with independent variable different from time could be chosen.

It is important to mention the spontaneous references to other aspects of the model (8 out of 36), such as the invariance of the daily-eliminated amount, the gradual increment of the amount of drug in the body in the future as well as the velocity of elimination. Only one student suggested that the image of $t = 1$ could be either 0.03 or 0.08. These actions are characteristic of modelling activity (OECD, 2013).

Surprisingly, no student discussed about the necessity of taking into account the time employed to inject the drug in order to check the continuity of the real phenomenon. For further research, no model would be provided in order to elicit students’ own proposals and specific classroom proposals could be planned according to PISA recommendations.

A comparison between strategies applied by mathematicians and mathematics teachers to solve a problem

Carolina Guerrero-Ortiz and Jaime Mena-Lorca

Pontificia Universidad Católica Valparaíso, Instituto de Matemáticas, Valparaíso, Chile, c_cguerrero@yahoo.com.mx

This study analyses the results obtained from comparing the paths shown by expert mathematicians on the one hand and mathematics teachers on the other, when addressing a hypothetical problem that requires the construction of a mathematical model. The research was conducted with a qualitative approach, applying a case study which involved a group of mathematics teachers and three experts from different mathematical areas. The results show that the process of constructing a mathematical model differs between these two groups mainly by the type of cognitive processes developed. It was observed that the modelling routes depended on the graphical representations used by the individuals to address the problem. The mental model related to the situation plays an important role in the externalisations of the participants.

Keywords: Modelling, representations, mathematics teachers, paths of modelling.

INTRODUCTION

In the context of mathematical modelling (MM), there are two approaches: applications and modelling for mathematics learning, and learning mathematics to develop skills in the construction of mathematical models. The first considers the use of modelling activities as a vehicle for the construction of mathematical concepts; the second involves the application of mathematics to build models (Niss, Blum, & Galbraith, 2007). These two approaches may occur simultaneously or in isolation, and involve a difference in the emphasis put in the development of teaching strategies.

Speaking of teaching activities necessarily brings to mind the teacher-student-task triad, where it is unarguable that the mathematics teacher has great importance, both fulfilling the role of modeller and participating in the preparation and/or selection of tasks in order to support the students to understand the mathematical concepts involved in the activity. Hence, this study focuses on the observation of modelling strategies developed by the teachers when they model a hypothetical situation. Our initial hypothesis is that mathematicians and mathematics teachers develop different ways of modelling. Therefore, we discuss some modelling strategies implemented by our two study groups: mathematicians responsible for the training of mathematics teachers, and in-service mathematics teachers receiving training.

In the literature related to strategies activated by expert and novice modellers when solving a problem, it has been observed that novice modellers do not take enough time to understand the situation in question, thus experiencing difficulties in selecting the relevant information and using it in the construction of a suitable mathematical model (Crouch & Haines, 2004; Crouch & Haines, 2007, Bransford et al., 2000). Therefore, it becomes clear that some of the obstacles in the construction and interpretation of mathematical models are related to difficulties in accessing appropriate mathematical concepts and procedures in order to find a solution.

The modelling process of novices shows a trend toward the use of linear rather than cyclical modelling strategies, while the validation of the obtained models is not a relevant element to them. As a result, they have difficulties recognising the model associated to a given situation and fail to relate their results to the situation that gives rise to it. On the other hand, expert modellers access relevant knowledge more efficiently. Moreover, some authors estimate that it is likely that many years of practical experience are needed to become to be an expert modeller (Haines & Crouch, 2010; Crouch & Haines, 2007). However, there is little research that focuses on the processes and strategies that novices and experts develop when involved in modelling activities. Therefore, we aim to contribute to previous research by showing some aspects of the construction of a model that both groups (experts and novices) use. We identify some elements that permit them to move more effectively through the various stages or nodes of modelling.

In the context of modelling as a vehicle for learning mathematics, a general question arises: Are teachers able to convey to their students the strategies that they themselves develop to model a situation? This is under the assumption that some of the steps that comprise a modelling path take place in the mind. Therefore, if the teachers are not aware of what they are doing mentally when modelling a situation, they will be incapable of conveying their thought process to the students. Therefore, the objective of this research is to identify some of the processes that mathematicians and mathematics teachers in training develop in order to help them to reflect on their own process.

Our research was conducted with two groups. One was a group of expert mathematicians who conduct research in pure mathematics and also participate in in-service teacher training. They are not necessarily involved in modelling activities as part of their research. The other group consisted of mathematics teachers who work at secondary or college level, they received a solid background in mathematics as part of their undergraduate training, but have little experience in the development of modelling tasks in the classroom. The intention of the study is not to make comparisons of the modelling competence between the two groups; rather, we aimed to identify the tools and representations that the members of each group use. This knowledge may serve as a guide to identifying those aspects that would be appropriate to develop both in in-service teachers and in pedagogy students. We argue that one way to address the problems related to the transition of students through the modelling cycle is to identify the strategies used by mathematicians (experts) and try to have students (novices) develop the same tools and skills. This becomes especially relevant since so many mathematicians are involved in training future mathematics teachers. It is clear that knowledge generated in the interaction between these two groups is what is ultimately passed on to students; so it is desirable to identify and analyse the strategies developed in each of our groups. Therefore, the question that drives our research is: What differences are there between the strategies mobilized by mathematicians to model a situation and those mobilized by mathematics teachers?

We present the results of analysing the modelling paths (Borromeo-Ferri, 2007) developed by the participant groups, taking into account the strategies and mathematical tools they rely on.

CONCEPTUAL FRAMEWORK

The main challenges that arise when modelling a situation are related to the transition from reality to the world of mathematics and to the reinterpretation of a Mathematical Model (MM) in terms of reality. For an expert, reinterpretation may be trivial, but not so for novices (Crouch & Haines, 2004). In connection with the transition from reality to the mathematical model, Borromeo-Ferri (2006) identified some stages in a modelling process, focusing mainly on the analysis of the cognitive processes involved, where she distinguishes four phases: Real Situation (RS), Mental Representation of the Situation (MRS), Real Model (RM) and Mathematical Model (MM).

The Real Situation (RS) represents the situation described in the problem; it can be an image or a text. When going from the RS to the Mental Representation of the Situation (MRS) the individual somehow understands the problem more, and she or he mentally reconstructs the situation; even if they do not fully understand the problem, they can start working on it.

MRS may be different in each individual, depending on his or her mathematical thinking style[1]. It can be visual in relation to the experience, or attention can focus on numerical data and relationships given in the problem, depending on the associations that the individual chooses while understanding the task. In addition, the MRS can differ depending on the role

1 Mathematical thinking style is defined as: "The way through which an individual prefers to present, understand and think mathematical facts and make connections between certain internal imaginations and/or outsourced representations" (Borromeo-Ferri, 2012). In individuals aged between 15 and 16 years three different thinking styles have been identified: visual, analytical and integrated thinking.

mathematical activity has for the individual professionally speaking. Borromeo-Ferri (2006) identifies two aspects that mark the difference between RS and MRS: 1) unconscious simplifications of the task, and 2) personal choice on how to deal with the problem.

In the passage from the MRS to the real model (RM), more conscious simplifications and idealisations take place in the individual, since in MRS phase the individual has already made decisions that influence the filtering of information. The transition process may require extra-mathematical knowledge, depending on the type of task.

The RM phase is related to MRS, as RM is practically built internally and external representations are the Real Model depending on the statements that the individual makes when externalising the model. When in transit from RM to the Mathematical Model (MM), an individual's mathematisation progress appears, in which, according to the task in hand, it may be necessary to also use extra-mathematical knowledge.

The MM phase consists of external representations in mathematical expressions or drawings. The expressions of the individual are more related to mathematical facts and to a lesser degree to reality.

The transitions that occur between these phases are crucial since the externalisation that the individual expresses through images, mathematical language and statements are representations of mental activities, which also depend on previous experience and knowledge.

In the transition from MM to the mathematical results (labelled 4 in Figure 1), an individual's mathematics skills are put into play, such as mathematical resources and strategies to analyse and explore the model and to obtain results or conclusions. The mathematical results consist of writing the results of the model. The transition (labelled 5) from mathematical results to real results is given by the reinterpretation of the solution in terms of the problem. Borromeo-Ferri (2006) notes that individuals often make this transition unconsciously.

In the Real Results phase, the mathematical results are discussed concerning their correspondence to the situation. During the validation of the results, the individual seeks relationships between his or her results and MRS, depending on what kind of validation he or she chooses, either intuitive validation or knowledge-based validation.

The items described play a fundamental role in the constitution of our conceptual framework. Mathematicians and mathematics teachers do not follow the same modelling route, since this is determined by their experience and expertise in the subject area and their thinking style, among others things. Blum and Borromeo-Ferri (2009) have shown how the individuals pass through different phases focusing on some phases and ignoring others. We add that visual imagery (Aspinwall, Kenneth, & Presmeg, 1997) also influences the way in which the individual moves through the modelling cycle, this is because some images may persist in the mind limiting other ways of thinking. Our interest is to document the mathemat-

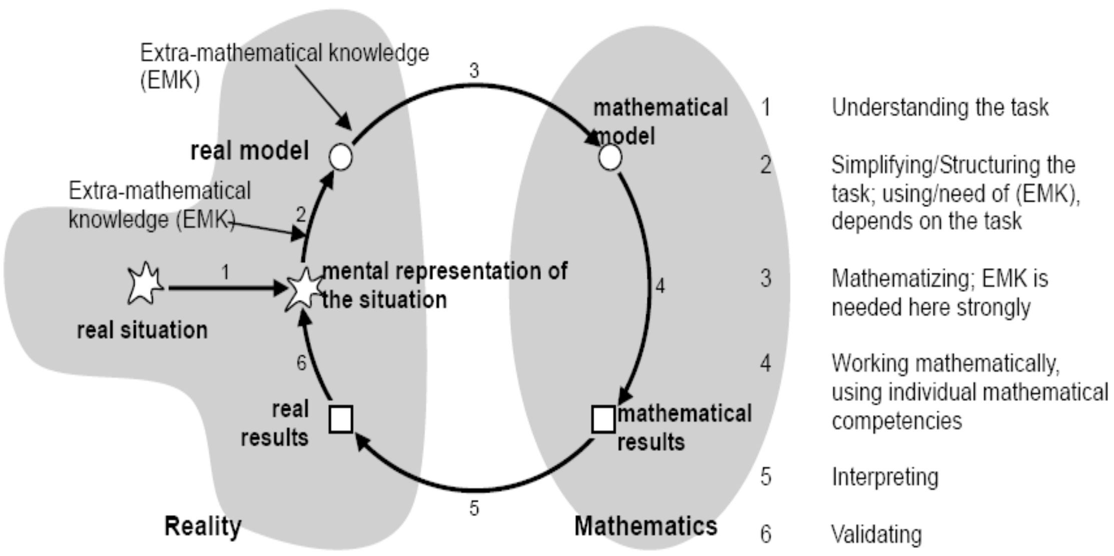

Figure 1: Modelling circle (Borromeo-Ferri, 2006)

ical processes that take place when our observation groups address the modelling of a situation.

METHODOLOGY

This is a qualitative research study (Miles & Huberman, 1994), aimed to analyse the behaviour of participants when they model a hypothetical situation. The data analysis is based on observation, interviews and written material of the individual work of the participants and their arguments while solving the proposed task.

Due to fact that cognitive processes are generally not directly expressed by the individuals, efforts were made to document the mental processes of the participants by analysing individual modelling routes (Borromeo-Ferri, 2010, p. 112). We analysed verbal expressions and representations externalised by the participants when building a mathematical model by asking questions such as: What are you thinking? Why did you do this? How can the situation be related to the representation?

Participants: Three expert mathematicians (Roger, Hugo and Evan) and 20 teachers in training on a Masters' program in Mathematics Education. All were given the same mathematical task. The mathematicians solved the task individually. They were asked to verbally express their thought processes and were interviewed regarding procedures that were unclear to the researchers. The teachers solved the task individually and expressed their reasoning and solving processes to their classmates.

The task was an adapted version of a Vasilyev and Gutenmájer's (1980) task, which can be solved by using knowledge of synthetic geometry and/or analytic Cartesian geometry:

A ladder rests against a wall; on the ladder, there is a cat. The ladder begins to slide on the ground, always touching the wall. What is the path that the cat describes? What would the path be if the cat were not sitting in the middle of the ladder?

DISCUSSION OF RESULTS

The analysis is organised into 4 sections: 1) Understanding the problem, which includes first ideas and impressions, 2) Searching for strategies to address the problem, 3) Model building, 4) Obtaining results and conclusions. The structure of the analysis is consistent with the phases of the cycle of modelling. The first block groups the transition from RS to RM. Block two analyses the externalisations made by the individuals, derived from the transition from MRS to RM. The third block considers the process of mathematisation. The fourth block includes transitions 4, 5 and 6 (Figure 1).

1. Understanding the problem – first ideas and impressions

This task conditions the solution process through the use of pictorial diagrams to explain the situation or to represent the problem, the pictures drawn by individuals bring to life their visual imagery related to the locus plotted by the dynamics of the situation. The mathematicians almost immediately moved the problem to a mathematical representation (Figure 2a) and focused on finding the mathematical formalism. All the teachers supported their solution processes with the use of diagrams to get an idea of the movement described in the situation and remained in this phase for an extended period of time (Figure 2b).

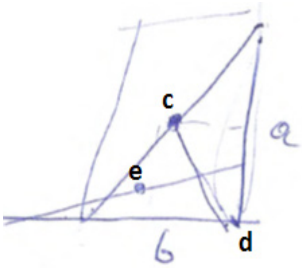

Figure 2a: Diagram made by Roger (mathematician)

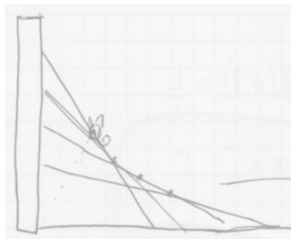

Figure 2b: Diagram made by one of the teachers

The transcriptions provide evidence of the simplification and idealisation that the teachers carried out. For example, they indicate that the cat is considered as a point, which has no weight, that there is no friction between the ladder and the floor, etc. These aspects show the transition between MRS and MR, highlighting the simplifications that the individual consciously performs. The mathematicians do not offer explanations of the characteristics of the phenomena or the elements that are idealised to build the model. They only allow us to observe the transition between the phases of the Real Model (RM) and the Mathematical Model (MM); this may be because the mathematicians immediately look at this situation as a mathematical problem. It appears that the teachers make more connections with reality while mathematicians quickly dissociate themselves from it.

2. Searching for strategies to address the problem

It is difficult to identify the exact moment when the participants begin to search for solution strategies because in many cases this process is determined by the understanding of the situation and the simplifications applied to it. These strategies can be mental operations that cannot be observed until the individual externalises them verbally or in written form. For example, Roger represented the problem geometrically (Figure 2a) and showed some aspects of his strategy only in the interview:

Researcher: What did you think first?

Roger: Of looking at whether the distance of this point [d] to the point that I drew [d and e] remained constant; for example, to see if that was a constant [segment cd],... then I tried to complete this figure like this, to see if the symmetry helped.

On the other hand, after the teachers analysed the problem and got a sense of the trajectory of the midpoint, they expressed different strategies for solving the situation. For example, one of them addressed the problem by placing it in a coordinate system and solved it with the use of tools of analytic geometry (Figure 3a). Another teacher turned to synthetic geometry by observing congruence between triangles (Figure 3b).

In this block teachers already knew the path of the cat so they focused on finding different strategies to determine the algebraic model. Many of their strategies did not help them build the algebraic model and they had to redefine how they achieved the solution. Conversely, we note that two mathematicians apparently reconstructed the locus while they were reading the problem.

3. Model building

The search for solution strategies and model building are closely related. When an individual follows a solution strategy and does not find a model that she/he considers relevant, he/ she tends to propose a new strategy, thus creating a cyclical process between understanding the problem, finding solution strategies and building the algebraic model. This transition was easier to observe in teachers, as the mathematicians went directly to the mathematical representation of the problem.

The teachers initially identified qualitative properties of the situation, and then they used geometric tools and located the problem in a coordinate system, seeking to obtain algebraic expressions that are traditionally associated with a locus (equation of the ellipse and circle); an example of this is seen in Figure 3a.

Two of the mathematicians offered a solution closer to the representation built in grasping the situation. Later they mobilized their mathematical resources for the construction of a mathematical model, showing preference for the use of concepts related to synthetic geometry. Only as a last resource they used analytic geometry tools.

Two moments in the construction of the mathematical model were identified: one related to the visual identification of the locus, and the other after the visualization and related to the construction of the algebraic model. Both moments are manifested in the transition from the mental representation of the situation (MRS) to the Mathematical Model (MM).

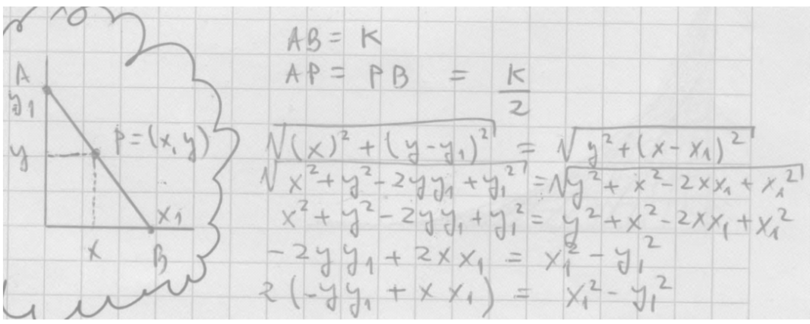

Figure 3a: Solution strategy show by a teacher using analytic geometry

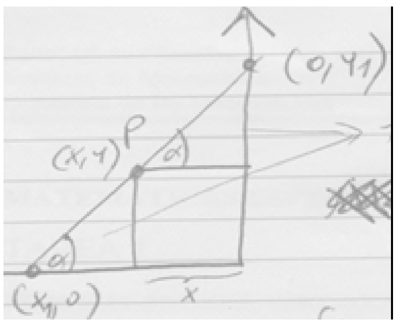

Figure 3b: Solution strategy using congruence between triangles

4. Getting results and conclusions

Finally all participants identified the path of the object. Different strategies were observed. Roger, although he knew the locus, did not refer to it, until he translated the situation to a geometric representation. Hugo did this during the construction of the geometric model. The teachers were aware of the fact that it was the locus of a semi-circle or an ellipse only after plotting different graphic representations and obtaining a mathematical model to represent it.

We summarize our main results in the next table.

CONCLUSIONS

The mathematicians and teachers use diagrams as a strategy to solve the problem. While Hugo and Roger mentally built the path generated by the movement based on its geometric properties and Evan found the locus by using additional geometric and dynamic construction, the teachers were not able to imagine the locus without the support of pictorial representation. For teachers the idea of a locus was also constituted by writing an analytical expression.

We found evidence of some differences in the mental representation of the situation (MRS) and the real model (RM) constructed by each individual. In the case of some of our participants, it can be wrong and largely mediated by their intuition of the behaviour of the situation, sometimes the erroneous visual imagery is persistent which leads to difficulties in obtaining the algebraic model. The fact that the mathematicians and teachers show different approaches to the modelling process can be associated with their experience and their domain of mathematical knowledge, but it can also be related to the way in which everyone is able to abstract the mathematics relationships in a problem. These aspects are links that determine the transitions of the participants in the modelling cycle in an efficient way.

Different strategies were identified when observing how the participants validate their results. For Hugo and Roger validation is associated with their prior knowledge of the locus and to a lesser degree with the verification of the mathematical procedure. For the teachers validation was based on the association of the algebraic model with its graphical representation.

We have shown some differences in the routes followed by mathematicians and mathematics teachers when solving a simple hypothetical problem, of course given a more complicated problem the differences would become more pronounced. In the educational context, we believe it is necessary to make teachers aware of the ability of abstraction possessed by some individuals (as characterised by the corresponding transition between the RS and MM phases), in order that they can make a rational effort to show their students the internal thought processes that occur when modelling a particular situation.

	Mathematicians	Math teachers
1. Understanding the problem -first ideas and impressions	They immediately visualise and construct a mathematical representation. They do not express the simplifications of the situation. It is only possible to observe the transition from RM and MM.	They use pictorial representations to help their understanding of the situation. They externalise the simplifications made to build the model. It is possible to observe the transition between MRS to RM.
2. Searching for strategies to address the problem	The strategies are related to the analysis of the mathematical properties of the situation.	The strategies are directed toward the algebraic solution of the problem.
3. Model building	Use of the Pythagoras and Thales theorem. They showed a preference for concepts associated to synthetic geometry and, as a last resort they used tools from analytical geometry.	The majority of the models were constructed using tools from analytical geometry.
4. Getting results and conclusions	Two of the participants reconstructed the geometric locus parallel to the construction of the MM.	They were aware of the geometric locus after drawing various scenarios. In some occasions they drew it until they determined the corresponding equation.

Modelling: From theory to practice

Britta Eyrich Jessen, Tinne Hoff Kjeldsen and Carl Winsløw

University of Copenhagen, Department of Science Education, Copenhagen, Denmark, britta.jessen@ind.ku.dk

Mathematical Competence Theory and the Anthropological Theory of the Didactic each offer different frameworks for the analysis and design of "modelling" as a central component of mathematics teaching. Based on two comparable cases from each research programme, we investigate how these differences appear in concrete design work, and what their practical consequences may be.

Keywords: Mathematical modelling, mathematical competence theory, anthropological theory of didactics, bidisciplinarity.

WHAT IS MODELLING AND DOES IT MATTER?

The fact that primary and secondary school students all over the world study a subject called "mathematics", with relatively similar contents and methods, is intrinsically linked to certain assumptions about the *relevance* if not *necessity* of this subject for every citizen in modern society. The formulation of these assumptions change over time and they are of course the object of constant debates, but an invariant common contention seems to be the *utility* of what is taught *in the actual or future lives of students*, or at least *its roles outside of school mathematics*.

One formulation, which has gained importance in the mathematics education community over the past 30 years, is based on the notion of *mathematical modelling*, defined roughly as "translations between reality and mathematics" (Blum & Borromeo-Ferri, 2009, p. 45). More complex descriptions of the modelling process, usually in the form of a *modelling cycle* (e.g., ibid, p. 46) have become commonly known and used in research into the ways in which these translations can appear in the school subject. It is a common assumption among researchers within this line of research that students' experience with all steps of the modelling cycle is essential to the justification of school mathematics in society (ibid, p. 46). In particular, Niss and colleagues (2002) proposed to consider *modelling competence* – the students' capacity to carry out mathematical modelling – as one of eight universal competence goals for the teaching of mathematics, linked to other goals equally defined in terms of competences. Their mathematical competence theory (MCT) thus integrates and develops earlier work on mathematical modelling, as an educational activity and goal, in a comprehensive framework for the analysis and design of school mathematics in a broad sense.

Another perspective on modelling stems from inquiries into the nature of mathematics as a school subject: how it is related to the science called mathematics, and more generally to "mathematical practices" appearing in society outside school? The anthropological theory of the didactical (ATD) emerged from the notion of *didactic transposition* (Chevallard, 1985) according to which school mathematics is a cultural set of practices and knowings which are inseparable from the institutions (schools) in which they are taught and learnt. In this theoretical framework, "mathematics" and "reality" are not *a priori* defined or distinguished; all human activity and knowledge is described in terms of *praxeologies* (Chevallard, 1999). Modelling has a wider meaning in this framework, as the elaboration of praxeologies in one domain in view of studying one or more *questions* in another domain. The school institution refers to this as "intra-mathematical modelling" when both domains are recognized as belonging to school mathematics, e.g. if school algebraic praxeologies are elaborated to study a question from school geometry (García, Gascón, Ruíz-Higueras, & Bosch, 2006). In ATD, modelling thus serves to create meaningful links between otherwise separate praxeological domains, whether or not these are considered as belonging to school mathematics or not.

The two theories are related to specific *design formats* which are often used for the design of teaching that involves modelling (cf. Miyakawa & Winsløw, 2009, for the distinction of theory and design format). In

MCT, it is *problem oriented project work* (PPW), in which students are to develop their competences while experiencing some or all steps in a modelling cycle (Blomhøj & Kjeldsen, 2006). In ATD, it is *study and research paths* (SRP), departing from one or more questions; the further development is sometimes represented with a tree like "map" of derived questions and praxeologies which students did construct while working with the questions (Barquero, Bosch, & Gascón, 2008; Jessen, 2014).

At this point, we have only hinted at some of the differences between two perspectives on modelling. The research question which interests us is a theoretical, but also quite practical, one: *What differences, if any, does it make for the design of new teaching practices, whether the theoretical control apparatus comes from MCT or ATD? In particular, are there differences between uses of the design formats PPW and SRP which can be related directly to the different theoretical notions of modelling found within MCT and ATD?*

We shall take an inductive approach to this question: we first present two cases of design of modelling activities for students in Danish upper secondary school, constructed from each of the two perspectives but otherwise similar in contents. Then we analyse the differences in view of providing tentative answers to the research question. To prepare that analysis, the presentations of the cases focus on the following variable features of modelling activities:

(V1) *Practical meaning of "modelling"* in the activity, as described by the authors

(V2) *Goals for the activity* (e.g. for student learning) *and their assessment*

(V3) *Organisation in time* of the activity

(V4) *Distribution of roles among students and teacher(s)*, in particular the way in which student autonomy is controlled (limited, furthered, differentiated, etc.)

(V5) *Adaptation to local conditions and constraints* (features of the activity which result from these adaptations, including choices made for (2)–(4)).

The case presentations given below are based on more extensive studies (Jessen, 2014; Blomhøj & Kjeldsen, 2006). V5 is further treated in these papers.

CASE 1: A STUDY AND RESEARCH PATH

The first case we will present comes from an experiment with study and research paths (SRP) in the context of Danish high school students' study line reports written in the second year of high school (a study line report is a bidisciplinary report students write in the second year as a preparation for the bidisciplinary "study line project", which is a high stake final exam in upper secondary school in Denmark, cf. Jessen, 2014, p. 2). The reports are about 15 pages long accounts of an autonomous work done by one or two students, within 6 weeks and with very limited access to help from teachers (V3). The study line of the students determines what disciplines are to be involved in the report. Before the 6 week period, the teachers formulate a set of questions for the students to work on (V4). For the study line of the experiment, the theme should combine the disciplines *mathematics* and *biology* with equal weight. These circumstances are constraints (V5) which affect the concrete design and in particular the variables V1-V4.

The aim for the study and research path (V2) was for students to develop new praxeologies in the domains of nervous physiology and differential equations by working with a certain generating question, given by the teacher together with some supplementary questions to ensure the involvement of both disciplines:

Q_0: How can a patient be relieved from his pain by painkillers like paracetamol – how does deposit medication work and how can we model this mathematically? Q_1: Explain the biological functioning and consequences of taking paracetamol orally versus taking it intravenously. Q_2: Create a mathematical model using differential equations that illustrates the two processes and solve the equations in the general case. Q_3: Give a concrete example, where the patient is relieved from pain and estimate from your own model how often paracetamol has to be dosed – which parameters (absorption, elimination factor, bioavailability) are important to be aware of? $Q_{3,1}$: Does it make any difference whether the dose is given oral or intravenously? Use your models while giving your answer. (*Translation of the original questions in Danish*)

Notice that in ATD, *modelling* means the elaboration of praxeologies in the two domains – done by students in view of answering the generating question (V1). However, in the assignment, "mathematical model" refers to a more restricted sense, which is closer to the notion of model found in MCT and, at least in outline, is the one found in official documents and text books for Danish high school.

The above assignment is based on a generating question Q_0 which the students can immediately understand, but not answer. In general, a generating question should be so strong, that it is necessary for the student to formulate derived questions Q_i, each representing a branch of inquiry, in order to answer Q_0. The answers R_i to the derived questions adds up to a final answer of Q_0 (Chevallard, 2012, p. 6). At the same time it is purposed that the generating question must be "alive" in the sense that students should be able to relate the question to things they perceive as interesting and real. These aims were deliberately pursued by the teaching design, knowing that several students in the class wanted to study medicine or similar after graduating.

The derived questions formulated by the teachers serve as supports for the students' study process (V4). In general, it is crucial that the students are not left with "big questions" that are unrelated to their praxeological equipment (Chevallard, 2012, p. 11); the relation to praxeologies from specific disciplines must be ensured. This was even more crucial in our context since no teaching activity was accompanying the SRP work of the students. Some students met after classes and formed their own working groups discussing strategies for answering the questions. The teachers were allowed to answer questions during the six weeks, and in order to keep track of the students working progress, the exchange of questions and answers was only permitted in writing (V4). For the same reason, students were asked to provide their immediate answer to the generating question Q_0 when it was handed out (without the derived questions Q_1–$Q_{3,1}$). After that, the entire assignment was given to them. After two weeks, and again two weeks later, the students were asked to answer the following questions in writing:

> What is your answer to the generating question right now? What have you done to answer the question? What are you planning to do next in order to come up with more fulfilled answers?

We cannot go into all the details of the analysis of this SRP, neither before nor after the experience (the latter being analyses of students' reports, cf. Jessen, 2014). However we notice that to construct the "mathematical model" asked for in Q_0, students must somehow examine the relationship between the amount of drug given, and the distribution of the drug in the body. How the pain is cured and how the drug is eliminated must be answered by praxeologies from the domain of physiology. The latter leads to consider that the pain is relieved in relation to how often the drug is given, the size of the body and the pain perception. Thus, the progressive development of a mathematical praxeology (involving tasks, which can be solved using techniques available to the students, e.g., CAS-based solution methods for differential equations) is closely articulated to the development of a biological praxeology. The modelling process in terms of ATD is not a question of following certain steps, it is an individual process where the students uses their praxeological equipment to investigate domains, form new questions, answer them with existing or new praxeologies unfolding the disciplinary organisation at stake (V1).

The intermediate answers from the students showed a variety in their working progress, which reflected different praxeological equipment among the students. Some students responded the first time, that they needed to know the half-life of the painkillers this indicates, that the students suspect, that there is a time dependence in the model, and that the model includes an exponential function. During mathematic classes they have seen that exponential equations are part of the solution to many differential equations. This implied, that they were trying to relate the generating question to the newly developed praxeologies in mathematics. Also they studied relevant medias since they were able to formulate relevant search topics. The students formulated derived questions such as the following: Q_1: How is pain registered? Q_2: How does paracetamol relieve pain (pharmaco dynamic)? Q_4: How can the dosing be modelled mathematically based on the biological knowledge? (Jessen, 2014, p. 11). The entire analysis shows that the students are constantly narrowing down their inquiry, by alternately studying the questions through physiology and differential equations.

The teacher involved was sure that for some students the generating question would not suffice to develop a reasonable model. It was for this reason that a part of the derived questions was handed out before the independent work of the students. Some of the students would otherwise not have been able to develop new praxeologies in the intended domains. With these more precise questions, they were able to identify relevant media (web-pages etc.) and although some of them uncritically adopted models constructed by others, they were all able to make use of them for simple calculations (e.g. of the amount of drug in the vein of a patient) (Jessen, 2014). Thus their modelling of the intended praxeologies was not as richly developed as in the previous case.

CASE 2: A PROBLEM ORIENTED PROJECT ON ASTHMA MEDICINE

Our second case presents a PPW on mathematical modelling related to the administration of asthma medicine. In MCT modelling competency is defined (V1) as

> A person's insightful readiness to autonomously carry through all aspects of a mathematical modelling process in a certain context and to reflect on the modelling process and the use of the model (Blomhøj & Jensen, 2003, p. 127).

The key words are *autonomy*, *modelling process*, *reflections*. PPW is particularly well suited to foster students' autonomous participation in the modelling process (Blomhøj & Kjeldsen, 2011). The goal for students' learning (V2) in MCT is to develop and/or enhance their competency.

A mathematical modelling process can be depicted analytically as a cycle consisting of six sub-processes (ibid., p. 387). Concrete modelling activities, like the case presented here, may have a variety of more specific goals for students' learning (V2) in order to adapt to local conditions and constraints (V5).

In a PPW, students work in teams with a problem for a longer period of time to produce a product representing the team's solution (V2+V3). The central idea is that the problem should function as the "guiding star" for all decisions made by the students in the sense, that all decisions should be justified by their contribution to the solution of the problem. This provides the students with (parts of) the responsibility of directing the project. It is crucial that the students are involved in (most of) the decisions taken in the modelling process and become involved in reflections upon the different steps in the modelling cycle. PPW opens for a distribution of roles among students and teacher(s) that makes it possible to direct the students' autonomy e.g. through specific requirements to the product of the project (V2+V4). PPW has the potential to foster in the students all the key elements in developing modelling competency which makes this format an obvious pedagogical choice in MCT.

The asthma project was designed by two teachers for first year students in mathematics in high school. The students were to: 1) work more independently than usually over a longer period (ten mathematics lessons of 1.5 hour each and a similar amount of homework); 2) develop new theory by working with modelling within a subject area (exponential growth) they hadn't worked with before; 3) work with a more complex and authentic problem for which they did not possess a standard method or technique such that the modelling, the mathematization, the interpretation of the results and the reflections about the modelling process and the use of the model became part of the project; 4) analyse a set of data in order to build a mathematical model; 5) use familiar concepts such as graphs and equations for functions in a concrete context; 6) develop their mathematical communication skills; 7) use ICT throughout the project. (V2)

These aims were achieved through a strict organization of time (V3) and a setup that allowed for and supported the students' autonomy (V4). The teachers divided the project into four phases (Figure 1). The teachers controlled phase 1–3, and the students controlled phase 4. The aim of the first three phases was to prepare the students for their independent work in phase 4. In phase 4, the teachers took on the role of

1. (1.5 module) Presentation of the problem (see Fig 2). Excel course, IT for project management, social contract. Crash course in the modeling process.
2. (1 module) Problem formulation Phase and decision.
3. (3 modules) Work with a set of four exercises related to the project in phase 4.
4. (4 modules) Working with the actual project.

Figure 1: The four phases of the design. 1 module corresponds to a 90-minute lesson (Blomhøj & Kjeldsen, 2006)

consultants (V4) that the students could ask for advice on specific problems.

In phase 1, the teachers introduced the students to a cyclic representation of the modelling process. The teachers used the process to inform the students about the various elements in mathematical modelling within MCT, and they asked the students to be aware of and to explain where in the modelling process they were at any given stage in their work. Hereby, the teachers made sure that the students became engaged in posing the modelling problem, constructing the model, solving the mathematical system and suggesting solutions to the problem (V2, V3 & V4/V5). In phase 2, the teachers trained the students' competence in posing mathematical modelling problems through discussions in the class room guided by the teachers (V1/V5).

The problem from phase 2 was given to all students with some data (Figure 2). The exercises in phase 3 were not included in the students' independent work. They served as inspiration and illustrated the level of mathematics, communication and documentation expected in phase 4. The product of the project work was a report, handed in by each group after phase 4 (V4/V5). The teachers formulated a set of requirements for the report to direct the students' autonomy in phase 4.

ANALYTIC COMPARISON OF THE CASES

A synthetic presentation and comparison of the two cases can be achieved using the five variables identified in the first section and indicated as they are "filled" by the above presentations (see Figure 3).

Despite evident similarities between Q0 in case 1, and the problem (Figure 2) underlying case 2, the contexts and constraints are quite different: in case 1, the students must work independently most of the time, and have to combine the two major disciplines (mathematics and biology) of their study line; while in case 2, the work is done as part of the regular teaching of one discipline (mathematics). In the Danish regulations for high school, *mathematical modelling* more or less understood as in MCT forms part of the competency goals for mathematics as a discipline (Niss et al., 2002); the bidisciplinarity required for study line projects is a more diffuse and general principle for the study line projects while in the case of mathematics, it is also often associated with the same notion of mathematical modelling. Despite these differences coming from the contexts, some more principal differences arising from the theoretical background of the two cases can also be identified.

Differences coming from the design formats

The variables V2–V4 are clearly shaped by the design formats. In PPW, everything begins with a *problem* defined in more or less commonly accessible terms, which should then be sharpened and translated into mathematical terms, in order to allow for applications of relevant mathematical machinery, either known in advance or developed through the project work. The PPW in itself does not suggest explicit structuring

Asthma patients' problems with exhalations may be alleviated medically by increasing the concentration of the drug theophylline in the blood of the patient. If the concentration of theophylline is below 5 mg / L it has hardly any positive effect. If the concentration is above 20 mg / L it has toxic effects. The problem is to administer medication such that the concentration of theophylline stays within a certain range in which the medicine is effective, say a concentration between 5 and 15 mg / L. The substance is excreted from the body through the kidneys; hence the amount of the substance in the blood will drop with time, which means that the patient will suffer, unless you "fill up" periodically. At the hospital where the patient is hospitalized you try, for the sake of the daily organization of work and to reduce the risk of errors, to schedule the medication so the patient is supplemented with an equal dose, D mg, with equal intervals of time, T hours. A doctor is examining how to choose D and T so that the concentration of theophylline remains within the range of 5- 15mg / L. On a patient, he has measured how the concentration of the substance decreases with time following an injection of 60 mg of the drug.

h	0	2	4	6	8	10	12	14	16	18
mg/L	10.0	7	5.0	3.5	2.5	1.9	1.3	0.9	0.6	0.5

Figure 2: The problem and the data (Blomhøj & Kjeldsen, 2006)

and requirements regarding the students' work besides the fact that the problem should be formulated in such a way that it can function as a guide. The formulation of the problem is part of PPW. Hence, it is left to the teacher to set the "scene" for the students' work within the given context, depending on his or her learning goals. A SRP begins with a *question* which, like the problem in PPW, is too open to allow for immediate, complete answers. In order to proceed, students need to work with subquestions arising from supplementary assumptions, suggested by the original question or by some first, intuitive hypotheses or answers. Both design formats leave the teachers with tools for *directing* the students work: in PPW, the structuring can allow students more or less autonomy depending on how the teacher choose to structure the work, and through specific requirements for the product – in this case a report - the students should deliver (Blomhøj & Kjeldsen, 2006, p. 168), while in SRP, the teacher may supply students with some derived questions to start with, some specific media to study, etc. (Winsløw, Matheron, & Mercier, 2013, pp. 271–282). In both cases, an initial planning may be adjusted to the work of the students, with the tree diagram of the SRP and the learning goals and (parts of) the modelling cycle as the main tools for control of these adjustments of the initial design.

Differences coming from the theories

MCT assumes a clear and evident boundary between mathematical and extra-mathematical phenomena, which implies (through the processes of problem formulation, demarcation of a domain of inquiry, and systematization), the construction of an object to be modelled. This object is then translated into a mathematical representation, which in daily work is also often referred to as *the model*. The preparation and conduct of the PPW can thus be structured according to the movements from the problem to the mathematical domain, and back – with an explicit notion of being "outside" and "inside" mathematics. ATD, on the other hand, is based on a general theory of human practice and knowledge, in which the organisation of praxeologies into disciplines is merely an institutional construction; the boundaries of what is called "mathematical" are not universal but contingent.

In MCT, it is part and parcel of mathematics teaching to develop students' explicit knowledge and experience of how mathematics (as a universal entity) *applies* to problems outside of that domain. In ATD, praxeologies are simply answers to questions which have been developed sufficiently to allow students to find culturally established answers through media or through research based on praxeologies they are familiar with; the main feature of modelling to experience is the development of praxeologies through this dynamics of study and research, independently of institutional classifications into disciplines of the praxeologies.

These theoretical differences have an impact on practice. In PPW based on MCT the disciplinary contents are in principle subordinate to the problem. The chief purpose is to reach a satisfactory solution to the problem through realisation of (specific features of) the

	Case 1: study and research path	Case 2: problem oriented project work
V1	Starting from a big question Q_0, develop derived questions and praxeologies which can answer these and in the end, at least partially, Q_0. Didactic theory is not taught.	Starting from a problem *P outside* mathematics, reformulate it as a mathematical problem, treat this, and evaluate solution relative to *P*. The modelling process is explicitly taught.
V2	Develop specific bidisciplinary praxeologies as answers to Q_0.	Modelling competency through phases of modelling of data and problem.
V3	Six weeks of independent work (individually or in pairs) based on Q_0 and some derived questions, with encouragement to search for media.	Project team work for ten 90-minute modules and similar amount of homework, structured by phases of modelling as shown in Figure 1.
V4	Teachers deliver Q_0 and some derived questions; students do study and research on these, with very limited access to teachers, to prepare their study line reports.	Teachers structure the work of teams according to the phases, with most autonomy required in the last phase (once mathematical formulation and expectations are established).
V5	Regulations of study line reports (combining math and biology)	Aims for regular mathematics lessons, which include mathematical modelling.

Figure 3: Syntheses of didactic variables as set by the two cases

mathematical modelling process including choosing disciplinary theory relevant for solving the problem. The mathematical content brought into play will depend on the mathematical competencies and knowledge of the modellers and their abilities to expand these. In the ATD approach to modelling, a more or less strongly directed SRP can be planned based on a priori analysis of its potential to realise certain institutionally defined disciplinary praxeologies as answers to the initial question. This could make the ATD approach to modelling implemented through SRP more attractive in institutional contexts where the disciplinary focus is strongly constrained. On the other hand, as we have argued and illustrated, the choice of design has theoretically determined consequences for the kinds and qualities of mathematical modelling activity, which students get to engage in. For further investigation one might analyse the activity students carry out in the classroom (how are answered produced and validated, etc.) and to what extend are the students able to solve other modelling problems in the future.

Evaluating the effectiveness of a framework for measuring students' engagement with problem solving episodes

Patrick Johnson and Seán Moylett

University of Limerick, Limerick, Ireland, patrick.johnson@ul.ie

The purpose of this study is to investigate the problem solving episodes that a group of post-primary students in Ireland engaged with during the problem solving process and to determine an effective assessment technique for measuring their problem solving abilities. A framework developed by Artzt and Armour-Thomas was implemented and evaluated within the classroom over a nine week period to assist students in developing their problem solving skills. Testing was conducted on the students to be able to differentiate between their abilities prior to the introduction of the framework. It was found that when students utilised the framework the number of episodes engaged with by the students increased and the number of correct answers to the problems also increased.

Keywords: Problem solving, episodes, implementation, assessment.

INTRODUCTION

With the introduction of a new post-primary mathematics syllabus in Ireland in 2008, named Project Maths, increased emphasis has been placed on developing students' problem solving abilities. Around this time worrying findings from reports such as the *Statement on Raising National Mathematical Achievement* (Expert Group on Future Skills Needs [EGFSN], 2008) highlighted concerns about students' capacity to engage with problem solving. When designing Project Maths the National Council for Curriculum and Assessment (NCCA, 2012) identified five key skills that they saw as being central to effective teaching and learning across the new curriculum. These are *information processing, being personally effective, communicating, critical and creative thinking* and *working with others*. The new syllabus has placed increased emphasis on teaching "through" problem solving as it affords students the opportunities to develop these key skills although there have been concerns raised about what exactly teaching through problem solving means (Lubienski, 2011). Regardless of this confusion an aim of the new syllabus is to allow students more time to explore mathematics and to move away from an over-reliance on drill and practice techniques as had been evident in the old syllabus (Lyons, Lynch, Close, Sheerin, & Boland, 2003).

Even though problem solving is seen as a means by which "students deepen their understanding of mathematical concepts by analyzing and synthesizing their knowledge" (Erbas & Okur, 2012, p. 89) this is not always the case. Posamentier and Krulik (1998, p. 15) pointed out that "a substantial portion of problem solving is done by rote. Students struggle through one problem in the section, the teacher reveals a model solution and the remainder of the problems in the section are solved in the same manner". Mimicking a teacher's solution strategy will work for some problems but when presented with unfamiliar or non-standard problems students still struggle (Harskamp & Suhre, 2007). Having a solid knowledge base, good past experience and knowledge of strategies are considered to be important in successful problem solving (Erbas & Okur, 2012). Now that problem solving has been officially cited as a learning outcome on the post-primary mathematics syllabus in Ireland it is imperative that teachers are aware of effective frameworks for teaching and assessing problem solving to guarantee the successful integration of problem solving into the classroom.

The purpose of this study was to implement an existing problem solving framework in a mathematics classroom and to then attempt to use this framework as a guide for assessing students' problem solving competence. The following research questions guided this study:

— Do teachers feel that this framework could assist in the implementation and assessment of problem solving in the classroom?

— Which problem solving episodes can be observed while students solve mathematical problems?

SELECTION OF A SUITABLE FRAMEWORK

With the increased emphasis placed on problem solving in the new syllabus the Project Maths Development Team [1] set about designing a modular course with the aim of providing teachers with practical advice on how to approach problem solving in the classroom as well as providing them with a holistic rubric for the marking of solutions. The rubric presented by the Project Maths Development Team primarily focuses on three activities of problem solving – choosing a correct strategy; explaining your choice of strategy and getting the correct answer. Unfortunately this rubric makes no attempt to measure all the remaining, and often important, tasks that individuals engage with during the problem-solving process. To this end a more detailed framework for implementing problem solving was sought by the authors with the additional requirement that a rubric for the assessment of problem solving activities could be easily developed around this implementation framework.

Schoenfeld (1985) developed a framework that separated the problem-solving process into a number of "episodes". He defined an episode to be "a period of time during which an individual or a problem-solving group is engaged in one large task" (p. 292). The initial episodes according to Schoenfeld (1985) were *read, analyse, explore, plan, implement,* and *verify*. Using Schoenfeld's framework as a foundation, Artzt and Armour-Thomas (1992) adjusted the framework to "delineate explicitly the type and level of cognitive processes individuals use" (p. 141). To this end modifications of the original episodes within Schoenfeld's framework were needed. For example, the original episode of *read* was separated into the episodes of *read* and *understand*. Artzt and Armour-Thomas (1992) finally settled on eight episodes when looking at problem solving in small groups – *read, understand, analyse, plan, explore, implement, verify,* and *watch and listen*. This framework, with the exception of the 8th episode as this is specific to small groups and our study focused on students working individually, was adopted by the authors for the purpose of this study as it was deemed to address all the major "stages" of the problem-solving process and it was felt that it could be easily implemented in a classroom scenario.

Additionally each of the episodes within the Artzt and Armour-Thomas (1992) framework is sub-divided depending on whether it involves predominantly cognitive or metacognitive processes. This is important as several researchers (e.g., Goos, Galbraith, & Renshaw, 2000; Teong, 2003) have confirmed the importance of the relationship between cognitive and metacognitive processes where in the words of Artzt and Armour-Thomas (1992) "an appropriate interplay between the two is necessary for successful problem solving to occur" (p. 162).

Due to the structure of this framework it was relatively straightforward to develop an assessment rubric where the focus is placed on each of the individual episodes. In this way no single episode would be overlooked and additionally no individual episode would be deemed more "important" within the problem-solving process than any other. Erbas and Okur (2012, p. 97) have correctly noted that "all episodes don't need to occur to find a correct answer" but since this study is more focused on the process of problem-solving rather than the answer the focus remained on the inclusion or omission of the problem-solving episodes from the student solutions. Additionally it should be noted that the students being assessed in this study could be termed as "novice" in terms of their problem solving abilities and so the authors felt it would be more beneficial to the students if they fully engaged with all the episodes of the framework at this stage of their mathematical development.

METHODOLOGY

Participants for this study were selected from a school in the mid-west region of Ireland. A second year (typical student aged 14 years) higher level [2] mathematics class was selected as the study group for the duration of the nine week study. The selected class was a mixed class of 21 students consisting of 12 boys and 9 girls. Seven of the students volunteered to participate in the study (4 boys and 3 girls). Four teachers also agreed to participate in the study by reviewing the frameworks presented by the authors and taking part in a focus group to garner their opinions on the suitability of the frameworks for implementing and assessing problem solving in the classroom.

Quantitative data was gathered from the study via testing. Students were tested on their problem solving ability prior to being introduced to the framework within their class structure. During the nine-week intervention one of the authors replaced the regular teacher in the classroom and taught the topics outlined by the regular teacher. Additionally the problem solving framework was introduced during this timeframe and then regularly revisited to consolidate this new problem solving approach among the students. Testing was conducted at intermittent stages throughout the nine-week intervention to gain a more comprehensive view on whether or not the students were integrating the framework into their daily problem solving routine. A total of five tests were carried out during the nine-week intervention – one pre-test and four tests during the actual intervention.

Each test consisted of one mathematical problem that students had to solve. The new Project Maths syllabus in Ireland places increased emphasis on the development of students' literacy skills and to that end the questions selected were not just purely mathematical but instead were what has typically in Irish circles been described as "word problems". Word problems, according to Verschaffel, Greer, and De Corte (2000), is the term often used to refer to any mathematical task where significant background information on the problem is presented as text rather than in mathematical notation.

The question utilised in each test was carefully selected in an attempt to maintain the validity and reliability of the study. In the end it was decided that the best way to select questions of a similar standard and difficult, that were relevant to the new syllabus, would be to utilise past examination papers and sample papers from the Junior Cycle [3] examinations. Each question was selected to be slightly more challenging than the questions that the students encountered during class. This was the case as it was hoped that students would need to employ the problem solving framework shown to them during the lessons rather than being able to solve the question immediately upon reading it.

To assist with the assessment of the test in terms of being able to measure students' success at each of the different problem-solving episodes a template was designed around which each question was structured. When designing the template it was necessary to ensure that each episode of the Artzt and Armour-Thomas (1992) framework was addressed. Unfortunately it was not possible to assess each of the episodes in the framework e.g. *Read*. Since certain episodes could not be assessed independently they were instead combined with other episodes, e.g., *Read* was combined with *Understand* as if students demonstrated an understanding of the problem then we assumed that they had successfully read the problem. For this reason some of the tasks in the assessment template are deemed to assess two of the problem solving episodes as outlined in the Artzt and Armour-Thomas (1992) framework.

The six tasks, along with the episode(s) (in brackets) which each task measured, that students were asked to engage with as part of the assessment template were:

1) Underline or highlight the important information/facts given in the question (Read and Understand)

2) What is the question asking you to do? (Understand and Analyse)

3) Is there a process or method involved in solving this question? (i.e., What methods have you used to solve similar questions like this before?) (Plan)

4) What is the first step in attempting to solve this question? (Plan and Explore)

5) Complete the question and display all your workings in the space provided. (Implement)

6) Does your answer satisfy what is being asked in the question? (Verify)

The scoring of the assessment rubric is rather straightforward. If a student displays evident of completing a particular episode then they are given a score of 1. If no evidence is found of a certain episode then a score of 0 is awarded. Therefore in each test a student could score a total of 7 marks depending on whether evidence of all 7 problem solving episodes was present or not. As previously stated it is not always necessary to carry out every episode when problem solving but since we are dealing with novice problem solvers an absence of evidence of an episode will be viewed as an omission on the part of the student.

To ascertain whether or not teachers of the new Project Maths syllabus felt that this was a suitable framework for implementing and assessing problem solving in the classroom a focus group was conducted with four teachers towards the end of the nine week intervention. A total of twelve questions were put to the teachers such as "Do you think this framework is relevant to the aims of the Project Maths syllabus?", "What strategies do you currently use to implement problem solving?" and "Do you think this framework would be easy to implement in your classroom?" and their responses and feedback were recorded and then analysed.

FINDINGS

Episode engagement

From the analysis of the results it is clear that overall there was an increase in the total number of episodes that each student engaged with as part of their problem solving process. Table 1 presents a breakdown of the episodes that students successfully completed in the test that they completed prior to being introduced to the Artzt and Armour-Thomas (1992) framework.

From Table 1 we can see that all students showed evidence of reading the problem with a similarly high number showing evidence of understanding the problem. Unfortunately these positive results do not continue as none of the students showed evidence of analysing the problem (episode 3) or even verifying their solution (episode 7). The lack of analysis by the students is worrying as the analysis episode is important as it is at this stage that students examine the relationships between the information provided in the question and what they are required to show. Similarly to the *Analyse* episode zero students showed evidence of completing the *Verify* episode. An additional goal of Project Maths is that students develop the skills to justify/explain/verify their answers. It is clear from these results that these students have had very little exposure to this methodology so far in their mathematical careers.

The results from the four tests conducted after the introduction of the Artzt and Armour-Thomas (1992) framework are more promising. Immediately upon introduction to the framework all students showed evidence of engaging with the *Analyse* episode of the problem solving process. The number of students completing the *Plan*, *Explore* and *Implement* episode all show improvement from the pre-intervention test although there is some minor fluctuation between tests regarding the number of students engaging with each episode. Regarding the *Verify* episode it can be seen in Figure 1 that it took longer for student to habituate this episode into their problem solving process but promisingly by the end of the nine week intervention all seven students were displaying evidence of evaluating the outcome of their work. Overall the trend appears to be positive with regards to student engagement with the problem solving episodes.

Correct solutions to problems

Irrespective of the number of episodes that students engage with during their problem solving process it is still necessary to consider the number of correct answers in the tests. Even if a student completed all the episodes it is still possible for them to arrive at an incorrect answer. You would hope that upon reviewing their answer at the *Verify* episode and realising they are incorrect students would persevere and return to earlier episodes and attempt to determine where

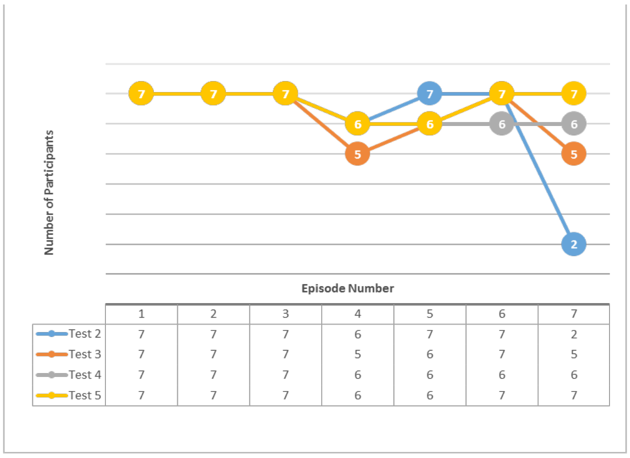

Figure 1: Results of episode inclusion during the intervention

	Read	Understand	Analyse	Plan	Explore	Implement	Verify
No. of students who completed each episode	7	6	0	4	3	3	0

Table 1: Results of episode inclusion in pre-intervention test

they have made a mistake along the way e.g. misunderstood the question in the *Understand* episode or overlooked a vital piece of information at the *Analyse* episode stage.

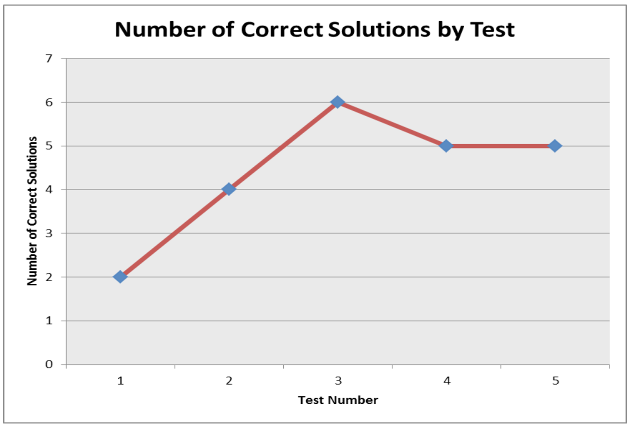

Figure 2: Results of Correct Solutions from Tests

Figure 2 highlights the trend regarding the number of correct answers across all 5 tests. The trend is positive, in general, showing that more students answered the questions correctly once the intervention commenced. There is a minor dip in the number of correct answers in the final two tests but even with this dip the number of correct answers is still higher than the results from test 1. The results regarding the total number of correct answers across the 5 tests offer additional justification regarding the effectiveness of the problem solving framework implemented but also highlight the need, in general, to introduce novice problem solvers to a structured approach to problem solving.

Feedback from teachers

Overall the teachers expressed satisfaction with the framework utilised by the authors to implement problem solving in the classroom. The teachers expressed their views that a framework like this would prove beneficial when attempting to familiarise students with the problem solving process. When asked if they had previously received or utilised any frameworks designed to assist in the teaching of problem solving the teachers stated:

> Teacher2: Well I would say I haven't. Have you?
>
> Teacher4: Yes I have, but I ignored it! Well we were given something like that (referring to Project Maths problem solving strategies poster)
>
> Teacher2: Yes that's the only thing, but I wouldn't say there was any time given in terms of training for teachers with the new Project Maths. In my opinion anyway, maybe it went over my head.

One teacher did go on to state that although she didn't utilise a "structured" framework she felt that within her class, and the classes of her colleagues, they embedded some of the problem solving episodes outlined in the framework.

> Teacher3: But I think to some extent that we do a lot of this. I mean I don't feel like this is something I've never seen before. We do say, well how would you solve this? What do we do now? What are you being asked? What are we looking for? Let's see, what are we missing? Do we have this? I think I do this, I'm sure everyone else does too. But I think that a structure where the kids know to put their information down, I think that this would help me.

This final comment about the students having a structure where they know to put their information down is referring to the assessment template structure outlined by the authors. This structure was also commented on by a fellow teacher who felt that it would be beneficial to students to have a structure, especially in an exam situation.

> Teacher1: But I think it would be useful maybe in an exam situation where all they see is a jumble of words and they just don't know where to start. At least they have a framework.

On a negative note one teacher commented that she felt it would take significant time to implement a framework of this type. Additionally she commented that trying to get students to focus on a problem for a long period of time might be an issue and that this could lead to discipline problems within the classroom.

> Interviewer: Just in terms of what you see there (Framework and Sample Question) do you think it would be worthwhile maybe trying to implement or trying to use this in a lesson?

Teacher4: I do think it would be, but what I do see this as is very time consuming. And in a classroom situation having each student reading and going through all of this a discipline issue probably would arise.

CONCLUSIONS

The results of this study showed that when teaching novice problem solvers it is important to offer appropriate instruction on problem solving so that these students can properly develop their problem solving abilities. This finding confirms Hembree (1992) and Higgins (1997) who observed similar results in their classroom studies. Once students engaged with the episodes of the problem solving framework the overall number of correct solutions to the attempted problems increased.

The result from the first test conducted as part of this study highlighted that very few students engaged with the *Verify* episode once they have reached a solution although almost every problem solving framework highlights the importance of this episode (Polya, 1973). This finding is also consistent with what other researchers such as Erbas and Okur (2012) have found. Encouragingly as the students became more familiar with the framework their results show that more and more of them conducted this episode and made some attempt to check their solutions with regards to the original problem statement.

Overall the teachers interviewed were positive regarding the structure and layout of the framework. Some issues around the time needed to problem solve within a class scenario were mentioned and other issues regarding students going off task when completing certain episodes were raised but neither of these concerns detracted from the overall positive comments from the teachers. The benefit of the framework as a resource within examinations was highlighted by the teachers as once students are familiar with the framework it should help them by scaffolding their problem solving efforts.

Finally it is worth mentioning as a discussion point the "age" of the original Artzt and Armour-Thomas framework upon which this work, and the work of Erbas and Okur (2012), was based. Does a more modern framework exist which would be more suitable for this purpose or is there a more up-to-date/adapted version of this Artzt and Armour-Thomas framework which might better aid teachers to implement problem solving in the classroom?

ENDNOTES

1. The Project Maths Development Team is a team of experienced teachers of mathematics who have been recruited to provide professional development support to post-primary teachers of mathematics.

2. All subjects studied at post-primary level in Ireland can be studied at either ordinary or higher level with higher level being the more challenging.

3. The Junior Cycle is the first three years of post-primary education in Ireland. A state-wide examination takes place at the end of the Junior Cycle. Students normally sit for the examination at the age of 14 or 15.

Student's interpretations of visual models

Thomas Lingefjärd and Djamshid Farahani

University of Gothenburg, Department of Mathematics Education, Gothenburg, Sweden,
thomas.lingefjard@gu.se, djamshid.farahani@gu.se

Humans perceive and interpret graphical representations of models daily. Student's ability to do accurate interpretations of graphical and symbolical represented information is an important goal for the educational system. A study on 17 student's interpretations of graphical and symbolical representations of linear motion is reported. The collected material consists of about 10 hours video recording divided into 20 sequences about 15–50 minutes each. The tasks used to approach student's interpretation of graphical representation of linear motion where related to distance-time graph and analytical representations of distance function. The theoretical framework used is the theory of conceptual change for learning developed by Chi together with Tall and Vinner's framework on concept image and concept definition.

Keywords: Representations, iconic, every-day and scientific discourse, lateral categories of conceptual allocations.

The research reported here is not aimed at only identifying or describing students' alternative conceptions but instead provide possible explanation of why some students interpret graphical representation differently than other students. Mathematical representations such as diagrams, histograms, functions, graphs, tables and symbols normally makes it easier for us to understand abstract mathematical concepts or phenomenon described in mathematical terms. Representations are, according to Wittmann (2005), usually structured systems with strong connections to theories and may be seen as constructions that links abstract and concrete mathematics together.

Humans of today are facing a world that is shaped by increasingly complex, dynamic, and powerful systems of information that we meet through various different media. Being able to interpret, understand, and work with complex systems involves important mathematical processes that humans need to understand and be able to address when facing interpretation challenges.

Mathematical representations, structures and constructions are also usual when you study other subjects, such as physics. We wanted to investigate upper secondary school student's understanding and interpretations of mathematical representations of linear motion. Our research question is therefore:

- How do upper secondary school student interpret graphical and symbolic representations of linear motion?

THEORETICAL FRAMEWORK

We humans develop alternative reference systems in order to explain and understand the physical world we meet. We do this through daily life experiences. Several thousands of studies has described students alternative and resistant opinions about mathematics and natural science (Duit, 2004; Pfundt & Duit, 1993), together with reports on how teaching could be altered and developed in order to counter act on students alternative opinions (Slotta & Chi, 2006, p. 262).

Research has also shown that alternative ideas sometimes can be incompatible with scientific models and theories (Hammer, 2000; Shaffer & McDermott, 2005). There are several different labels on individually alternative opinions concerning daily life phenomena such as children's science, alternative ideas, intuitive ideas, and common sense beliefs.

The source of our daily life conceptions is shaped, according to diSessa (1993), by a row of well-developed intuitive ideas which diSessa defines as "Phenomenological primitives" or p-primes. P-primes are generalizable and different than our memories from events we have experienced. P-primes are also different than learning of scientific theories which generally are studied with a specific purpose, while p-prime are constructed and built rather unconsciously, less formal, intuitively and without a specific aim.

A p-prime can be either right or wrong, it may be compatible with scientific theories or not. To run a bike in hard upwind is more strenuous (p-prime: one has to work harder when the resistance is greater), motion with constant speed demands constant force (p-prime: there is always a force in an objects direction) or gravitation only applies to objects in movement (p-prime: no movement no force). A p-prime is generalizable since it may be used by the individual in different contexts. Even if we never had been closed to an earthquake, we still could determine we would run in a different direction (p-prime: the closer we come to a source, the stronger impact). A p-prime could be correct but used in the wrong context. The fact that the weather (on the northern hemisphere) becomes warmer in the summer is not because we are getting closer to the sun.

A collection of p-primes form the first and most elementary educational system, something diSessa calls the intuitive physical sense of mechanism. The way we humans interpret our surrounding world is the foundation for our learning of basic physics.

> The intuitive sense of mechanism contributes substantially to understanding school physics. (diSessa, 1993, p. 105).

diSessa claims that all p-primes are valuable and necessary and not misconceptions that we need to erase. diSessa also uses knowledge in pieces, intuitive conceptions or persistent false intuitions when he talks about p-primes. It seems that a p-prime sometimes needs to be modified, enhanced, or to be generalized.

GRAPHICAL REPRESENTATIONS

Representations, according to Wittmann (2005), are normally from a structured system with clear relations to theories and may be seen as constructions that connects abstract and concrete mathematics. A representation is something that stands for something else (Duval, 2006, p. 103). An object's speed or acceleration described through a speed-time-graph may be determined from the graphs slope, something not explicit obvious from the graphical representation.

Elby (2000) argues for a specific form of p-prim which activates with interaction with graphical artefacts. Elby calls this "What-you-see-is-what-you-get", or WYSIWYG:

> In my view, that's because the hill mistake and similar iconic interpretations spring, in part, from the activation of a cognitive structure, specifically, an intuitive knowledge element I call What-you-see-is-what-you-get. (Elby, 2000, p. 483)

Elby (2000) refers to a study where the students are asked to interpret a speed – time graph describing a bicycle path. See Figure 1.

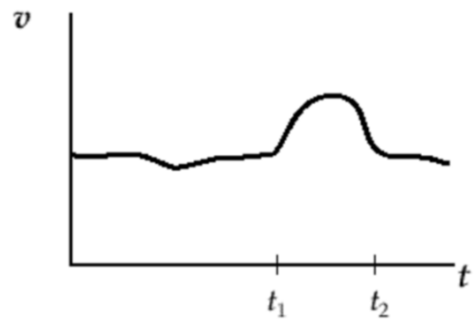

Figure 1: A bicycle path (Elby, 2000, p. 487)

Some students interpret this as evidence that the bicycle path goes over a hill. Some representations include special attributes which quickly catch our attention. Elby call this Compelling visual attributes. It may be all visual qualities and shades that are imbedded in the graphical representation, such as vertex, edges, contours, etcetera.

> My claim is that, even though what-you-see-is-what-you-get is not cued strongly in all contexts, it is cued strongly with respect to the compelling visual attribute of a representation. (Elby, 2000, p. 484)

Which one of these visual properties we notice first is strongly context dependent. We need to know what a bicycle is before we can connect its path to a graph.

> The over-literal readings call to mind the "what you see is what you get" (WYSIWYG) knowledge element proposed by Elby (2000), where students interpret a representation in the simplest, most literal way possible (a bump on a graph corre-

> sponds to a hill). This WYSIWYG element is a representational analog of the phenomenological primitives (or p-prim) described by diSessa (1993) which include such basic reasoning elements. (Kohl, 2001, p. 107)

CONCEPTUAL CHANGE

In order to understand information presented in a graph, we need to understand the underlying concepts of the phenomena presented. Conceptual understanding springs from the idea that knowledge is constructed actively by the individual for instance by testing alternative ideas. All concepts relate to other concepts and most concepts have both definition and image in our mind. Tall and Vinner (1981) said:

> We shall use the term concept image to describe the total cognitive structure that is associated with the concept, which includes all the mental pictures and associated properties and processes. It is built up over the years through experiences of all kinds, changing as the individual meets new stimuli and matures.

On the other hand:

> The concept definition [is] a form of words used to specify that concept. (p. 152)

Gray and Tall suggest three mathematical worlds to explain development of mathematical understanding. This involves a parallel development of conceptual embodiment, as the complementary use of human perception and action and proceptual symbolism, involving manipulation of symbols that arise from operations. The term 'procept' address something that can be used flexibly as process or concept, including numbers, fractions, algebraic expressions, derivatives, integrals, and so on (Gray & Tall, 1994).

A key challenge to research in conceptual development and learning is to understand how individual constitute aspects of a scientific understanding of a concept. Knowledge acquisition is viewed as a process that involves actively generating and testing alternative propositions. Conceptual change refers to any change in conceptual understanding.

Three main perspectives on conceptual development are: the epistemological, the metaphysical and the cognitive perspective. The epistemological perspective on conceptions is based on criteria for difference. Our understanding regarding the world around us and how it is constructed relates to three ontologically "lateral" categories; mental state, entities and processes (Chi et. al., 2012). See Figure 2.

When we humans learn concepts, we also learn where the concept belongs in an ontological sense. What is the weight of the world series in soccer sounds like a strange question since the weight of something belongs to "Entities", while the world series in soccer is categorized as an "Event". Since the two concepts belong to different categories they cannot create an understandable context.

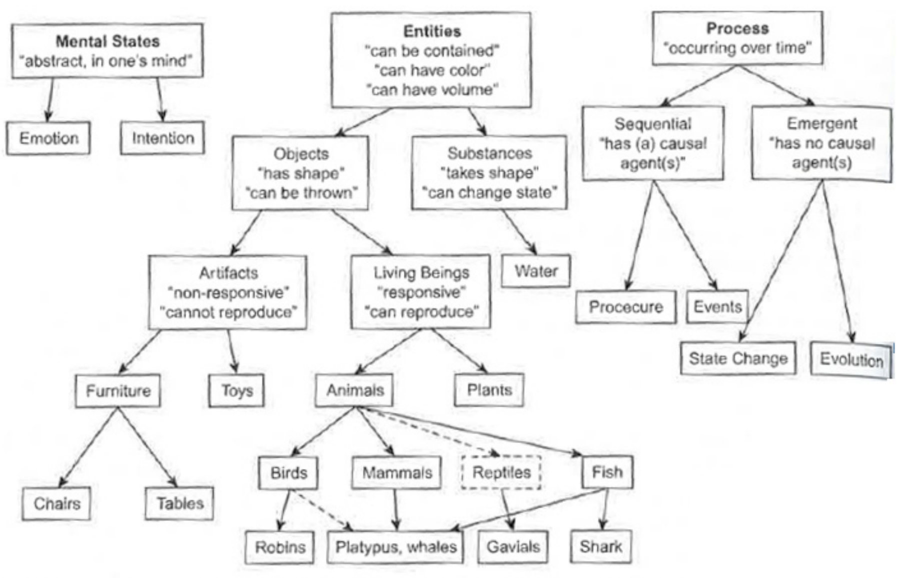

Figure 2: Conceptual change in an ontological structure (Chi et al., 2012)

Even close sub categories under the same branch might be ontological different lateral categories. Most young children know the difference between artefacts and living beings. Conceptual change occurs when we address concepts to different ontological categories. This constantly ongoing process happens inside us and strives for interpretations of new situations and to make them understandable.

Sometimes our interpretation of the world place concepts in the wrong place. One such well known phenomenon is the fact that students might view light or electrical current as material substances. Scientifically theories describe electrical current and light as sequential processes (Chi et. al., 2012, p. 57).

Conceptual understanding from the metaphysical standpoint is described as a restructuring of concepts over ontological lateral (not hierarchical) categories. Sometimes learning of scientific concepts is difficult since the process requires concept has to be re-assigned to an ontologically distinct category (across trees). The cognitive perspective on conceptual understanding is based on nature of misconceptions. Sometimes there are clear qualitative differences between the individual's (alternative interpretations, p-primes) and scientific models or expert's descriptions of a phenomenon.

Conceptual understanding based on a cognitivist's perspective can be seen as a process that tends to obtain a gradual increase in the correlation between alternative ideas (knowledge into pieces) and scientific theories (diSessa, 1993; Elby, 2002, & Hammer, 2000). The cognitive perspective on conceptual change starts in identifiable qualitative differences between an individual's (alternative interpretations, p-prime, and knowledge system) and scientific models or expert's description of systems.

METHODOLOGY

Our cohort consisted of 17 upper secondary school students (9 girls and 8 boys) at the natural science program, all enrolled in year 2. All students' volunteered to take part in the study. The students were grouped in small groups with 2 or 3 students in each group; a video camera was mounted to record the discussion. No observer was present to help the students to be natural in their comments and attitudes. Students written solutions and notes were collected.

Our intention was to record the individual students responses but we considered that this was easiest done by encouraging group discussions. The students responded to 13 questions all together, this article will present the dialogue in relation to a distance – time graph. The students took note and did some calculations on paper, which we collected. We will only present some short results here, depending on page limitations.

Problem

The graph in Figure 4 illustrates a train that moves during 4 hours. The distance s is in kilometer and the time t is in hours

1a) When do the train run at the highest speed?
1b) How do you know that?
1c) Are there more than one occasion when the train has this high speed?
2a) When do the train run at the lowest speed?
2b) How do you know that?
2c) Are there more than one occasion when the train has this low speed?
3) What could be said about the train's direction by interpretation of the graph?
4) Sketch a graph to describe the trains speed during these 4 hours.

RESULTS

Student group Arman, Alexander and Gideon – written answers

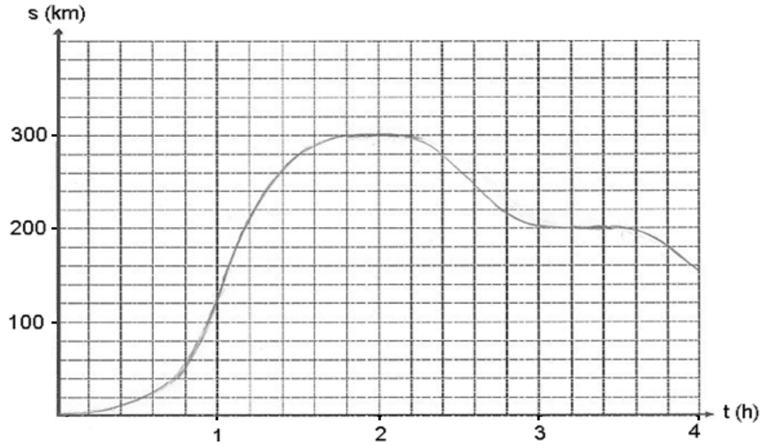

Figure 3: A moving train

Student: 1a. The train has the largest speed at 2 hours.
Student: 1b. Because that is the highest point in the graph.
Student: 1c. Yes, at 1.48 and 2.12. That speed last for 24 minutes.

Student group Arman, Alexander and Gideon – video recording

Student1: The train is fastest up here or ...
Student2: Write when it has the largest speed at 2 hours.
Student1: Here it goes down a hill; here it goes up a hill, up and down...
Student2: I think we should be careful writing about hills...
Student3: I do not think I never have seen a train go up a hill like that
Student1: Well, maybe when it is going up or around a mountain or something...
Student3: Like a rollercoaster? In an amusement park?
Student2: In San Francisco they have cable cars where you can hang outside...

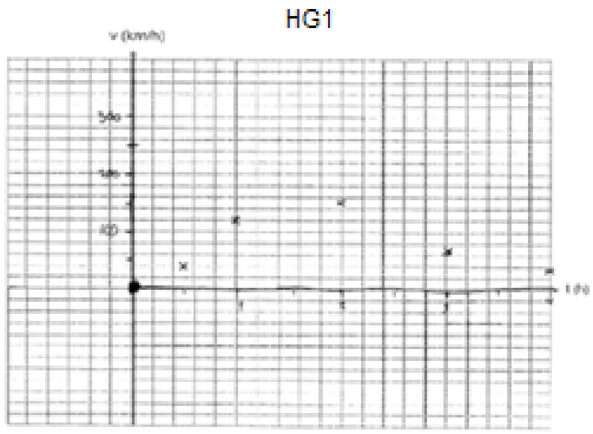

Figure 4: Alexander's response to task 4

Arman claims that the largest speed occur after 2 hours. His interpretation of the graph is built on the opinion that the graph is illustrating a train going "up a hill" and "down a hill". Arman interpret the graph as a "true image" which is called an iconic interpretation.

Alexander Shares the opinion that the speed is highest "at the top point up here" and that the train is going up and down. Alexander also connects the graph to the streets of San Francisco. Gideon, after some doubts, associates the graph to a rollercoaster in an amusement park.

Students' alternative iconic interpretations of graphical representations are well known from research and also obvious in this study. Arman's, Alexander's and Gideon's interpretation of the distance – time graph could be seen as an alternative descriptive model. The students talk about different places, refer to different events, and gives examples in different ways. Nevertheless, one thing they do have in common. Their interpretations seem to be iconic and they are all focusing on the wrong attribute.

Alexander's description that "In San Francisco they have cable cars where you can hang outside ...", or as Arman express it "Here it goes down a hill; here it goes up a hill, up and down...", are example of intuitive ideas and daily life concepts That seems to be deeply imbedded in the imagination world of these students. In reality it is probably impossible for a train to go up such a steep hill. The interpretation process together with the need to create a context for the train seems to be more important for the students than to think about the models validity and reliability. This in turn keeps their alternative ideas safe and resistant towards change.

Student group Jakob, Maria and Linnea – written answers

Student: 1a. When the curve has the steepest slope.
Student: 1b. Longest length on shortest time.
Student3: No, once.

Student group Jakob, Maria and Linnea – video recording

Student1: One box up in the graph paper is a fifth equal to 20 km, so the train is moving 20 km in short time while over here the train is going 20 km in a long time.
Student2: Yes, it is faster there.
Student3: It is fastest where the slope is steepest since the graph is showing us the real speed, the moment speed, so we have the answer to 1a.

One qualitative aspect of students understanding of a *distance – time graph* is found in Jakob's reasoning.

Jakob illustrates a good technique for determination of the slope of the graph. The discussion also reveals that the group manages to separate the meaning of distance and speed.

Written answers to question 2a-2c

Student: 2a. When the curve's slope is zero.
Student: 2b. Distance is not changing although the time is running.
Student3: Yes, at three occasions.

Quotations from transcribed video material related to 2a-2c

Student1: When the slope is zero, the train is standing still.
Student2: The train goes to one point and the back again and then it is standing still for some time.
Student3: Positive direction upwards and negative direction downwards means that the train is going back but not the whole way.

Through this conversation, the students are validating and develop their reasoning concerning the meaning of the graphs slope. The student's responses show that they are not confused by the graph, instead they are arguing for the relation between the slope of the graph and the movement of the train. The fact that they are not doing any iconic interpretation of the graph, allows them to give a full description of the meaning of the graph. As a result, they arrive to a quite different graph of the speed – time graph asked for in task 4.

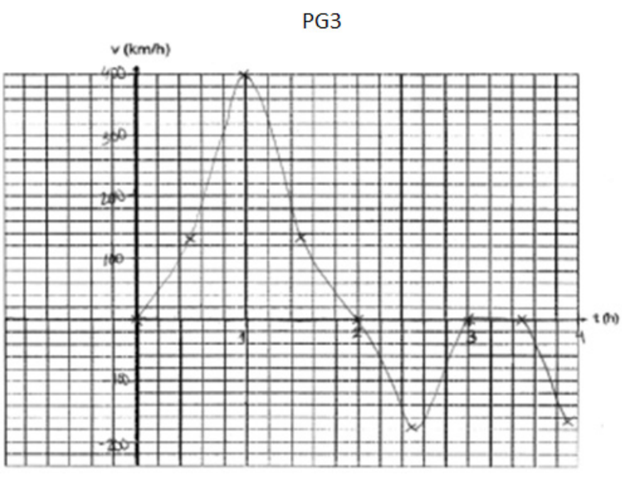

Figure 5: Maria's response to question 4

CONCLUSIONS

Sometimes may daily life experiences be too strong and to overwhelming when students try to make interpretations of graphical representations. This is obviously the case of Arman, Alexander and Gideon. We have shown you the results of two groups here, results that may be seen as the two extremes in our collection of results.

When students relate to iconic interpretations as cable cars in San Francisco, they do this because such interpretations have some advantages. They are easy to remember, seemingly realistic, easy to identify in a daily life language, easy to compare, and sounds convincing.

Our results indicate that the more a student build on iconic ideas as model for explanation, the more demand he or she will also need for daily life concepts in the arguments.

It is important for us to underline that we do not see the results as misconception, more as misplaced concepts. When Arman, Alexander and Gideon and probably many other students with similar iconic interpretations, are trying to explain the distance – time graph, they seem to relate the meaning to an event. This is important, since a distance – time graph should be seen and interpret as a representation of a sequential process. Event and sequential process are two close sub categories in Figure 2 (Chi, 2013). The fact that the students we studied are so called specialists in mathematics and science indicate that it is perhaps harder to make this restructuring than researcher have thought so far.

As researchers we might marvel over how much material that was derived from these students discussions regarding a situation with a train. But this article is also something teachers in general could read and discuss. The fact that humans in general may misinterpret some of all the graphic information we meet on a daily basis is nothing strange. How could we do otherwise? This article might help teachers to support student's learning and understanding of both mathematical entities and mathematical processes in a more successful way.

In the discussions between students regarding the train's movement we could identify occasions when students learned from each other. Even though this was a research study, it is beneficial when students learn from the organization of the study.

Differences in the situation model construction for a textbook problem: The broken tree or the broken bamboo?

José Antonio Juárez López[1], Josip Slisko Ignjatov[1], Lidia Aurora Hernández Rebollar[1] and Mónica Monroy Kuhn[2]

1 Benemérita Universidad Autónoma de Puebla, Puebla, México, jajul@fcfm.buap.mx, lhernan@fcfm.buap.mx, jslisko@fcfm.buap.mx

2 Universidad Popular Autónoma del Estado de Puebla, Puebla, México, monica.monroy@upaep.mx

The present study addresses the differences in the construction of ninth graders' situation models, when they were confronted with an application problem that is found in middle-school mathematics textbooks in Mexico. This study focuses on the reading-comprehension phase, better known as the situation model, which is considered a prerequisite for the mathematical model construction of word problems. Four versions of the problem "The broken tree by the wind" were given to a total of 192 ninth- grade students. Students' drawings were analyzed in order to identify any possible causes by which few of the students were able to build an adequate situation model. The results suggest a potential influence of problem wording on students' visualizations and ways of interpreting mathematical problems during the situation model construction.

Keywords: Situation model, word problems, mathematics textbook.

INTRODUCTION

Text comprehension in mathematical word problems has been investigated in order to improve problem-solving processes (Cummins, Kintsch, Reusser, & Weimer, 1988; Mayer & Heagarty, 1996). Researchers have been trying for some time to get an insight into the causes that affect such performance in order to improve it (Kintsch & Greeno, 1985). Students' difficulties increase when problems imply a mathematical modelling process (Galbraith & Stillman, 2006).

It is already well established, both theoretically and experimentally, that the modelling process comprises several phases (Borromeo-Ferri, 2006). The first one consists of the situation model (SM) construction that the problem refers to, and it is necessary for the understanding of the mathematical problemand its further resolution, which is considered as "...a mental representation of the situation described by the text..." (Kintsch, 1986, p. 88).

Some results in a recent exploratory investigation (Juárez & Slisko, 2013) show that middle-school students have great difficulties to build the situation model of a problem named "The fallen tree". The mental images or models of the situation were studied through the requested drawings. The statement of the problem is the following:

> The wind has broken a tree trunk in such a way that two of its parts form a right triangle with the ground. The upper part forms a 35° angle with the ground, and the distance, measured on the floor, from the trunk to the fallen top of the tree is 5m. Find the height of the tree (Mancera, 2008, p. 333).

Juárez and Slisko (2013) found that after thirty middle-school students had been given "The broken tree" problem, only ten of them were able to depict the actual situation described in the text. However, these ten students interpreted it in different ways.

This problem and its various formulations appear in several middle-school textbooks published in Mexico authorized by the Ministry of Education. In some of them, it is just an application problem (Briseño, Carrasco, Martínez, Palmas, Struck, & Verdugo, 2007, p. 223; Waldegg, Villaseñor, García, & Montes, 2008,

p. 205; Farfán, Cantoral, Montiel, Lezama, Cabañas, Castañeda, Martínez, & Ferrari, 2008, p. 202). In certain books, its historical origin is mentioned (Pérez & Pérez, 2008, pp. 227–228; Arteaga & Sánchez, 2008, p. 75; Sánchez, 2008, p. 216).

The results mentioned above motivated us to conduct a more comprehensive study, where the factors and processes involved in the situation model construction as a prior step leading to a resolution of the problem could be investigated. In particular, we were interested in analyzing the possible effects of changing certain elements from the text of the problem, i.e. the title and the object of the problem, on students' text-comprehension process and their corresponding situation models.

Results of previous studies based on students' drawings have shown that students find it difficult to imagine the situation. What makes it hard for most of them, is the mental image of a "tree" (the trunk's thickness and the treetop formed by branches and leaves), because it is hard for them to "get rid" of the treetop. This study central assumption is that if students get a version of the problem, where the tree is changed for a simpler "tree" plant, like a "bamboo" (it has a straight shape and it does not have any branches that hamper the floor support), they will perform better in the development of the situation model than the students who get "the broken tree" version.

So, our research question is the following: Do changes in the problem's title, as well as in the object used in the text have an effect on middle-grade students' situation model construction?

THE CONSTRUCTION OF THE SITUATION MODEL AND MATHEMATICAL WORD PROBLEM SOLVING

Polya's model for problem solving has played a significant role in Mathematics Education since it has clarified many of the cognitive processes involved in it (Polya, 1976). In the first stage, the understanding of the problem, strategies can be found that help with the representation of the situation and the comprehension of the problem's conditions. The importance of using some heuristics is also emphasized here, like 'draw a picture or a diagram'.

Nathan, Kintsch and Young (1992) propose a theoretical model, where students have to read and understand the statement first, and then the information obtained is "organized into a (qualitative) situation model and mapped into a (quantitative) problem model that captures the algebraic structure" (p. 332).

According to Diezmann (2000), to make a drawing of the problem situation may be crucial for a person trying to solve it. In this way, many word problems describing a real situation are presented to the student as if its mental representation was an immediate process. However, it is a translation process that involves linguistic information decoding and visual information encoding. In this sense, Heagarty and Kozhevnikov (1999) investigated the relationship between mathematical visualization and mathematical problem-solving, being the first one understood as an individual's ability to use images or diagrams. They classified visual-spatial representations as schematic or pictorial and, in their study, schematic representations, which encode spatial relations described in the problem, were positively correlated with success in mathematical problem solving. On the other hand, pictorial representations, which are related to the visual appearance of the objects described in the problem, were negatively correlated.

In the same line, Edens and Potter (2007) examined the relationship between student performance on particular drawing tasks and their achievement in mathematical problem solving. They provided evidence that teaching strategies based on drawings can help teachers in obtaining useful information about their students' level of spatial understanding.

From a cognitive perspective, several studies have focused on the complex process of reading comprehension during word problem-solving, both in algebra and realistic problems, as well as in arithmetic problems (Vicente & Orrantia, 2007). These researchers acknowledge the need to create a model of the problem situation, by applying the real-world knowledge possessed by the student. Meanwhile, Reusser (1988) suggests that it is necessary to produce what he calls an "episodic model of the situation" between the text base and the problem's mathematical model.

One of the consequences that the lack of an appropriate situation model construction would have, for example, is the student's behavior strongly linked to practices, as mentioned by Reusser and Stebler (1997):

> As a result of schooling, students' behavior is pragmatically functional if they take into account any information they can draw from both problem texts and contexts. That is, their mathematical sense-making is functional if they actively and continuously construct a mental representation not only of the specific task (problem model…), but also of the socio-contextual situation which they are in (construction of a social context model)… (pp. 325–326).

Despite the amount of research indicating the importance of the situation model for understanding the text of the problem, some researchers such as Voyer (2010) argue that the question of the influence of the model constructionon student performance in solving word problems remains open. This conclusion might be correct for some arithmetical problems used in Voyer's research. Nevertheless, it seems that in trigonometric problems, the situation model construction influences significantly posterior students' problem-solving performance. It is easy to agree with van Dijk and Kintsch (1983), who emphasize that "… we know very little about the conditions that promote or inhibit the construction of situation models from texts …" (p. 346).

METHODOLOGY

The participants were 192 students in 9th grade at a public middle school in central Mexico, all divided into four different groups. In terms of the curriculum, the ninth graders had already been exposed to the Pythagoras Theorem and trigonometric ratios.

Each student was given a worksheet containing one of the four versions of "the broken tree" problem and they were asked, after reading the text of the problem, to draw the described situation. There was no time limit, and they were not asked to solve the problem.

Each version of the problem was applied to a different group. Two central objects were used, i.e. the tree and the bamboo, resulting in two distinct texts. In addition, two titles for each one of them were drafted, yielding four versions of the problem that are shown in Table 1.

The data collected for this study included only students' drawings, since the focus of the study was on the situation models built by the students. In order to describe them, the collected drawings were categorized via our definition of situation model mentioned above. Students' responses were grouped by identifying those drawings that had common characteristics in their situation models, in the sense that they were leading to the mathematical model construction.

RESULTS AND ANALYSIS

From the analysis of the drawings, four categories were obtained: Situation Model with a Right Triangle (SM-RT), Situation Model with an Arbitrary Triangle Related to the Situation (SM-AT-RS), Situation Model with an Arbitrary Triangle Not Related to the Situation (SM-AT-NRS) and Situation Model Without Triangle (SM-WT).

	Version 1	Version 2	Version 3	Version 4
Problem's title	The broken tree that forms a triangle	The broken tree	The broken bamboo that forms a triangle	The broken bamboo
Problem's statement	The wind has broken a tree in such a way that two of its parts form a right triangle with the ground. The upper part forms a 35° angle with the ground, and the distance, measured on the floor, from the trunk to the fallen top of the tree is 5m. Find the height of the tree.		The wind has broken a bamboo in such a way that two of its parts form a right triangle with the ground. The upper part forms a 35° angle with the ground, and the distance, measured on the floor, from the bamboo's base to the fallen top is 5m. Find the height of the bamboo.	

Table 1: Four different versions of the "the fallen tree" problem

Different SM for the version "The broken tree"			
SM-RT	SM-AT-RS	SM-AT-NRS	SM-WT
29.5% 13/44	29.5% 13/44	9% 4/44	32% 14/44

Table 2: SM classification for the first version of the problem

Version 1: The broken tree

The number of students that constructed a particular type of SM for the first version of the problem "The broken tree" is shown in Table 2.

The above table shows that almost 30 percent of the students produced the SM considering a right triangle, but only one of them drew up the situation model correctly. This finding is consistent with what Diezmann (2000) reported with primary school children, that although 'drawing a diagram' is advocated as a useful strategy for solving problems, to generate an appropriate diagram is problematic for many students.

On the other hand, the same number of students built their SM with an arbitrary triangle related to the situation described in the problem. Figure 1 shows the SM of one of these students, Victor, where its construction could have been affected by the interference of his real-life knowledge evoked while imagining the situation.

Version 2: The broken tree that forms a triangle

The number of students that constructed a particular type of SM for the second version of the problem "The broken tree that forms a triangle" is shown in Table 3.

In most of the situation models, a high number of realistic elements related to the scenario were included, such as wind, tree branches, and leaves, as well as clouds and rain. When compared to the first version of the problem, the same percentage of students did not include any triangle in their situation models, even though the expression "...that forms a triangle" was present in the title of the second activity. It seems not to have influenced the understanding of the situation or the corresponding situation model. These results suggest that the change in the problem's title had no effect on the construction of the SM.

However, the percentage of students that included an arbitrary triangle not related to the situation increased when compared to the first version. Figure 2 shows a situation model, for example, where Daniel drew an arbitrary triangle that has nothing to do with the situation described in the text. It seems that the explicit reference to a triangle in the activity's title forced the students to draw a triangle, without taking into account the rest of the information included in the text.

This behavior can be explained according to what Borromeo-Ferri (2006) claims:

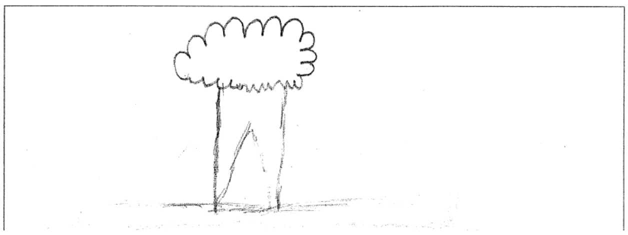

Figure 1: SM drawn by Victor (arbitrary triangle related to the situation)

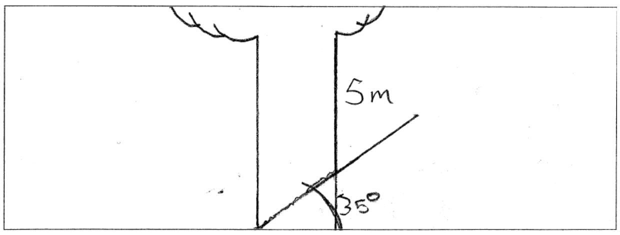

Figure 2: SM drawn by Daniel (arbitrary triangle not related to the situation)

Different SM for the version: "The broken tree that forms a triangle"			
SM-RT	SM-AT-RS	SM-AT-NRS	SM-WT
20% (10/50)	32% (16/50)	18% (9/50)	30% (15/50)

Table 3: SM classification for the second version of the problem

> The individual has a mental representation of the situation, which is given in the problem. This MRS can be very different, for example depending on the mathematical thinking style of the individual: visual imaginations in connection with strong associations to own experiences; or the focus lies more in the numbers and facts given in the problem, which the individual wants to combine or relate. (p. 92)

Version 3: The broken bamboo

The "broken bamboo" version was given to 48 students. Table 4 shows the percentages for each SM. Only 12 of them (25%) included a right triangle in their model. In the second column it can be observed that 40% of the students constructed a SM with an arbitrary triangle related to the situation. This could mean that, changing the tree for the bamboo could have been the cause for more students to include a triangle in their situation model. In Figure 3 one example of this type of situation model is shown.

Version 4: The broken bamboo that forms a triangle

For the problem's version "The broken bamboo that forms a triangle", 26 students out of the 50 (52%) that were given this version of the problem, were able to draw the right triangle required in the statement. This percentage is significantly higher when compared with versions 1, 2 and 3, thus confirming our hypothesis about the positive effect of including the "bamboo" instead of the "tree" in the statement of theproblemand "...that forms a triangle" in the title. Figure 4 shows an example of such drawings. Also, 26% of the students included an arbitrary triangle related to the situation in their SM.

The number and percentage of students' types of situation models for the problem's version "The broken bamboo that forms a triangle" is shown in Table 5.

FINAL COMMENTS

After analyzing the drawings made by students when confronted with a mathematical word problem, we note that the construct 'situation model' as conceptualized in the literature, was effective to account for the various productions and elements that hamper reading comprehension, and therefore the construction of mental representations corresponding to the situation described in the problem.

One of the first interesting findings in this study is the fact that a very low percentage of students created the situation model so as to enable them to solve

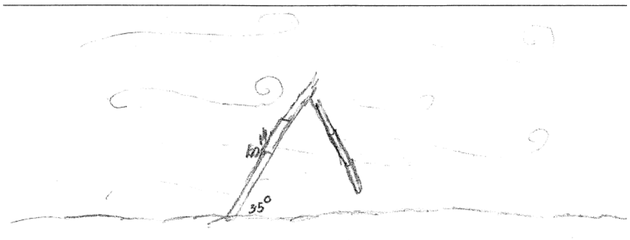

Figure 3: SM drawn by Monica (arbitrary triangle related to the situation)

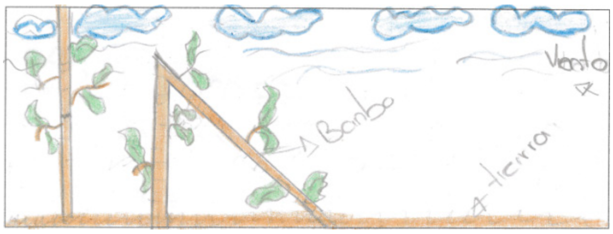

Figure 4: SM drawn by Giselle (right triangle)

Different SM for the version "The broken bamboo"			
SM-RT	SM-AT-RS	SM-AT-NRS	SM-WT
25% 12/48	39.6% 19/48	4.2% 2/48	31.2% 15/48

Table 4: SM classification for the third version of the problem

Different SM for the version "The broken bamboo that forms a triangle"			
SM-RT	SM-AT-RS	SM-AT-NRS	SM-WT
52% 26/50	26% 13/50	8% 4/50	14% 7/50

Table 5: SM classification for the fourth version of the problem

the problem in any of the four versions presented to them. This shows, once again, the importance of the proper construction of the situation model as part of the text comprehension process and as a step towards the development of the mathematical model.

Students' productions in this study included a variety of triangles, and although they do not represent the real situation, we realized that in the problem's version "The broken bamboo that forms a triangle", it was more natural and easier for them to imagine a situation where a triangle is formed than in "The broken tree that forms a triangle" version. One possible explanation is that for students it is more likely to imagine how the wind can break the vertical and thin bamboo structure than the one of the tree, possibly because in the latter case it might be thought that its root is stronger and its trunk is thicker, and therefore more difficult to bend.

It has been observed that in many mathematics textbooks, the text comprehension phase in word problems is presented as if the coherent situation model construction was a trivial process. This phenomenon could be one of the reasons students do not distinguish and are not able to sense its main characteristics. We believe that the findings of this study can be used to conduct further research to help clarify the entire understanding process and to serve as a reference in textbooks design and development, specifically related to word-problem solving.

Mathematical models for chemistry and biochemistry service courses

Victor Martinez-Luaces

University of the Republic of Uruguay, I.I.Q.-Fing., Montevideo, Uruguay, victorml@fing.edu.uy

In this paper, applications and modelling problems for chemistry and or biochemistry courses are analysed. They obtain better results than others, in order to motivate students of chemical careers towards mathematical problem solving, since these problems are specially tailored for their needs. A teaching experience, carried out during two decades is analysed and a particular example is exposed with further details. The results of this experience led us to several conclusions that are included in the last section of the article.

Keywords: Nonlinear models, chemical careers, students' motivation.

INTRODUCTION

In chemical careers mathematical courses like numerical methods, differential equations and statistics are widely used to solve problems concerned with modelling real problems relevant for chemistry and/or biochemistry.

Nevertheless, most mathematical texts include only physical problems more relevant for other disciplines, like mechanics or electromagnetism. The need for relevance was highlighted by many writers as being important in motivating students when learning mathematics. For example, Bajpai, Mustoe and Walker (1975) suggested a range of improvements including a modelling approach and providing more relevant examples. In the same direction, according to McAlevey and Sullivan (2001), there is a need for using real-life problems since 'Students are best motivated by exposure to real applications, problems, cases and projects'.

For this reason, several previous articles (Martinez-Luaces, 2003, 2006, 2009a) have focused on how modelling may be used to motivate students in those careers. In particular, ordinary differential equations (O.D.E.) linear systems appear regularly in Chemical Engineering, Food Technology Engineering and Environmental Engineering courses. This is due to the usefulness in modelling chemical kinetics (Martinez-Luaces, 2012a), or water solutions, mixtures and reactors problems (Martinez-Luaces, 2005).

The introduction of chemical and/or biochemical problems help to motivate students and can be widely used for modelling and applications examples, particularly in differential equations (Martinez-Luaces, 2006), probability and statistics (Martinez-Luaces, Velazquez, & Dee, 2009) and numerical methods (Guineo Cobs & Martinez-Luaces, 2003).

In previous papers and in a pair of books (Martinez-Luaces, 2009b, 2012b), problems involving chemical kinetics, mixing problems, reactors, etc. have been exposed and analysed from its educative potential viewpoint. In this paper, more simple models will be considered and a concrete example will be discussed in the third section. Despite the simplicity of these models, they appear regularly in several branches of chemistry and biochemistry; they allow teachers to pose interesting questions and even project work to be carried out by the students in small groups.

Conclusions based on the results of the teaching methods used, will be drawn for differential equations, statistics and numerical methods courses for chemical careers. Several of these conclusions can be easily extrapolated to other mathematical service courses.

A PARTICULAR EXPERIENCE IN URUGUAY

In the late 90's, a small group of teachers and researchers was formed in the Chemistry Faculty at the University of the Republic of Uruguay (UdelaR), having their members an applied profile. For several years, this team included chemists, engineers and applied mathematicians. This group – in addition to other tasks as mathematical and engineering consultants – was appointed to be in charge of a course called Mathematics III, created in 1996 especially for Food Engineering students. The original syllabus included Ordinary Differential Equations (ODE), Partial Differential Equations (PDE) and an introduction to Laplace Transform, with emphasis towards applications and other disciplines. After the change of plans in year 2000, this course was replaced by another two – Mathematics 005 for Food Technology Engineering and Mathematics 105 for Chemical Engineering – with more class hours per week and a greater presence of modelling activities and applications.

Since the beginning of this course, direct and inverse modelling problems were proposed to the students (Martinez-Luaces, 2009a). Three thematic areas were especially suitable for this purpose: Chemical Kinetics (Martinez-Luaces, 2012a), mixing problems (Martinez-Luaces, 2009b) and Mass Transfer (Martinez-Luaces, 2003).

Chemical Kinetics is an important source for interesting problems. In our research work, the most refined versions of those problems were published in books, papers and proceedings, such as: Guineo Cobs and Martinez-Luaces (2002), Martinez-Luaces (2005, 2009b, 2012a, 2012b). Examples of these problems are: mutarotation of glucose, mechanisms with two or three reactions in series, carbon dioxide adsorption on platinum surfaces, etc.

Mixing problems have been another important source for modelling problems, such as: interconnected tanks system, tank divided into several compartments, stirred tank with recirculation, etc. These problems and many others have been included in papers published in international journals (Martinez-Luaces, 2005, 2009a), in books (Martinez-Luaces, 2009b, 2012b) and conference proceedings (Martinez-Luaces & Alfonso, 2000; Martinez-Luaces, 2007).

Finally, with regard to the problems involving parabolic PDE applied to Mass Transfer real situations, there are many examples that can be mentioned. For instance: drying a vegetable through its faces, sugar diffusion in a cherry, chives drying process, dissolved oxygen electrode, packed bed chemical reactor, diffusion of pollutants in the Chernobyl accident and pollution in the Rio Uruguay. These problems were presented briefly – with its analytical and/or numerical solution discussed – in an article published in New Zealand Journal of Mathematics (Martinez-Luaces, 2003), but there are also full versions of the modelling process with further details of the resolution in a book published a few years later (Martinez-Luaces, 2009b). Partial preliminary versions of those problems were presented in mathematical education conferences like Martinez-Luaces and colleagues (2000, 2001), Guineo Cobs and Martinez-Luaces (2003) and Martinez-Luaces and Guineo Cobs (2005), among others.

A NONLINEAR MODEL USEFUL FOR CHEMICAL CAREERS

The nonlinear mathematical formula $y = \frac{ax}{x+b}$ (Eq. 1) is widely used in chemistry and biochemistry for different purposes. For instance, the Michaelis-Menten kinetics is a well-known model in biochemistry of the form $v_0 = \frac{v_{\max}[S]}{K_m + [S]}$ (Eq. 2) where v_0 and $v_{\max}$ are the initial and the maximum velocity of the enzymatic reaction, $[S]$ is the substrate concentration and K_m is a constant (called Michaelis constant), which depends on the enzymatic reaction considered (Nelson & Cox, 2008).

Irving Langmuir, a Nobel Prize winner in chemistry, developed an equation that relates the coverage or adsorption of molecules on a solid surface to gas pressure or concentration of a medium above the solid surface at fixed temperature (Masel, 1996). The equation is $\Theta = \frac{\alpha P}{1 + \alpha P}$ (Eq. 3) where Θ is the fractional coverage of the surface, P is the gas pressure (or concentration in the case of liquids) and α is a constant. A very simple algebraic manipulation gives $\Theta = \frac{P}{1/\alpha + P}$ (Eq. 4) which is just a particular case of (Eq. 1).

The last example is a mathematical model for the growth of microorganisms proposed by Jacques Monod (1949). The mathematical formula is $\mu = \frac{\mu_{\max} S}{K_S + S}$ (Eq. 5), where μ is the specific growth rate of microorganisms and $\mu_{\max}$ represents its maximum value, S is the concentration of limiting substrate for growth and K_S is called the "half-velocity constant" (Martinez-Luaces, 2009b), since it corresponds to the value of S when $\frac{\mu}{\mu_{\max}} = \frac{1}{2}$ as well as the constant K_m in (Eq. 2).

The Monod equation has the same form as the Michaelis-Menten equation, but it was developed empirically whereas the Michaelis-Menten model is based on theoretical considerations.

A typical problem that arises in the treatment of data corresponding to these equations is the parameters determination since all of them are nonlinear models. In order to solve this problem, several methods were proposed to linearize these equations, being Lineweaver-Burk, Hanes-Woolf, Eadie-Hofstee, Scatchard, and Eisenthal-Cornish-Bowden the most important ones (Nelson & Cox, 2008).

For instance, the Lineaweaver-Burk (or double reciprocal plot method), proposes a graphical representation of $\frac{1}{V_0}$ vs $\frac{1}{S}$. It is easy to observe that the reciprocal of (Eq. 2) gives $\frac{1}{V_0} = \frac{K_M}{V_M}\frac{1}{S} + \frac{1}{V_M}$ (Eq. 6), so the x−intercept of the graph represents $-\frac{1}{K_M}$ and the y−intercept is equivalent to the inverse of V_M. An alternative way is to obtain the coefficients of a linear regression (i.e. $\frac{K_M}{V_M}$ and $\frac{1}{V_M}$) and finally get K_M and V_M from these coefficients.

Other methods propose a different linearization or another mathematical procedure for recovering K_M and V_M from experimental data.

All these methods can be compared in terms of exactitude and precision (Martinez-Luaces & Silva, 2014), using simulated data perturbed with Gaussian noise with different amplitudes. This comparison is particularly significant when the relation between trend and noise tends to increase.

Since equations (2), (3) and (4) represent the same mathematical model (Eq. 1), one of them (the Michaelis-Menten equation) may be chosen as an example in order to show the methodology to be followed.

In the selected equation, the parameters are K_M and V_{max} and variables are [S] and v_0. In a previous paper (Op. cit., 2014), typical values of these parameters and variables were chosen and theoretical curves were obtained. A Gaussian noise with different amplitudes was superimposed to the theoretical data obtained from (Eq. 2) with typical values of V_M, K_M and [S].

The graphics in Figure 1 show the simulated curves for the Michaelis-Menten equation (initial velocity vs substrate concentration) with the Gaussian noise multiplied by coefficients 1, 2, and 3, respectively.

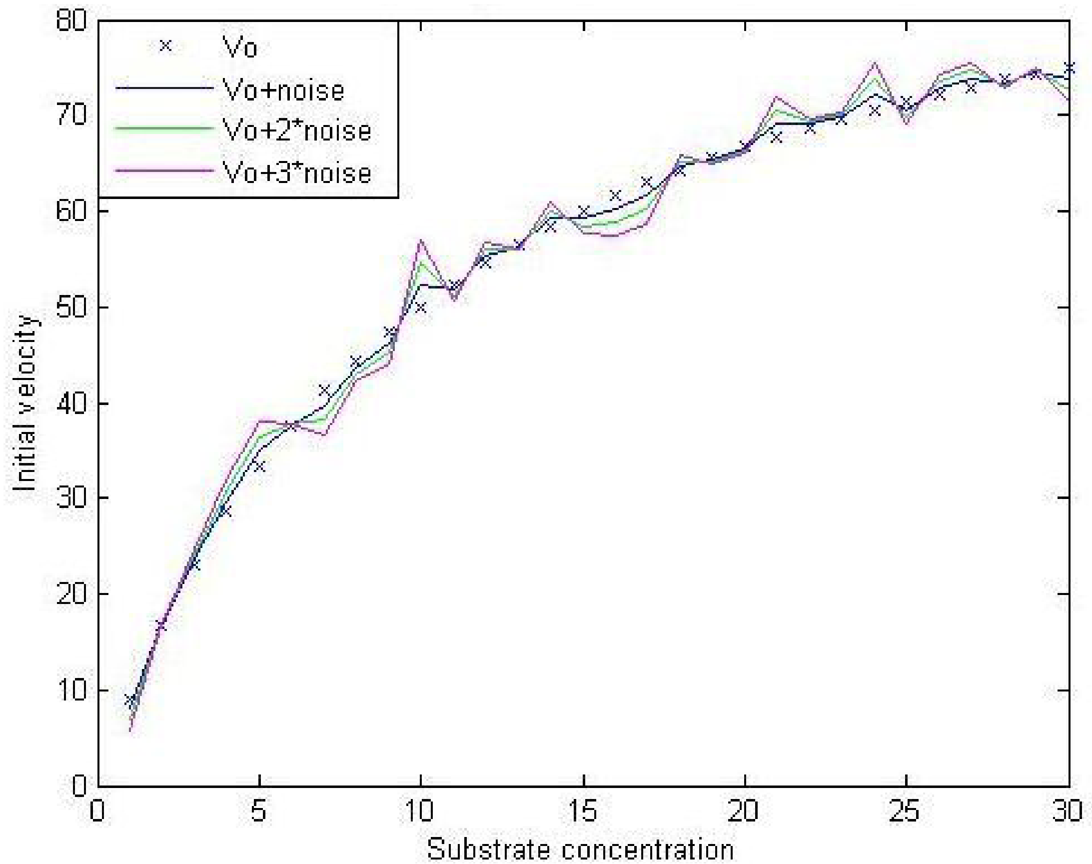

Figure 1: Simulated data for the Michaelis-Menten equation

Noise	Min. abs. error Km	Min. abs. error Vm	Min. rel. error Km	Min. rel. error Vm	Min. abs. Error Method Km	Min. abs. Error Method Vm	Min. rel. Error Method Km	Min. rel. Error Method Vm
Amplitud Noise 1	0,0167	0,3243	0,0017	0,0032	CBE	CBE	CBE	CBE
Amplitud Noise 2	0,0883	0,2823	0,0088	0,0028	H	CBE	H	CBE
Amplitud Noise 3	0,3941	1,4027	0,0394	0,0140	CBE	CBE	CBE	CBE

Table 1: Comparison of the results for the different methods

These simulated data took the place of the real experimental data and were used to determine the parameters K_M and V_M, which real values were known, so the different methods were easily compared in terms of exactitude and precision. Table 1 shows the minimum absolute and relative errors in K_M and V_M and which methodology was the best in each case, depending on the noise amplitude.

The method due to Eisenthal and Cornish-Bowden (CBE in Table 1) was the best one in all the cases, except when the Gaussian noise had double amplitude and K_M is the considered parameter. In this last case, Eadie and Hofstee's method (H in Table 1) obtained the minimum absolute and relative error in the parameter K_M, but not in V_M where once again Eisenthal and Cornish-Bowden gave the best estimate.

A similar methodology was followed in another article devoted to Electrochemical Noise studies (M. Martinez-Luaces, V. Martinez-Luaces, & Ohanian, 2006).

RESULTS

Modelling was introduced in UdelaR Statistics and Differential Equations courses for Chemical Engineering and related careers in 1996. Since then, modelling and application problems regularly appeared in final examinations and other forms of assessment. A similar situation took place in other subjects like Design of Experiments and Numerical Methods, as it was analysed in previous papers (Martinez-Luaces, 2005, 2009a; Martinez-Luaces et al., 2009).

Throughout this teaching experience, as it was already remarked, modelling problems and applications were not just discussed in class, but they also played an important role in the assessment. This is a very important issue, for example Smith and Wood said that "...appropriate assessment methods are of major importance in encouraging students to adopt successful approaches to their learning. Changing teaching without due attention to assessment is not sufficient" (Smith & Wood, 2000).

In this experience with students of Chemical Engineering and Food Technology Engineering, several surveys of student opinions were conducted through anonymous questionnaires. The transcribed below are some of the students´ responses to those semi-open questionnaires; they reflect a very positive attitude towards the courses themselves and the problems proposed during those courses:

> Now I find that mathematics can be useful.

> A really super course, I got a great deal out of it.

> An interesting course, with quite a lot of applications in real life.

Specifically, about tasks related to modelling and applications, they had this to say:

> If these topics were omitted, the course would just be another standard maths course, a 'hard' subject filled only with methods, calculations and numbers.

Once the new study plan was started, the course known as Mathematics III was replaced with Mathematics 005 and 105. After these changes, the students were again consulted by means of semi-open questionnaires. These are some of their views:

> Very directly applicable to my undergraduate professional career; it renewed a taste for mathematics and it was well taught, guiding the solutions to the exercises and not working them all out.

> I thought the course was very useful and dynamic, and I think it will have very useful applications in coming years.

As for the modelling, applications, and the problems set, these were some of their comments:

> The problems were motivational because you can see the usefulness of mathematics in daily life, and they clearly show the interaction that exists with other subjects.

> I have taken courses in which the applications dealt with here were relevant.

> Very useful examples for future years of undergraduate study.

As can be seen, the students reacted very positively not only to the course they were taught (before and after the initiation of a new study plan), but also in particular, within the course, they appreciated everything to do with the problems, involving modelling and applications.

The statistical results of these surveys – published in Martinez-Luaces (2009a) – confirm those views corresponding to several selected opinions.

CONCLUSIONS

The main goals of the activities described in the previous sections are both technical and educative. From the technical viewpoint the results obtained with simulated data showed that the method most widely used (Lineweaver-Burk) it is not the most accurate and this fact constitutes a surprising result for the majority of the students. From the mathematical education viewpoint students' positive reactions can be explained in terms of the following characteristics of the studied problems:

a) relevance
b) applicability
c) specificity
d) authenticity
e) low pre-requisites

The need for relevance was specially remarked in the discussion at CERME9, TWG06. The example considered above is especially relevant for students of several careers such as Chemistry, Biochemistry, Chemical Engineering, Food Technology Engineering and Environmental Engineering. The problem relevance – at least in this case – is linked with the problem applicability and its specificity. The results showed that students usually react more positively to these problems than to other application problems which are not so specific (like problems about circuits or mechanics, etc.).

Other issue that was widely discussed in the TWG06 was the need of authenticity for the modelling activities. In this case not only the models are real models, even more, the methods for recovering parameters are the "real ones", in the sense that these are the methods that the students will use in other subjects like Biochemistry, Microbiology and Physical Chemistry.

Last but not least, pre-requisites are an important constraint when choosing modelling and application activities. The problem described above and the corresponding linearization methods have very low pre-requisites and they only need some algebraic manipulations to be understood. For the proposed activities (i.e., the data simulation and the recovery of the parameters) the students only need a previous course in Probability and Statistics and some basic skills when using MATLAB® or any other software.

It is important to remark that very simple mathematical models, like the one discussed above, are excellent sources for this kind of problems. Moreover, there exists an important set of real-life problems from these areas, which remain almost unexplored from the point of view of their mathematical education richness.

Searching for new real-life problems to be used for project-work in chemical and biochemical careers represents an interesting challenge for mathematical education researchers. At the same time, it provides a good opportunity for an interdisciplinary work with teachers and researchers from other disciplines with the resulting benefits.

School mathematical modelling: Developing mathematics or developing modelling?

Chris Olley

King's College London, London, UK, chris.olley@kcl.ac.uk

In this paper, I will examine mathematical modelling as a pedagogic activity. I will contrast this activity with mathematical modelling in other professional settings and with mathematics in a school and professional setting. Mathematical modelling is commonly drawn on in the literature as a resource for supporting the learning of mathematics in schools, often as a motivating or contextualising mechanism. I will argue, however, that the activity of modelling is mythologised in these instances, since the recognition rules for the practice of modelling per se are frequently not deployed. Instead, I will argue, illustrated by a school activity, that school mathematical modelling may be distinguished from its professional counterpart as a distinct pedagogic activity.

Keywords: Modelling, school, activity.

MATHEMATICAL MODELLING: WHAT IT IS AND IS NOT

Mathematical modelling is a tool used by engineers, financiers, in medicine and so on. From a brief review of papers describing mathematical models (e.g., Mendoza-Arriaga, Carr, & Linetsky, 2010; Gunzelmann, Gross, Gluck, & Dinges, 2009; Stolz, 2002), it is clear that when modelling is deployed to engage with issues where the issue itself is the purpose of the deployment, the level of complexity is far beyond the scope of a school course in mathematics. In each case an issue is raised in a setting which is not itself mathematical, for example; sleep deprivation and performance (Gunzelmann et al., 2009), regrowth of tissue cells (Whittaker et al., 2009), equity derivatives and pricing derivatives (Mendoza-Arriaga et al., 2010). A mathematical model is created in which key indicators are specified and measures constructed to generate the variables in the model. A mathematical structure is then presented which generates an interrelationship between the measures similar to that which exists with the indicators. This structure is the model itself. The model is validated by measuring the extent to which the output it produces is sufficiently accurate for the specification of the issue. The cyclical nature of the modelling process in which a model is suggested, critiqued and refined is a central feature which will necessarily have been a key component of the work in reaching the stage of publication, although in the examples cited, this is not made explicit in the final work.

Blum, Galbraith, Henn and Niss (2007) provide a comprehensive overview to the modelling process, viewed from the perspective of educational practices:

> The modelling perspective begins with the conceptualisation of some problem situation … Through a process of mathematization, the relevant objects, data, relations, conditions and assumptions from the extra-mathematical domain are then translated into mathematics … mathematical methods are used to derive mathematical results … [which] must then be translated back into the extra-mathematical domain …The problem solver then validates the model … the model is evaluated … when one of these 'tests' is deemed unsatisfactory, the whole process needs to be repeated …(Blum et al., 2007, p. 9).

In modelling there is little interest in a specific solution, but instead a solution which is good enough. This aspect is particularly alien to school mathematics. In the educational setting mathematical modelling is presented in different ways. Most commonly it is represented by the contexts that authors of school materials use for their examples and exercises. Burke (2013) presents examples from leading English school teaching text books. In a text designed for middle achieving students, the path of a rugby ball being kicked over the posts is to be matched against graphs of its speed against time. Firstly, this is an example of what Paul Dowling (1998) refers to as the myth of reference. Clearly, the kicker cannot be credibly perceived as constructing the graph as a purposeful aid to the kick and moreover none of the graphs given is a particularly reasonable representation of the change of speed and time of the ball. As Burke suggests; "the activity is reading a graph and the apparent non-mathematical context is a way in, a 'selling' point, for the problem" Burke (2013). This is not an example of mathematical modelling, in that it does not present any of the features of the modelling process suggested above. The problem is posed such that validation would need to reside with the rugby player, whereas the solution can only be validated as school mathematics. Nonetheless, it has the appearance of an example of modelling with a 'real-world' problem solving context with a mathematical model, yet is of a very common type in school text books. The learner is apprenticed into an apparent version of mathematical modelling which does not contain its essential features.

Sometimes the credibility of the problem leads mathematics educators to validate solutions without reference to the setting being used. Galbraith (2011) reports a question from the PISA project which provides a multiple choice set of answers to the question of how many fans could stand in a field at a concert 100m by 50m. The correct answer is given as C. 20,000. However, there is also an answer B. 5,000 which must be taken as incorrect. Galbraith says; "This sample item involves spatial insight, as students need to decide on a suitable model to quantify the amount of space occupied by a human, then perform an appropriate calculation to estimate how many people would fit into a given space. Only about 26% of the multinational sample of students answered the item correctly (C), illustrative of the depressed performance associated with contextualised problems" Galbraith (2011, p. 9). The field is 5000 square metres and the correct answer suggests that 4 people per square metre could reasonably fit. Naturally, this would need to be an average, since it would be hard to conceive of every square metre being completely full especially around the edges, hence some of the square metres would need to fit rather more than 4 people. The UK Health and Safety Executive publishes it's Purple Guide (HSE, 1999, p. 17) which says; "Generally, 0.5 m^2 of available floor space per person is used for outdoor music events." Here, the mathematics educator engages with a particular mathematisation of a problem from a given (non-mathematical) practice, which at least is open to critique within that practice, but nonetheless is taken as the 'correct' model, where, at least in the UK, a different answer would be more correct. One significant feature of mathematical modelling is that the model is critiqued by the owners of the problem who will be expert in their field, and not the owners of the mathematics.

MODELLING IN SCHOOL MATHEMATICS; MODELLING TASKS OR MATHEMATICS TASKS?

Dowling (2009; 2013) suggests a structuring of the domains of pedagogic action. This contrasts the esoteric domain of a practice with its public domain in terms of the strength of institutionalisation found in the expression and content of the text (Dowling, 2007). He represents this schematically:

	Content	
Expression	I+	I-
I+	*Esoteric domain*	*Descriptive domain*
I-	*Expressive domain*	*Public domain*

Figure 1: Domains of Action (after Dowling, 2009)

I have presented a characterisation of the esoteric domain of mathematical modelling with strongly institutionalised expression and content (the modelling cycle, the indicator/measure relationship, validation, etc.). This constructs a public domain of mathematical modelling characterised by low levels of institutionalised expression and content. Here, problems are solved by the deployment of mathematics without reference to the modelling process. So, rugby players can improve their kicking without a critical engagement with the relationship between the indicators and measures or indeed any requirement for validation of the outcomes.

Realistic Mathematics Education is a theoretical and curriculum development strand in mathematics education in which the term model is used in a mathematical context. It is presented here as a rich example within mathematics education where the idea of mathematical modelling is presented as an important feature. Gravemeijer (1999) gives a description of the central methodology thus; "what is aimed for is a process of gradual growth in which formal mathematics comes to the fore as a natural extension of the student's experiential reality" (Gravemeijer, 1999, p. 156). This is seen as a modelling activity, in which students construct increasingly formal (esoteric domain) mathematical statements developed from their public domain discourse in mathematical settings. The modelling process starts from the practical setting; "... RME models are not derived from the intended mathematics. These models are seen as student generated ways of organising their mathematically grounded activity" (Gravemeijer, Bowers, & Stephan, 2003, p. 53). It is apparent that the purpose remains rooted within school mathematics practice. Issues of validation are entirely within mathematics practice and directed at an induction into the esoteric domain of mathematics. For example, describing a sequence of teaching for students on co-variance, the setting of T-cell counts in AIDS patients is used as the data. However, when the students' work is analysed, a series of issues are suggested as being the key development points for the next stage in this topic. All three of these are clearly framed in terms of esoteric domain mathematics: to better describe the shapes of the datasets, to structure the datasets in terms of patterns and multiplicative reasoning (Cobb, McClain, & Gravemeijer, 2003). Despite the potency of the data, there is no discussion of the engagement with it in the extra-mathematical setting. Again, this does not contain any of the esoteric domain of mathematical modelling and hence, can only be seen as a practice in school mathematics.

Cyril Julie (Julie, 2002) set a group of teachers a series of tasks rooted in issues of potential concern to them or their communities. Two contrasting examples were firstly, to find a model for pay scales in school, on the basis of equal pay for equal work. Secondly, a model of the accumulation of plastic shopping bags on school fences (a current environmental concern to that community). Julie notes that different teachers were more or less engaged with these tasks differentially according to the immediacy of the outcome to their professional position or political interest. It is clear here that where teachers engaged enthusiastically, the outcomes were potentially interesting models. The contrast I wish to make, is that the teachers were engaged in the practice of mathematical modelling. They used only the resources they already had, to engage with the central modelling issues of the construction of the model and the validation of the outcomes. Effectively, they looked for a formula which fitted well enough to appear workable. When prompted to improve their model they made minor changes to the formula rather than engage with what might count as an effective model.

SCHOOL MATHEMATICAL MODELLING AS A DISTINCT PRACTICE

I will describe as school mathematical modelling a practice where the explicit intention would be to apprentice learners into the esoteric domain of mathematical modelling. I have argued above that this includes a critical engagement with the relationship between problem and model, together with issues of the relationship between measure and indicator and issues of accuracy and validation.

In this sense, although Julie's teachers are engaging in a mathematical modelling practice, they are doing this in a 'common sense' way. So, there is no esoteric domain engagement in the practice of school mathematical modelling. That is not to say that the practice is neither valid, nor useful. It is clear that they have found models which they have found useful in their professional lives, beyond the pedagogic setting. Indeed the informal judgements of validity could be seen as esoteric domain practice in professional modelling, because here the realisation principle would include an effective solution, which there was. However, in school mathematical modelling practice, the esoteric domain would require an elaboration of the mechanisms for validation of the model, not just a statement of it. Here, the central modelling features would be engaged with directly, rather than being deployed as they would in mathematical modelling practices. For example, how the model is constructed, what counts as acceptable validation, how measures are constructed for the indicators.

For the teacher to be able to communicate the mathematics, they can constitute their conception as a 'map' of the practice (see Burke & Papadimitriou, 2002). This may be entirely implicit or as a teacher development strategy; explicit, external and structured in detail. Necessarily, the map will have elements which are personal and rooted in the subject and pedagogical knowledge of the teacher, nonetheless often with a closeness of fit to a presumed pre-existing definition of the practice.

This map can be constructed which structures school mathematical modelling as the cyclical creation of critique and refinement of a mathematical structure, finding good enough measures for the key indicators which generate outcomes, validated as sufficiently accurate with reference to the problem posed. The recontextualisation from originating practice to mathematical practice is the central phase, generally referred to as generating the 'model'. The validation of the acceptability of the model can only be tested ultimately by the project commissioner, who has expertise in the originating context. Hence, we construct a teaching narrative which will seek to make these issues explicit and engage overtly with the location and basis of judgements of validity. This is school mathematical modelling, a pedagogic practice, with the aim being to apprentice the modeller into the practice of modelling.

Gabriele Kaiser gives a detailed overview of the parameters proscribing the reported practice of mathematical modelling in a pedagogic setting (Kaiser, 2013). She suggests that the role of the teacher has been insufficiently researched. Indeed the centrality of the nature of the modelling process and of possible models themselves form the main part of the overview. Our aim here is to focus on the role of the teacher in creating and negotiating the apprenticing relationship, through explicit planning of school mathematical modelling practices. Presenting school mathematical modelling as distinct from school mathematics appears to be suggesting a *separation approach* (Kaiser, 2013, italics in original) where mathematical modelling is taught as a separate course. However, "The most advanced approach, the *interdisciplinary integrated approach*" would require each participant to generate their own map and narrative of the aspects of which they were the key expert; problem owner, mathematical modeller, mathematician. This potentially presents an opportunity for apprenticeship in the totality of the mathematical modelling, certainly a school mathematical modelling practice.

PIZZA DELIVERY: SCHOOL MATHEMATICAL MODELLING IN PRACTICE

I wish to contrast the preceding examples with an activity expressly designed to induct learners into the esoteric domain of mathematical modelling, hence operating in the esoteric domain of school mathematical modelling. Here, a project sets out a narrative based on a story problem about the delivery of pizzas. This is a pedagogic activity located in the practice of school mathematical modelling. It was originally developed for the Bowland Trust by Burke, Hodgen and Olley (Burke, Hodgen, & Olley, 2007). The activity is presented for a teacher audience in Olley (2011). The description is a compilation of experiences from two London schools; one selective and suburban, the other non-selective and inner city and from groups of mathematics and science teachers.

The initial phase of the narrative aims to imbue a sense of purpose. The problem is placed in the context of the owner of a new pizza outlet, who wishes to recruit a consultant to advise on the range of issues to consider in determining the profitability of the new enterprise. Mathematics educators are generally expert in neither running a pizza shop, nor business management, so it is important that their expertise is made clear. So, the activity begins with a public domain discourse on pizza shop management. This always throws up one central issue (amongst many others): you can reach more customers if you can keep your pizza hot for longer. The students have experience in pizza purchasing and hence are aware of the variety of packaging that pizza shops use to keep their delivery products fresh and the means by which they deliver them. Up to this point, there has been engagement in a marketing relationship. The educator has an activity to sell: mathematical modelling, and the marketing strategy is through the use of a compelling and apparently engaging setting. Pizza shop ownership has been mythologised; the educator has no means to credibly validate the outcomes in the practice of pizza shop ownership.

Measures for the key indicators need to be found. 'Sufficiently fresh' is indicated by a minimum topping temperature of 48°C (which was found initially with a 'taste' test in which a pizza cooled and was tasted until the taster considered it unacceptable). 'Reach more customers' is indicated by the time taken for the pizza to cool to 48° (given that we can find the average speed that the scooters delivering them travel at, and hence a circular route of that now calculable distance seems credible as a deliverable zone). The relationship between measure and indicator is a very important site for critique, although at this stage the first iteration of the modelling process progressed with these face value acceptable measures.

An experiment in which a pizza was heated, then allowed to cool, plotting its cooling against time, was then set up. The educator again must be clear to stress the limit of their expertise in issues of experimental design. Collaborating with the science department who can focus on this aspect would be better. The narrative then reached the point where participants needed to reflect on the rate of change. Hence, a data sheet was given out which asks participants to say what they thought the 'just cooked' temperature would be and give a reason. The experiment was then started and participants estimated the temperature after one minute, giving a reason. At the one minute point the temperature was announced and participants estimated for the end of the second minute and so on up to 10 minutes. As the experiment progressed, they were encouraged to refine their 'reason' and increasingly express it as a calculation, increasingly with more than one element. Finally, they were estimated the long term temperatures (30 mins, 2 hrs, 24 hrs).

As the pizza cooled, participants watched a graph of the cooling against time being generated by data logging apparatus connected to a temperature probe. Over the 10 minute period of the experiment, the cooling graph looked very linear indeed. Asked to describe the basis on which they estimated successive temperatures, a common response would be; "it's going down by roughly 2.4°C per minute". Some participants said that the rate of decrease was changing from around 2.6°C per minute to about 2.2°C per minute. Amongst groups of teachers discussion of first and second differentials frequently emerged at this point. Participants were asked to hold the thought of the changing rate and see the effect of the initial model. This led to the generation of a model; the starting temperature minus the rate of decrease times the number of minutes, i.e. something like $92 - t \times 2.4$. At this point participants could solve the pizza shop owner's problem. Here, pizza is still just acceptable at time t where $92 - (t/60)2.4 = 48$.

One complete iteration of the modelling process had been completed. So the results needed validation: where they good enough? The graph looked very linear over the range of the experiment and the solution was commonly only a small multiple of the experimental range. It quite probably would be good enough for the pizza shop owner. Again, the owner is a fiction, we are simply keeping up the marketing ploy. However, the narrative set up some unease, notably the expectation that in the medium term the temperature of the pizza would plateau at the temperature of the room. Using the functional model and values of t for 30 mins, 2 hrs and 24 hrs, generated absurd values for the temperature. When the graph was rescaled with the maximum value of t changed to these value s the gradient appeared extremely steep. However, the context provided a clear basis for critique. Participants knew that pizzas, left to themselves do not freeze of their own accord. That the rate of change was slowing was then incorporated to generate an improved model. This suggests a quadratic, but again the context provides a critique; unattended pizzas do not heat up again. This left two possible functions which meet both conditions; a reciprocal function and an exponential function. These provide extremely good fits to the data and meet both criteria (plateau at room temperature and a diminishing rate of change) and hence appear validated in the context of the problem. The next iteration of critique demands validation beyond the scope of the mathematician. Why Newton's law of cooling is exponential requires an explanation rooted in chemistry and physics. Again, the mathematician must be clear about the limits of their expertise.

MODELLING ACTIVITIES FOR SCHOOLS AND THEIR MATHEMATISATION STRATEGIES

The narrative is designed to preserve the focus of the learner on the construction of the model. In an earlier paper we refer to this as the mathematisation strategy (Burke, et al., 2014, p. 33). We set out an analytic framework describing the different strategies according to two axes: the first concerns the extent to which there is a rationale for deriving the relationships in the model (A Quantification rule) and the second concerns the rationale for the rule itself (A Mapping rule). The strength of these is determined by its discursive saturation (DS+/DS-), being the extent to which the principles of evaluation are contained within the practice (Dowling, 2013). This generates four mathematisation strategies (Burke et al., 2014, p. 33) (Figure 2).

The use of modelling in RME is as the construction of a relationship between the originating context and the model. This is beyond the reach of the student (and indeed the teacher) as it is generated at the level of author/researcher. So, it operates as a derived mathematisation. A mapping whose principles can be evaluated (DS+ Mapping), but with no access to

Quantification rule (external syntax)	Mapping rule (internal syntax)	
	DS+	DS-
DS+	*Definitive Mathematisation*	*Ad-hoc Mathematisation*
DS-	*Derived Mathematisation*	*Originative Mathematisation*

Figure 2

the means of construction (DS- Quantification). By contrast, Julie's teachers constructed their models with clear relationships between problem and model (DS+ Quantification) but do not provide a theoretical basis for their models (DS- Mapping), an ad-hoc mathematisation. In both cases, throughout the pedagogic practice, the mathematisation strategy is fixed. There is no possibility to engage with the practice of mathematical modelling per se and hence this is unrealised as a pedagogic practice. There is no school mathematical modelling.

For the pizza narrative, we describe "a move from originative through ad-hoc mathematisation that results in a definitive mathematisation". (Burke et al., 2014) This provides the apprenticeship, the mechanism by which the student is exposed to the processes of mathematical modelling. The relationship between teacher and student remains central as the narrative unfolds with the teacher having planned the inclusion and suppression of elements of the dialogue, to preserve the focus on the process of creating the model.

The detailed presentation of the pizza delivery narrative is intended to argue the case that the outcomes of the activity would be recognised as mathematical modelling by a professional, but the practice inducts the participant into the esoteric domain of mathematical modelling, by strategically emphasising key elements of the modelling process. It is clearly a pedagogic activity. The narrative is structured to selectively expose and suppress the elements of the modelling process in strategic ways, because we are in fact not solving a real problem, which allows us to extend the remit of the original problem to see the effects of requiring a higher level of validation. I make no claims for this as a school mathematics activity. It may be the case that students have learned some mathematics in doing this, but that would need to be tested empirically. What I do wish to claim is that the activity is constructed as a school mathematical modelling practice, created from a reflection on a map of that practice. This provides a structure from which a principled narrative is constructed, through which the participant comes to operate in the esoteric domain of school mathematical modelling.

IMPLICATIONS FOR RESEARCH AND FOR EDUCATION

This paper has set out an argument to clarify a distinction between the practice of mathematical modelling and pedagogic activity aimed at developing skills in mathematical modelling. I have used examples from the literature in which mathematical modelling is presented in an educational context but there is no intention in the activity to develop modelling skills. I would suggest further work within this research area to identify and potentially develop further instances where the activity can be identified as the pedagogic activity; school mathematical modelling. Here, the specific intention is to focus on the development of aspects of the modelling process and how this can be achieved as in the pizza delivery example I have given. Other elements of the modelling cycle would be amenable to this way of thinking and notably I would see the issue of validation as central to the modelling process and a potential next step for focussed pedagogic activity.

In educational policy, there is an increasing emphasis on solving problems in mathematics and framing these problems in a real world context. In the new UK National Curriculum (DfE, 2014), problem solving is one of the 3 foregrounded components (the others being reasoning and fluency). Students are required to; "begin to model situations mathematically". As I have argued, they will not be able to develop skills in this unless there is an explicit focus on mathematical modelling. Here, the elements of the modelling process need to be developed through explicit pedagogic activity. This is an issue for curriculum planning and materials design. The pizza delivery example provides one activity with a focus on one specific aspect of the mathematical modelling process. It could potentially fit in to a more systematic collection providing a more complete curriculum in school mathematical modelling.

Thought structures as an instrument to determine the degree of difficulty of modelling tasks

Xenia-Rosemarie Reit and Matthias Ludwig

Goethe-University Frankfurt, Institute for Mathematics Education, Frankfurt, Germany, reit@math.uni-frankfurt.de

Although efforts have been made to integrate the concept of mathematical modelling in school, studies show that it has not arrived yet in everyday school classes. From a teacher's point of view, multiple solution approaches and a varying task difficulty complicate especially the development and assessment of modelling tasks. Taking up this issue, this study aims at developing a method to determine the degree of difficulty of solution approaches of modelling tasks based on so called thought structures of student solutions. Thought structures of student solutions provide information about the task difficulty and can be taken as a basis for a well-founded rating scheme. We want to consider the question of whether the method used to describe the degree of difficulty can be reproduced by empirical results.

Keywords: Mathematical modelling, assessment, degree of difficulty, task space.

INTRODUCTION

Within the community of mathematics education there is a broad consensus that the integration of mathematical modelling and applications must be promoted and increased. Of course this awareness is not new and efforts have been made during the last decade. However, several studies provide evidence that modelling is far away from playing an integral role in daily school teaching in Germany and also elsewhere (Blum, 2007). The proportion of modelling in daily school routine is rather low (Jordan et al., 2006). When researching into that problem it is worthwhile to have a closer look on the teachers' point of view. What prevents teachers from teaching modelling tasks? Schmidt (2010) found out that teachers often mention complexity and lack of predictability as motives for waving modelling tasks. A look in textbooks shows that modelling tasks are still rare, especially those which can be used in a normal school class setting in contrast to modelling tasks used within larger projects encompassing several lessons. The development of modelling tasks leads, more than ordinary task formats, to difficulties concerning the estimation of the task space, the task difficulty and finally also concerning the assessment.

The study presented here takes up the issues from a teacher's perspective and aims at a better structuring of modelling tasks in terms of a better manageability for teachers. In detail we developed a method to determine the degree of difficulty of modelling tasks and an assessment scheme, both, building on solution approaches with its particular thought structures. Empirical results will show whether the theoretically determined degree of difficulty is verifiable and certifies a good applicability.

THEORETICAL FRAMEWORK AND METHOD

A common instrument to determine the degree of difficulty is the solution rate by applying a dichotomous rating. Since the answer format of modelling tasks is open and compared to others rather extensive, this procedure seems not adequate to reflect the full scope which is provided by modelling tasks. Cohors-Fresenborg, Sjuts and Sommer (2004) applied a method analysing the text of the task. They identified task specific indicators for the difficulty of tasks by investigating PISA-2000 items. The task format of the investigated items was not restricted to modelling tasks. Since the task space of modelling tasks is, compared to other task formats, rather large, this aspect would get lost by focusing on the text of the task. In our study this specificity of modelling tasks is taken into account since the method for determining the degree of difficulty comes directly out of the solution approaches of the student solutions.

In a first step we analysed the student solutions of every modelling task to identify main solution approaches. On the one hand, this classification was based on the mathematical model used and, on the other hand, on the solution process, which can be different although the same mathematical model is used. Each solution approach has a specific structure which can be revealed by dismantling the solution approach into its single thought steps, which provide the opportunity to consider solution steps from cognitive aspects. This idea builds on structural considerations in the field of word problems. In this context Breidenbach implemented the term "Simplex" as a task consisting of three items and every item can be determined by the two others (Breidenbach, 1963, p. 200). By visualizing the logical structure of the mathematical operations to be done in terms of such Simplexes he built up a kind of arithmetic tree or flow chart. These flowcharts have been refined by Winter and Ziegler (1969) and serve as a basis for the so called thought structure analysis of the study described here. For the present study we refined Breidenbach's definition by identifying the single cognitive steps, here called thought operations, which have to be carried out in order to arrive at a solution. We define thought operations as follows:

A thought operation is a necessary (intermediate) result which is obtained directly (without intermediate calculations) from one or several (initial) data.

These thought operations can then be arranged as a kind of flow chart which illustrates the incremental proceeding and in addition, also the complexity of the solution process (see Figure 1).

A natural but empirically not yet validated conclusion is that the complexity of a mathematics task is dependent on the number of simplexes and the nesting of them (Graumann, 2002, p. 93). Cohors-Fresenborg and colleagues (2004) emphasize in this context the simultaneity and nesting of thought steps. With the help of theories within the field of cognitive psychology, we can operationalize the effects of nesting and simultaneity on complexity. Fletcher and Bloom (1998) found in their study about text comprehension, where they assumed text comprehension to be a kind of problem solving process, that information being the direct predecessor of another information must be kept actively in the working memory. Under the assumption of a working memory with limited capacity (Sweller, 1988) these findings indicate that several aspects in a task which are related to each other and have to be considered and understood at the same time, may load the working memory. Thought operations are considered to be parallel if they either originate from the same thought operation or determine the same thought operation of the subsequent solution level.

By applying the findings from above to the thought structure considerations, especially the amount of parallel thought operations (as it is the case in level two of Figure 1) of a solution approach appears to be a difficulty generating aspect. Thus, during the process of determining the degree of difficulty, parallel thought operations complicate the solution approach to a greater extent than those being processed consecutively. To describe this circumstance we developed a model which gives more weight to parallel than consecutive thought operations. Each level in the thought structure contributes to the overall degree of difficulty according to its number of parallel thought operations. From the number of parallel thought operations per solution level we calculate the factorial and then finally all levels are added up. In the following we want to reconstruct this procedure by taking modelling task "Potato" (Figure 2) as an example.

One solution approach, which we could identify, is called "Layer" (Figure 3, left). Based on the given length of the potato the student assumes a height and a diameter or depth of the potato. Together with an assumption about the measures of a potato stick the student is then able to calculate the number of sticks

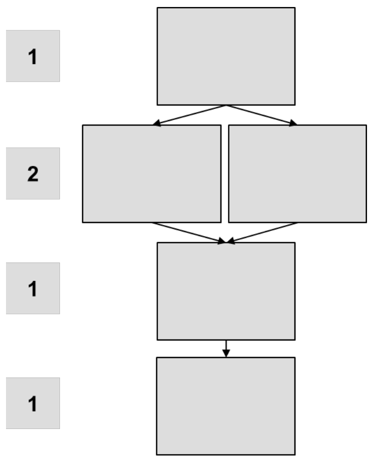

Figure 1: Exemplary thought structure of a solution approach together with the number of thought operations per level

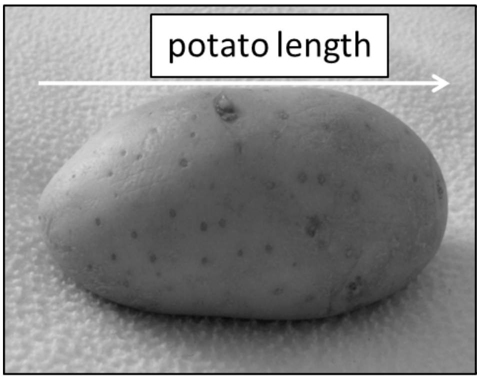

Industrial manufactured french fries are supposed to be equal in size and the single sticks are cut out lengthwise. Therefore not the whole potato can be used. The potato tubers look similar to the picture above, are regularly formed and approximately 10 cm in length.
How many of these potato sticks can be obtained from one potato? Reason mathematically.

Figure 2: Modelling task "potato"

per layer in height and depth. Multiplication of these two numbers leads to the total number of potato sticks. The corresponding thought structure has been developed which arranges these thought operations as sort of arithmetic tree (Figure 3, right). Besides the chronological order of the calculations to be made, the thought structure also provides information about the difficulty of the solution approach. The numbers right next to each solution level indicate the number of parallel thought operations to be completed per thought structure level. As explained above summing up the factorial per level yields the degree of difficulty of the solution approach.Thus, in case of solution approach "Layer", the degree of difficlty is 1!+2!+1!+1!=5 (see grey Figure 3, right).

Based on these considerations an assessment scheme has been developed to utilize the full scope of the promising method on the one hand and to verify the theoretically determined degree of difficulty on the other hand. When observing the assessment routine of mathematics teachers it becomes clear, that assessment of tasks is based on a sample solution and its important partial aspects. The teacher compares each solution with a sample solution and awards important intermediate results. Our assessment scheme is based on this everyday school routine procedure. Intermediate results are represented here by thought operations and are assessed according to whether they have been conducted correctly or wrong. For partly right thought operations half points can be awarded. That means that thought operations are scored 0, 0.5 or 1 dependent on their completion. Thus, the maximum score per solution approach is defined by the number of thought operations. In case of solution approach "layer" the maximum score is 5 (number of thought operations (grey boxes) in Figure 3, right).

Before being able to solve the task, one has to identify the relevant information of the presented linguistic context. According to Cohors-Fresenborg & Sjuts (2001) difficulties are especially evoked by linguistic constructions concerning the logical structure and formulations conditioned by the authenticity of the situation. The textual differences of the tasks are integrated in the process of determining the level of

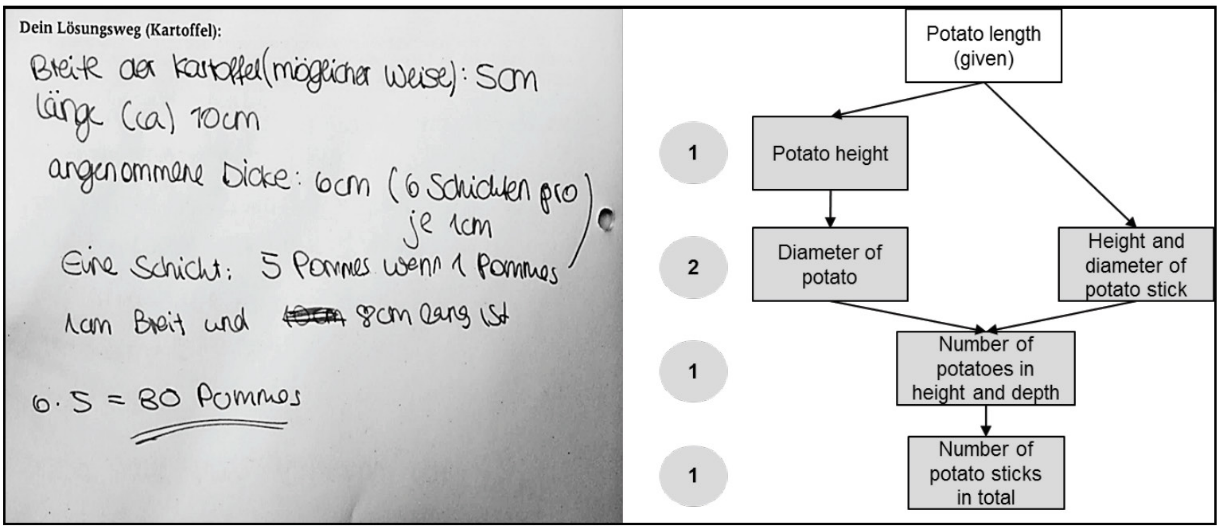

Figure 3: Solution of solution approach "Layer" and corresponding thought structure

difficulty by adding zero, one or two single thought operations according to the linguistic requirement of the task text.

0 Picture and/or text contain all relevant data. Only simple main clauses are used.

1 Missing data has to be estimated and there are several main and subordinate clauses due to a larger text, containing explanatory but mathematically irrelevant text passages.

2 Picture and/or text do not explicitly clarify the dimension of the object of the task, e.g. the two dimensional picture of a potato is out of keeping with the three dimensional reality leading to not include a third dimension in the calculations.

Modelling task potato has been assigned to linguistic level two according to its requirements coming from the text. Therefore we additionally add two single thought operations to the solution approach based degree of difficulty. Thus the total degree of difficulty of the solution approach “Layer” consists of linguistic requirements (2) and solution approach specific thought operations (5) and finally adds up to 2+5=7.

STUDY DESIGN

Five modelling tasks have been developed according to predefined criteria (see Reit & Ludwig, 2013):

— Authentic context (Maaß, 2007)

— Realistic numeric values (Müller et al., 2007)

— Problem solving character (Maaß, 2007)

— Naturalistic format for questions

— Openness relating to the task space

Authenticity and relation to reality are core elements of modelling tasks. We want to avoid ostensible relations to reality like they are often used in word problems in textbooks. There is no a priori known solution algorithm for the task which can be directly applied by the students. That means that the solution makes itself out to be a problem on students’ level. The questioning is supposed to either be close to the living environment of the students or take up a realistic question which could arises in reality. Openness of tasks is reflected by the task space. There has to be more than one solution approach which leads to a solution. The solution approaches distinguish themselves by their mathematical model. Thereby the students are able to have more options to arrive at a solution. Openness should rather be based on the alternatives of mathematical models to solve the tasks than on approximating sizes. Demanding this we do not deny that making assumptions is an important part of mathematical modelling but we want it to be limited to a degree which ensures an assessable solution interval.

The study splits up into pilot study and main study. The pilot study encompassed

— an a-priori definition of the task space of the tasks,

— the identification of the thought structure for each solution approach

— and the establishment of a rating scheme for each solution approach.

The implementation into a normal 45-minute lesson also required a time limitation of approximately 10–12 minutes per task. During the main study from December 2013 until April 2014 approximately 1800 students of grade 9 (15/16 years of age) of German grammar schools took part and solved three modelling tasks each.

To validate the thought structure method it must be investigated in how far the theoretically determined degree of difficulty is empirically reproducible. In other words, will tasks, which have been rated as difficult, be solved worse than those rated as rather simple? To do so the student solution together with its assessment is associated with the predetermined degree of difficulty of the respective solution approach.

VALIDITY OF THE THOUGHT STRUCTURE ANALYSIS

The modelling tasks, which have been developed especially for the purposes of the study, show a good variability of applied solution approaches. Although this was an important criteria during the process of development it could not be stated with certainty how the students solve the task. At least three target aimed solution approaches could be identified per modelling task (Figure 4). Hence, from the viewpoint of openness in the sense of an adequate task space the developed modelling tasks seem to meet the requirements.

The main objective of the study is the validation of the thought structure method to determine the degree of difficulty by comparing the student performance with the statement of the theoretical model. Hereafter we consider the question of whether the method makes a valid statement about the degree of difficulty of the modelling tasks.

Within a modelling task the student performance verifies the degree of difficulty in terms of scoring higher using solution approaches determined as easier and vice versa. This situation is illustrated in Figure 5. Taking three of the five modelling tasks into account (modelling task “Cola” and “Bridge” are not yet analysed completely) we can see a distinct decrease of the average score when using a solution approach being determined as more difficult. The value of the power of the regression function is in case of modelling task “Tennis” and “Taj Mahal” nearly similar what indicates that the coherence of score and degree of difficulty reacts almost in the same way. The degree of difficulty of modelling task “Potato” seems to have a firmer influence on the average score than it is the case with the two other modelling tasks. An increase in difficulty results in a steeper deterioration. In general a comparability of solution approaches within a modelling task, based on the theoretical degree of difficulty is reasonable.

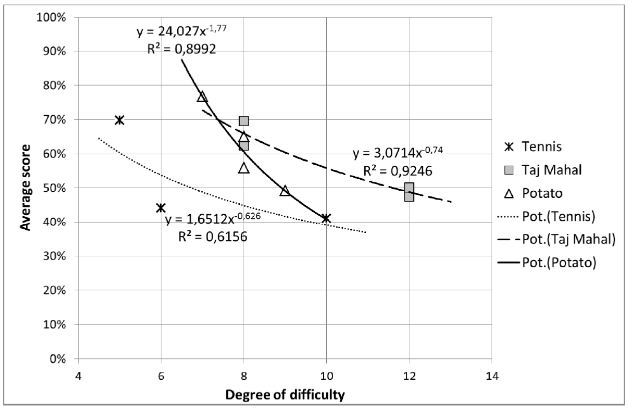

Figure 5: Coherence of score and degree of difficulty concerning the solution approaches per task

Another interesting question is to what extent the determination of the degree of difficulty can be used in a cross-task context. What statements can be made by comparing different modelling tasks? To answer this question we compared the average score of a modelling task dependent on its average degree of difficulty. The decreasing tendency of the average score with increasing degree of difficulty is in evidence (Figure 6). In detail the power of the regression function suggest that if the degree of difficulty doubles, then the score will half.

SUMMARY AND OUTLOOK

Especially when considering modelling tasks it is challenging to estimate the degree of difficulty and to assess their solutions reasonably and satisfying for students. On the part of teachers this brings along uncertainty and might contribute to a restrained attitude towards modelling tasks in everyday teaching. The presented study considers that problem and de-

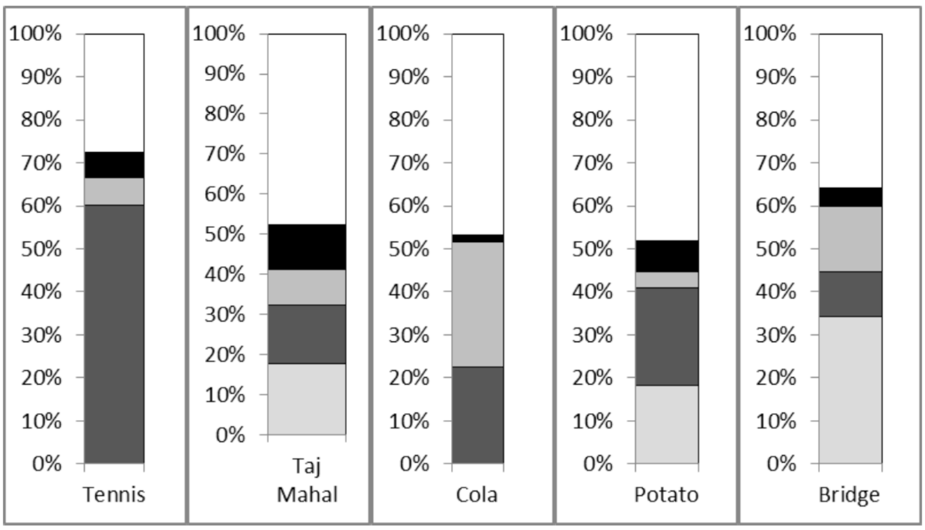

Figure 4: Distribution of solution approaches per modelling task (target aimed solutions in greyscale, others white)

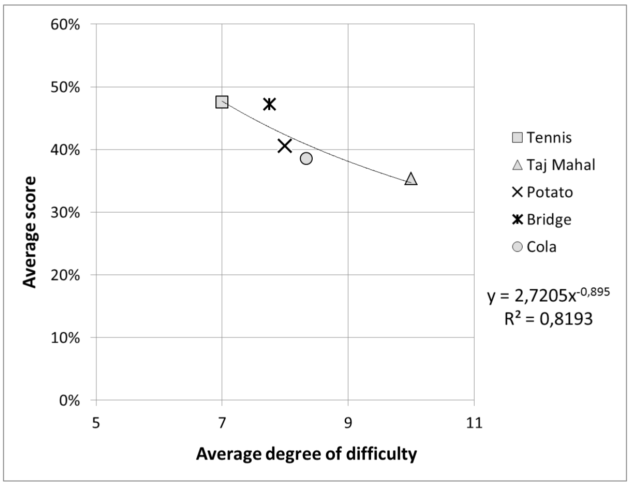

Figure 6: Average score of the modelling tasks subject to the degree of difficulty

veloped a promising method to firstly determine the degree of difficulty and secondly to form the basis for a reasonable and conclusively substantiated assessment scheme. The analysis so far encourages the assumption of a good applicability. The results up to now show that using the thought structure based method to determine the degree of difficulty is in line with the empirical results. Students show better results when using those solution approaches with a rather low degree of difficulty and vice versa. Similar results could be obtained considering the modelling tasks as a whole. The average student performance is better at easier tasks and worse at tasks being rated as more difficult. Additional analysis especially to modelling tasks "Potato" and "Bridge" will show how reliable and convincing the method is. Besides these affirmative outcomes modelling task "Potato" gives rise to questions concerning the limits of the method. The divergent results of this task may be due to the fact that their solution approaches are somehow intertwined in the sense of being difficult to distinguish. This sometimes leads to the problem of false solution approach classification, thus to a falsification of results. This may support the conclusion that a distinct discriminability is a necessary requirement for the thought structure method. Further reflection and the complete analysis of the two remaining modelling task may give deeper insights to that aspect.

A multidisciplinary approach to model some aspects of historical events

Gemma Sala, Berta Barquero, Vicenç Font and Joaquim Giménez

Universitat de Barcelona, Faculty of Education, Barcelona, Spain, gsala@ub.edu, bbarquero@ub.edu, vfont@ub.edu, quimgimenez@ub.edu

This paper focuses on the problem of integrating a multidisciplinary approach to the study of extra-mathematical questions where mathematical modelling appears as a central tool in the teaching and learning processes. We present here the design, implementation and analysis of a sequence based upon a historical context, the war of Spanish Succession in Catalonia during 1714, which was implemented in two courses with 12–14-years-old students. We also show to what extent these implementations help to integrate an interdisciplinary study where history and mathematics will have to work together.

Keywords: Mathematical modelling, inquiry, multidisciplinary approach, historical and cultural context.

INTRODUCTION

The main aim of our research is to find complex situations of real life that can give rise to the design of a sequence of tasks that can promote inquiry and modelling students' competences. These real situations will be the origin of the design of a sequence of questions and tasks, integrating the necessary didactic devices enhancing students to mobilize the necessary cognitive processes to face them. More concretely: (1) to integrate diversity of tools coming from different disciplines and subjects and (2) to integrate mathematical modelling as an essential tool to facilitate a multidisciplinary approach to face such situations.

It is in this context of fostering the inquiry and modelling in which the selection of initial situations that will originate the process of design of tasks' sequences takes real importance. This situation leads to the formulation of the following specific research question that will be at the core of our research:

> Given the classical description of contents of different subjects (Mathematics, History, Languages, etc.) at Secondary school level, and given the traditional isolation between these disciplines, how can we design didactic devices which locate problematic questions at the starting point of the study process where: (1) mathematics (and mathematical modelling) appear as fundamental tools to provide answers to them, and (2) can the mathematical study inhabit and interact with other disciplines (or subjects) to validate and enlarge the study?

Here we consider the particular case of Secondary school level. The sequence described in this paper was named '*Understanding the incidents of 1714*' ('Valorant els fets de 1714'). The main purpose for students (and also the final task) was to participate in a literary contest about the consequences of the war of Spanish Succession in Catalonia, which happened 300 years ago. Students were asked to face quite an open starting historical problem about this war. They had to begin by looking for real data in some historic resources, and to use mathematical tools for the analysis, understanding and looking for answers to some initial historical problems. Finally, they were asked to individually write a short story as means to share and officialise their final responses and conclusions about the consequences of the war. This short story was sent to a literary contest announced by a Catalan publisher[1] opened to all secondary schools.

In this paper we describe some of the main traits of the didactic sequence's design that was finally implemented. We also analyse how it contributes to the development of students' inquiry and modelling competences by using the talks' registers, productions from students and their answers to a final questionnaire, but also by describing the a priori mathematical and didactic designs in which researchers and teachers work together.

THEORETICAL APPROACH

In the design of the sequence of tasks different approaches interact. On the one hand, the mathematical and didactic design quality is justified based on the three criteria of didactic 'suitability' proposed by the Ontosemiotic Approach, EOS (Godino, Batanero, & Font, 2007): 1) the emotional suitability, 2) the epistemic suitability and 3) the ecological suitability. The aim is to design a sequence of tasks in which different suitabilities were included. For instance, its 'emotional suitability' can be justified by the fact that students were asked to participate in a literary contest from which some winners were selected (as it finally happened); its 'mathematical quality' (the epistemic suitability) can be justified based on the view that implementation allows students to trigger relevant processes of mathematical activity, in particular of mathematical modelling processes. In its turn, the 'ecological suitability' is justified by the fact that the curricula of these secondary-school students have a competency-based approach, where the teaching and learning processes provided by the curricula should promote competences to deal with complex and varied real-life situations.

These curricula guidelines are on the same directions of recommendations from other countries and international organizations like the National Research Council (NRC, 1996). For instance, according to the NRC, teachers should support the development of abilities of inquiry. These inquiry abilities are hardly related to modelling perspectives, and sometimes it is difficult to find the differences between both processes (Artigue & Blomhoj, 2013). A recent discourse of inquiry in mathematics education focuses on the use of methods and mathematisation processes, promoting the construction of mathematical hypothesis and models, and the need for arguing, valuing and controlling in an appropriate way to solve the contextual problem (Elbers, 2003). From our viewpoint, placing mathematical modelling processes at the core of activities involves promoting other kind of processes important in a rich and functional and mathematical activity (understood as mathematical richness of quality processes).

On the other hand, a way to get a high epistemic suitability is to design the sequence of tasks using the notion of study and research paths (SRP) (Chevallard, 2006; 2012) as a didactic device to facilitate the inclusion of mathematical modelling in educational systems, and more importantly, to explicitly situate mathematical modelling problems in the centre of teaching and learning processes (Barquero, Bosch, & Gascón, 2008). We assume and use the structure of SRP (Barquero, Serrano, & Serrano, 2014) as the main theoretical construct to design the didactic sequence we will present in this paper: (a) The starting point of a SRP will be a 'lively' generating question with real interest for the community of study (students, teachers and researchers); (b) During a SRP, the study of the generating question will evolve and open many others 'derived questions'. The study of all these questions will lead to successive temporary responses, which would be tracing out the possible 'routes' to be followed in the effective experimentation of the SRP; (c) The teacher will thus have to assume a new role of acting as the leader of the study process, instead of lecturing the students; (d) An important dialectic that will be integrated in the SRP is the task of posing questions and that of the continuous search for answers; (e) Against the temptation of imposing some answers that are acceptable within the educational institution, the group of students needs to be invited to defend the successive answers they provide; and finally (f) The dialectics between the media and 'milieu' will be also essential to control what exiting resources and answers are available 'outside' the classroom (in the media), but also what tools will help us to validate and integrate them in our study.

The proposal presented in this paper uses some historical contexts to develop inquiry and modelling competences in the same line as some previous works, for instance: Vilatzara Group (2003) used historical questions context questions to introduce mathematical modelling processes or Sala, Giménez, & Font (2013) proposed a selection of tasks in historical and cultural context to promote inquiry.

CONDITIONS OF THE DESIGN AND IMPLEMENTATION

The starting question that opened the teaching sequence was placed in the context of Barcelona's siege during the war of the Spanish Succession.

> S_i: Which were the consequences of the incidents of 1714 for the society, culture and political organization of Catalonia?

Students were asked from the beginning to write a short story about the war' consequences for Catalonia with their own conclusions from their study developed in the classroom work. It was important this story was rigorous enough, based on contrastable historical data and involving a robust study about some related phenomena, like: Barcelona's demography evolution, economical changes for the society or for some guilds of the city, etc.

The teaching sequence was implemented during the course 2013/14 with two experimental groups at Secondary school level (12–14 years old) of 29 and 30 students respectively, in a high school in Badalona (Catalonia, Spain). Its experimentation was carried out during two weeks for each group, with a total of 7–8 weekly hours. One exceptional condition was that the subjects of History, Mathematics and Catalan literature were linked along this experimentation. They acted together in what was called the 'Mathematical-Historical workshop'. Along the workshop, the teachers of these subjects were all involved in the experimentation, with the help of the first author of the paper, who acted as observer and guide of the implementation. For their part, the students were organized in 'inquiry teams' that changed along the different stages of the workshop.

The study began describing the general initial situation S_i that was broken into some more concrete questions (some of them explained below) to better distribute and coordinate the inquiry-teams' work. They all began with the analysis of some real data (concerning each topic) in order to quantify and value the consequences of the incidents occurred in 1714 in Barcelona. Through the study of the initial question, together with the need of getting historical knowledge, evolved towards some other derived questions. The students had to search information outside the classroom in all available media (webpages, historical resources with real data, etc.). These teams had to build up and use different mathematical models to study some of these derived questions and to contrast the validity of their proposals by using tools from mathematics and also from history.

Most of the information related to the mathematical-historical workshop (initial worksheets, topics and questions to study, phases followed along the workshop, etc.), and also some of the results from its implementation, are available in the blog called 'Understanding the incidents of 1714': http://valorar1714.blogspot.com.es/. This blog was basically structured in four parts: a central part, where students could read teacher's posts with the aim of encouraging students to keep on working and temporizing each of the phases and tasks; on the right part, there were some materials and resources that students could use to do the first tasks of the workshop (historical frame contextualization). The left part contained the blog archive, the search bar, some links of interest and other resources 2.0 related to S_i; on the top, four different boxes contained the worksheets grouped by topics and other documents concerning each of the topics. The didactic sequence was organised in the following stages:

First stage: The historical frame contextualization. Cooperative work teams (the so-called 'inquiry teams') were formed and each student assumed different roles and some concrete tasks. Students were also asked to individually sign a contract about the compliance of certain working rules. Each team prepared, exposed and defended a poster board) where they had to explain a part of the historical frame since the beginning of the war. The rest of the students had to listen to, question and assess the rest of the poster boards and presentations. After that, new couple-teams were responsible for carrying out a time line with the free software 'Timetoast' to ensure they had a clear idea of the chronology of the historical events.

Second stage: Inquiry teams facing different topic related to S_i. The students, organized in the inquiry teams of two or three members, focused on the study of some phenomena (proposed by the teacher) related to S_i. Some real information was also provided to allow students to initiate an accurate study. To begin, all the teams had a general introduction about data's origin, historical resources and some other information to contextualize the inquiry. S_i was broken into different lines of research that were grouped in three main topics: A, B and C. After the general introduction, the teachers, who acted as supervisors of the inquiry, assigned each topic to each of the inquiry team.

Topic A focused on the demographic dynamics of Barcelona' population before and after 1714. It was composed by four worksheets (one for each inquiry team):

> $Q_{A.1}$: Evolution of the population between 1600 and 1720; $Q_{A.2}$: Evolution of the births in Catalonia between 1600 and 1715; $Q_{A.3}$: Evolution of the illegitimate births between 1600 and 1715; and $Q_{A.4}$: Comparative study of the salaries and prices between 1680 and 1800.

Topic B focused on the study of Barcelona's guilds before and after 1714, composed by seven dossiers that introduced the question of describing and fostering the evolution of the following guilds before and after 1714:

> $Q_{B.1}$: The fishermen and sailors' guild; $Q_{B.2}$: The weavers' guild; $Q_{B.3}$: The wool crafters' guild; $Q_{B.4}$: The shoemakers' guild; $Q_{B.5}$: The tanners' guild; $Q_{B.6}$: The tailors' guild; $Q_{B.6}$: The 'blanquers' (another type of tanners) guild.

Topic C focused on the study about the changes in the configuration of the city before and after 1714, composed by two worksheets:

> $Q_{C.1}$: The construction of 'Ciutadella' (a citadel) and its consequences for the city; QC.2: Changes on the configuration of the city (Barcelona).

Each of these inquiry lines, starts with the contextualization of the particular topic included in the worksheet, which was structured in different parts (two at least) including questions from less to more complexity (all of these questions are available in the worksheets published in the blog). Students were always asked to add new questions to follow with their study, but some feasible questions were included in the worksheets to help teachers to guide the study. For instance, if we focus on the topic A – $Q_{A.2}$ about the births' evolution in Catalonia between 1601 and 1700, it was introduced with the analysis of real data collected by Sant Just parish church (Barcelona) (Figure 1 – data provided by Ferrer, 2007). We began with the following general question:

> Given the data of the number of births in Catalonia during some years before 1714, how can we describe the evolution of the number of births? Can we identify any change? How can we make forecasts about the future number of births? How can we contrast prediction and reality?

Franges d'anys	Nombre de fills il·legítims
1601-1605	49
1606-1610	40
1611-1615	53
1616-1620	32

1696-1700	48

Figure 1a: Number of births per every period of five years

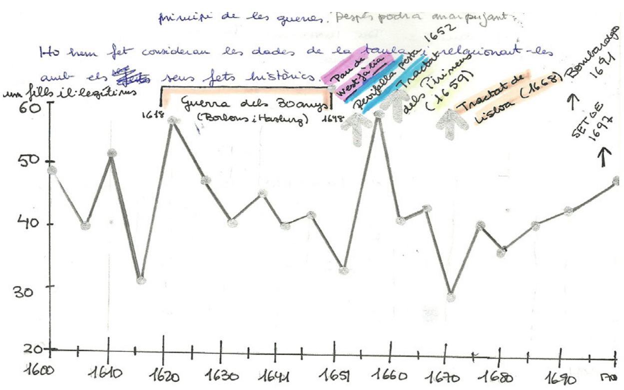

Figure 1b: Part of the partial report of an inquiry team working with $Q_{A.2}$

The first part focused on facing questions concerning the description of real data about the number of births between 1600 and 1714, with some other questions about how to predict the births' evolution around to 1714. Most of the students began using the graphical representation of real data (see Figure 1b) to complement the numerical analysis and to describe, for instance: the year intervals when births increase or decrease, linking the growth description to some historical events, etc. Despite all the rich description most of the teams provided, mathematical tools were not rigorous enough to provide forecasts about the short- and long-term births' evolution. At the end of the first part, students began to propose the use of discrete models (recurrent sequences models) or some basic continuous functions (constant or linear) to fit real data and also to predict birth's evolution. The second part expanded the previous answers and results. It was focused on creating tools to compare and contrast forecasts provided by the mathematical models with real data (more data about real births from 1714 were given to the inquiry teams). Furthermore, between the first and the second phase, each group had to prepare the 'interaction report' with which different teams working with similar topics (A, in this case) had to interact. From this interaction some common questions arise that could need some help from the teacher to follow with the activity (comparing proposals, introducing some unclear mathematical concept, formalising mathematical tools, etc.). At the end, each inquiry team was asked to complete, describe and report their work by writing their 'final report' about this line of research.

Third phase: Sharing the conclusions from the inquiry teams. In this final phase, each inquiry team had to prepare a presentation to share their study and conclusions. Some more 'interaction' moments were planned, depending on the conclusions they had found. For instance, it was necessary that some teams dealing with $Q_{C.1.}$ about the construction of 'Ciutadella' interacted with teams on $Q_{B.i.}$ about the changes on the guilds in the city. To better understand and explain why some changes in the city cause some movements in where guilds were placed.

Another example of the interlinked and necessary interaction between different lines of inquiry was shown by the work within $Q_{C.1}$ (see Figure 2) and $Q_{C.2}$ (topic C, Figure 3) about the creative proposals about the construction of the trenches (Torras & Sobrequés, 2005). In the first phase of the study, each team focused on its own topic:

> $Q_{C.1}$: The 'Ciutadella' was built a few years after the defeat of September 11th, 1714 with a special architectural structure (Figure 2). What role do you think it had? What benefits could its architectural structure provide to the city (in military terms, protection of inhabitants, etc.)?
>
> $Q_{C.2}$: It's been documented that the structure of the trenches (Figure 3) during the War of Succession introduced some innovative changes. What kind of novelties did this system include? What elements allow us to compare the shape of the trenches with the advantages in number of deaths?

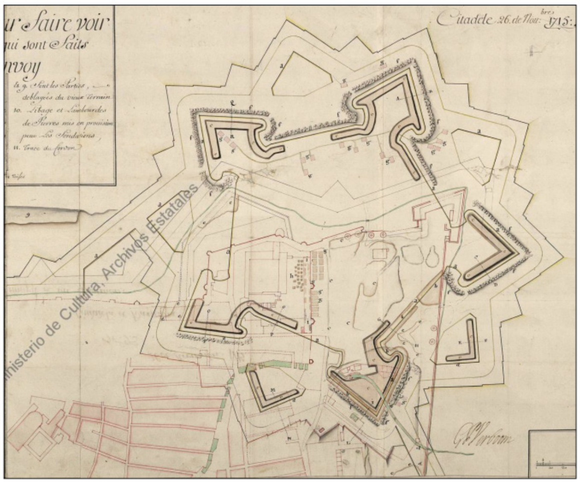

Figure 2: Part of the plan of the citadel (1715). Available in http://ves.cat/l9_P

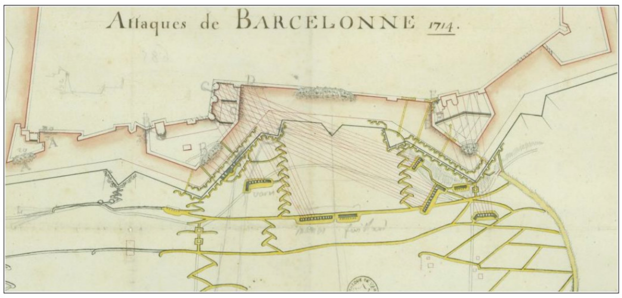

Figure 3: Trenches to the walls of Barcelona during the siege of the War of Succession in 1714. Available from http://gallica.bnf.fr/ark:/12148/btv1b7100421p/f1.zoom

After each team developed its own study of their particular lines, some new questions were asked to link both lines. They mainly focused on studying the relationship between the structure of the 'Ciutadella' and the defensive strategy and the resistance capacity of the trenches structure to bear the continuous attacks during the siege.

At the end of this phase (as forth stage), student had to individually draft a short story, based on the work done by all the groups working in the class, following the rules of the literature contest. After a process of co-evaluation of their writings, their writings were sent to the contest. The good news were that one of our students won the second prize of the contest (named 'Catalan memories'!)

RESULTS AND DISCUSSION

In all the work developed around the initial situation S_i (what were the consequences of the war of Spanish Succession in 1714 to Catalonia) and derivative questions that characterize each topic, it was essential that the students assumed many responsibilities, traditionally assigned exclusively to the teacher. For example: work in a inquiry team; schedule their own study; discuss the proposals and results in the classroom; question the historical validity according to their answers; analyse real data and look for patterns to build models and make predictions; contrast their conclusions with the most appropriate experimental milieu (looking for data in external resources, trying with other models, etc.); summarize results and defend them orally and in writing; check the validity of the mathematical tools that are being used; raise new questions to continue with the study, etc. Moreover, students had to compare, search agreement with team members and also with other teams based on their own productions and results.

This way of working helped students to place themselves in a critical perspective towards the reality around them and gave them tools to come up with their own decisions and ways to analyse situations in our society (Vanegas & Giménez, 2010), like the initial situation we have presented in this didactic sequence. That is, despite the path of tasks planned and followed by the students in this implementation, the teaching sequence promoted autonomy and a critical thinking thanks to the openness of the questions.

Among other devices that were available to students and teachers, we emphasize the importance of the 'inquiry guide', and some documents that each inquiry group had to write so that the teachers could follow the progress of the study. These documents are: two partial reports (Inquiry teams had to fill them at the end of the first and second research phase respectively, presenting a synthesis of the issues treated, and explaining their responses and the mathematical tools used); an 'interaction report' between groups (it had to be completed to guide the interaction between inquiry teams); and a 'final report' that they had to write at the end of the study. This final report helped the students to individually write the short story to send to the literature contest.

However, we want to emphasize the importance of planning some sessions to share all teams' work and approaches with the rest of the teams. Students answered a questionnaire that allowed us to know their perception on various aspects of their learning. They said that they had had a lot of difficulties on: understanding in the beginning what it was being asked and why, integrating their contributions and results in their research, generalizing their results, synthesising their work and writing the team's reports, etc. However, in general, their opinions were positive. It was in these 'sharing sessions' where the teacher had to act as guide or as mediator, helping students with all these new tasks that they had assigned.

Finally, we think that the final task of submitting an essay to a literary contest was a key element to engage students in the research project. Moreover, the integration and use of new didactic devices, as the ones described, that are not usually integrated in school reality help students to assume many responsibilities that are traditionally assigned only to teachers.

FINAL REFLECTIONS

The research we have presented in this paper describes some of the characteristics of the teaching sequence of 'Understanding the incidents of 1714', which was designed giving an especial role to inquiry, modelling and the interdisciplinary approach. The design gives special importance to this interdisciplinary approach in order to allow students to consider mathematics, and specifically mathematical modelling, as a tool for finding answers to questions (in this case, from History). Besides the first resistances of students to use and mix tools and information from different subjects (history and mathematics, in our case), mainly doubting that teachers were 'asking' for this combined used, they could finally go into the 'dialogue' and interaction of such traditionally isolated disciplines. History was not only providing the initial context where the initial questions where posed, its tools were constantly integrated along the study to validate their responses. And in the same way, models and mathematical tools were at the disposal of the research activity, they had to help us to follow with our inquiry activity and all proposals had to be persistently checked with the appropriate historical-mathematical milieu.

Along the SRP students were asked to build up their own 'piece of history' through: the formulation of hypotheses based on the analysis of real data and historical information, looking for mathematical tools to enlarge the answers to historical problematic questions, contrasting the validity of mathematical tools with historical resources, posing new questions to follow with, etc. That is, as Dean (1995) describes, learning by 'doing history', approaching History as a scientific discipline but also, learning by 'using mathematics' as a fundamental tool to provide answers.

Finally, considering all resistances manifested by the students and also by the teachers facing this implementation, we plan to continue searching on what kind of new design and didactic devices are necessary to integrate this kind of studies in which a 'real study' of questions will require to combine and 'make' interact tools emerging from several disciplines, where, in particular, mathematics and mathematical modelling will have an essential role.

The link between the cognitive structure and modelling to improve mathematics education

Laura van de Weerd and Nellie Verhoef

University of Twente, Institute for Teacher Training and Professional Development, Enschede, Netherlands, lauravandeweerd@gmail.com

This study focuses on the aspects in the cognitive structure that should be trained to develop Dutch students modelling without actual modelling lessons. The research used 16 fifth-grade beta coursed students to study the development of the cognitive structure and its relation to modelling. The methodology is based on the Conceptual Content Cognitive Map Method of Kearney and Kaplan (1997), while Tall's (2013) theory is the theoretical framework. Data are collected by a cognitive test and a modelling test. The results show that students with a rich cognitive structure develop compression. Thus, teachers should focus on the connections between mathematical concepts as a solution for this problem.

Keywords: Modelling, cognitive structure, student learning, cognitive map.

INTRODUCTION

Modelling is an important discipline in beta sciences. However, it does not belong to the curriculum of Dutch secondary schools, which results in a gap between secondary school and university (Renkl, 1997; Savelsbergh, 2008). This problem has been studied from different points of view. Barquero, Bosch, and Gascón (2008) investigated a new didactic device to teach mathematical modelling at university. Verhoef, Zwarteveen-Roosenbrand, Joolingen, and Pieters (2013) studied the themes for mathematical modelling that interest Dutch students in secondary school. Lots of studies searched the cognitive structure, but only a small amount used quantitative analyses for measurement. Therefore this research focuses on the relation between the cognitive structure and modelling in a quantitative way, by use of cognitive maps. To quantify this, the study was well-delineated to trigonometry. This leads to the following main question:

> *Which aspects of the cognitive structure of secondary school students are determining factors in their development of modelling?*

To answer this question the theoretical framework contains theory of the cognitive units, the cognitive structure and modelling. The method is formulated by means of the Conceptual Content Cognitive Map method of Kearney and Kaplan (1997), because of the quantitative analyses.

THEORETICAL FRAMEWORK

Cognitive units and structure

The human brain is a complex biological structure that forms a multi-processing system. It is able to make decisions and focuses on important information as a result of the electrical communication among nerve cells, also called neurons. Signals are sent from a neuron's axon and will be received by another neuron's dendrite. The signal frequency of the neurons produces neurological activity. Increasing activity results in stronger connections, as decreasing activity results in weaker connections. The more often a connection is used, the thicker the connection will be. This is a result of long-term potentiation, which is a long-term increase of the spiking frequency of the neurons. This is very important in the formation of brain structures. It is directly related to the memory (Purves, 2008) and makes subconscious actions possible (Barnard & Tall, 1997; Starzyk, Li, & Vogel, 2005). The plasticity of neuron connections makes change of thoughts possible by opening and closing the connections. The working memory, that can be used to solve problems, is a result of this plasticity in closely connected neurons (Barnard & Tall, 1997; Crowley & Tall, 1999; Starzyk et al., 2005; Vogel, 2005; Widrow & Aragon, 2013). Such densely packed neurons form interneurons. Activation of a neuron in such interneuron group, activates all connected neurons if the connections are strong, called compression (Barnard & Tall, 1997; Purves, 2008).

In this study a schematic representation of the brain is used to simplify this theory. Terms as cognitive unit and cognitive structure are used. A cognitive unit is a small piece of information that the brain can focus on. As Tall (2001) says: "A cognitive unit consists of a cognitive item that can be held in the focus of attention of an individual at one time, together with other ideas that can immediately be linked to it." (Tall & Barnard, 2001, p. 2). We define a rich cognitive unit, when the cognitive unit contains a great amount of connections between small pieces of information (Vogel, 2005). The cognitive structure can be described in different ways. According to Hiebert and Carpenter (1992) it can be described by the two metaphors; vertical hierarchies or webs. Tall and Barnard (2001) combine both and define the cognitive units as the nodes of the cognitive structure. The related cognitive units are connected by the threads of the web. In a rich cognitive structure there are many connections.

Compression is also an important schematic term in mathematical thinking. It describes the way in which small, rich cognitive units are formed within a cognitive structure. The junctions in the spider's web are so close that they touch each other (Tall & Barnard, 2001). This process is important because all cognitive units will be activated if one part of the information have been evoked, which is important in the thinking process. According to Tuminaro and Redish (2007), secondary schools focus too much on the students' results, while the connections and the learning process are more important.

Modelling

Modelling activates learning processes and confronts the scientist with the effects of his theories. Blum studied the difficulties with modelling and tried to explain these difficulties by the students' cognitive demands of these tasks. He emphasised that mathematical modelling has to be learnt specifically by students, and that modelling can indeed be learned if teaching obeys certain quality criteria, in particular maintaining a permanent balance between teacher's guidance and students' independence (Blum & Ferri, 2009).

In our study we focus on the cognitive aspects that are required for the development of modelling. By understanding the differences in the cognitive structure between students that are bad in modelling and good in modelling, we try to find the key aspect that is necessary in teaching modelling. For this study a mathematical model will be used which should comply with the conditions of modelling. According to Blum (2002), a modelling process contains five steps: a) Simplifying the real problem into a real model; b) Mathematizing the real model into a mathematical model; c) Searching for a solution for the mathematical model; d) Interpreting the solution of the mathematical model and; e) Validating the solution within the context of the real-life problem the real model into a mathematical model.

The Conceptual Content Cognitive Map Method

Lots of studies investigated the cognitive structure, but only some used quantitative analyses for measurement. Because this study also requests a quantitative measurement of the cognitive structure, the methodology is mainly based on the Conceptual Content Cognitive Map (3CM) Method[1] of Kearney and Kaplan (1997). Not only does their research show to be reliable and valid, their method is also a good basis for this study (Kearney & Kaplan, 1997; Somers, Passerini, Parhankangas, & Casal, 2014).

RESEARCH METHOD

Participants

Sixteen 16–17 aged students were subjected to the tests. They all had a beta programmed curriculum (physics and chemistry) with mathematics education.

Research instruments

This study used four instruments: a) the cognitive test; b) its evaluation, c) the modelling test and d) the grade list. Cognitive structures and modelling are respectively measured by the cognitive test and the modelling test. The study started with a cognitive test as a benchmark. One week later the modelling test followed, testing the students' modelling and their increasing insight in trigonometry and the ability to make connections between concepts. A week later, the second cognitive test studied the development in modelling concerning trigonometry. This second test was the same as the first cognitive test, so the differences in the results could be used to study the

1 For a detailed description of the 3CM Method, read http://eab.sagepub.com/content/29/5/579.full.pdf+html

cognitive development. After each cognitive test the students were asked to fill in the evaluation form and to note their grades for mathematics, physics, chemistry and if such is the case, informatics. Figure 1 shows an overview of the research method.

a) For the construction of the cognitive tests (used for the first and second cognitive test) mathematics concepts were collected. Therefore new participants were selected by their expertise, experiences, field of study and/or age. This results in a list with the following participants: a professional mathematician (f), ten master students (m/f) and one secondary school student (f). The participants made mind maps as a spider's web, which resulted in 68 concepts.

To test the cognitive test two of above-mentioned participants were used. They were chosen by their result of the mind map, because they had respectively the widest and deepest order. On basis of this pilot study the instructions were improved. This was tested by two secondary school students, which showed no further additions were necessary.

For the implementation of the cognitive test all participants (fifth-grade students) got an envelope filled with 68 concepts, one instruction form and one A_2 paper with in the middle the term trigonometry. The instruction form explained the participants to make a mind map around the word trigonometry in 15 minutes time. They could only use the concepts on the cards and a pen to connect them. Not all concepts had to be used. After 15 minutes the result was photographed and later analysed. The cognitive test measures the cognitive structure by constructing a mind map, called a cognitive map.

b) After each cognitive test the participants filled in an evaluation form. The answers to these questions were an underpinning of the results of the cognitive tests. The form contained the questions:

- *What was the assignment according to you?*
- *Did you know all used concepts?*
- *Would your cognitive map be different if you had more time? If so, what would be the differences?*

c) The modelling test was based on the theoretical framework of model conditions. The participants for this test's pilot were five master students (m/f) and two secondary school students (f). The pilot study showed that an illustration of a schematic representation had to be added to the test instruction. The modelling test was a trigonometry based problem, so the students should find connections between the right triangle, unit circle and sine as signal as function in time. The problem was a riddle that had to be solved to crack a safe. This riddle had to be decoded in goniometric steps. The students were asked to answer this problem by constructing a mathematical model. The problem mainly focused on the first two steps of a mathematical model (Blum, 2002), but could be solved with all modelling steps. The results were analysed by the following scale: insufficient, sufficient, good and very good. If the results didn't satisfy the first steps of a mathematical model it was graded insufficient. Any further step in the model resulted in a better grade.

d) The student's grades were collected during the cognitive tests. The students wrote their grades of mathematics, physics, chemistry and informatics (only if such is the case) on the envelopes, which were collected at the end of the tests and the grades were listed.

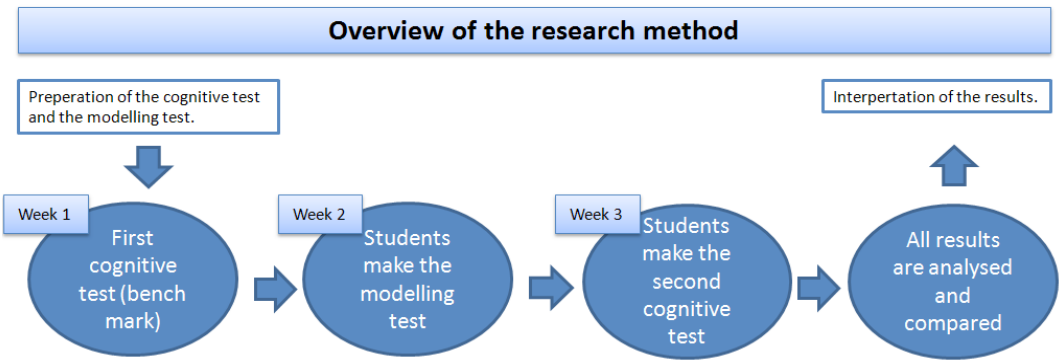

Figure 1: Overview of the research method

Data analysis

The four research instruments were each individually analysed and gathered in the overview table, which relates the data.

a) Cognitive test

The results of each participant were categorised by the depth of the cognitive map. As Figure 2 shows, the depth was determined by the amount of concepts counted from the main concept 'trigonometry'. For instance, if the maximum depth of a cognitive map was two concepts, the participant was placed in class 1. The class division was counted up to 5, as the pilot showed that a maximum of class 5 was enough. The pilot also showed that students who have a depth further than five can be placed in class 5.

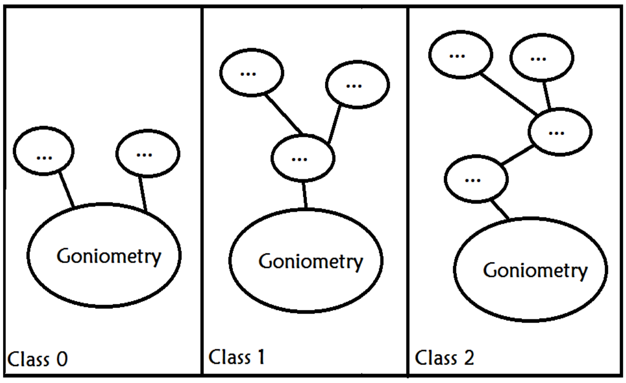

Figure 2: Examples cognitive map classification

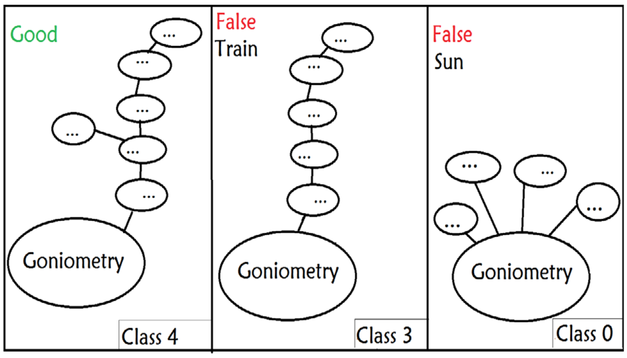

Figure 3: Cognitive maps containing 'trains' or 'suns'

There are some conditions in the classification of the cognitive maps. If students create 'trains' or 'suns' (Figure 3) in their maps it shows lack of depth. As 'sun' has no depth and a 'train' can be divided in more branches. That's why 'trains' longer than three concepts will be counted as three. Every deeper concept won't be counted, because it is always possible to further connect a concept this deep. This could mean that a cognitive map with depth 4 will be classified in class 3. The results of each participant were translated to a matrix, irrespective of classes.

The results were processed in three different kinds of matrices. Each a 68x68 matrix, constructed of *concept* x *concept*. Matrix type I was formed for each participant. The matrix cells were filled with '1' if the concerning concepts were connected. If the concepts were not connected the cell was filled with '0'. In matrix type II each [*ij*] element states the percentage of participants that connected the concept *i* with concept *j*. So, if 80% of the participants connected concept *i* with concept *j*, element *ij* was filled with 0.8. Matrix type III is a deviate of matrix type II. Each percentage smaller than 0.5 was equalled to 0. Percentages of 0.5 or larger than 0.5 were equalled to 1.

The correlation between matrix type I and matrix type III was calculated. This was done per participant per class. That means that the results of each participant was compared with the results of the other participants in the same class. The results were listed in the overview table (Table 3).

b) Modelling test

The results of this test were graded by the scale shown in Table 2.

c) Grade list

The school grades of mathematics, physics, chemistry and informatics (if such is the case) of each participant were listed. They are scaled from 1 to the upper val-

Result	Grade	Abbreviation
No form of a model and clearly no attempt to	Insufficient	I
Attempt to model, contains some elements of a model	Sufficient	S
Model, but result misses some model elements	Good	G
Model, clear and strong structure	Very good	VG

Table 2: Explanation for the evaluation of the modelling test

ue 10. The results were collected by forms that were handed out during the cognitive test.

d) Overview table

The results of each participant were collected in Table 3. The results of the cognitive test were expressed in the correlation between the students' test and the class average. This correlation represents the degree of connected concepts in the student's cognitive test compared to the class average. Students with a correlation smaller than 0.25 were selected. Based on the 3CM method, the results of these students deviate from the average results. This means that a student makes more or less connections than the average student.

RESULTS

Table 3 shows an overview of the collected results, sorted per student. It is noticeable that most students rose in classes and that more than half passed the modelling test. Also most students show sufficient results for the school grades.

Students 3, 4, 6, 7, 9, 12, 14 and 16 show correlations smaller than 0.25, but Table 3 shows no mutual connections. That means every cognitive map had to be analysed individually. Starting with the students that have a correlation smaller than 0.25, three students are insufficient graded for their modelling test. As students 3, 6 and 14 have different cognitive maps, all show little connections between the used concepts. The students with a correlation smaller than 0.25 and with a "very good" for the modelling test are students 12 and 16. Both seem to use many connections between their concepts. The results of the three other students that are graded with a "very good", 5, 10 and 13, show the same. In general, most striking cognitive maps are those of student 5 and 12. Both students use many concepts that are linked in many ways. Figure 4 shows the cognitive map of student 12. The student makes many connections, that even form loops which is not by all students. In fact, the opposite can be found in the results of student 2, 8 and 11.

CONCLUSION AND DISCUSSION

The results show some noticeable students that should be discussed, like students 3, 4 and 16. As the grades of student 3 were very high, the modelling test was graded insufficient. So it seemed that this student is highly talented. Student 4 showed a huge increase in classes. According to his cognitive maps, this seems to result from the amount of used concepts and the development in the used connections. This student seemed to give a clear result regarding the influence of the modelling test and the repetition of the cognitive test. The same applies for student 16. This student showed no progress in classes and used a small amount of concepts. Though he increased the used

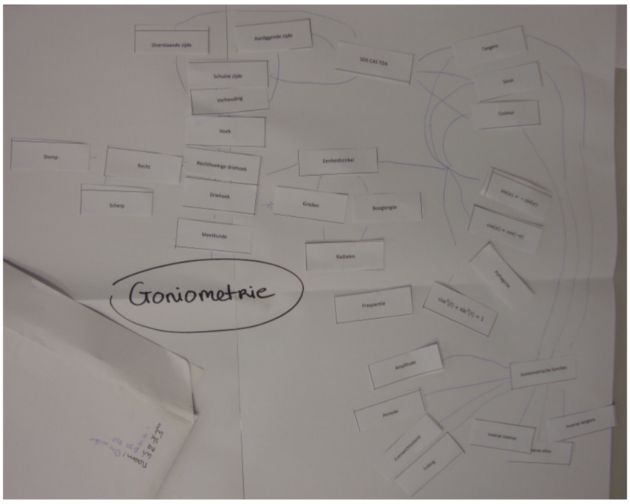

Figure 4: Cognitive map of student 12

connections in the last cognitive test. Only, it is not clear what influenced this development, was it the modelling test or the repetition of the cognitive test? This effect should be studied in further research. The results of this study prove to be a good indication for a large scale study. Although, it would be better for the analysis of the modelling test to use a more detailed checklist for evaluation. This would make it more reliable and valid.

It follows from the results that Dutch students are better in modelling if they have many connections between the concepts in their cognitive maps. This can be interpreted as the connections in the students' cognitive structure. It also follows from the results that the amount of the used concepts defines the category of the cognitive map. This represents the cognitive unit. Evident examples for this conclusion are the result of student 3, 4, 8, 12, 13, 14 and 16. So it can be stated that:

Students that are good in modelling have a rich cognitive structure. Students that are placed in a high class have a rich cognitive unit. When a student is good in modelling and is placed in a high class, there is compression. These students have a rich cognitive unit as well as a rich cognitive structure.

The cognitive structure can be developed to a rich cognitive structure by repetition. This seems to emerge from the connection between the results of the first and the second cognitive test. Repetition is definitely of indirect significance in the development of modelling

RECOMMENDATIONS

As this study shows good and useful results, it can be recommend to repeat this study with a larger group of participants. Further research should be focussed on the influences of the repetition, regarding the modelling test on the development of the cognitive structure. This study focussed on the mathematical subject trigonometry, but it can be useful to focus on different mathematical items.

ACKNOWLEDGEMENT

The authors wish to thank Michael Hekker for his contribution in this research.

Understanding issues in teaching mathematical modelling: Lessons from lesson study

Geoff Wake, Colin Foster and Malcolm Swan

School of Education, University of Nottingham, Nottingham, United Kingdom,
geoffrey.wake@nottingham.ac.uk, colin.foster@nottingham.ac.uk, malcolm.swan@nottingham.ac.uk

This paper challenges the conceptualisation of the OECD's PISA model for assessment of mathematical processes and questions common approaches to modelling in the classroom. Drawing on evidence from research using a lesson study model, we argue that the crucial formulation phase of modelling, in which bridging between context and mathematics takes place, is undervalued. Consequently, we conclude that teaching towards assessment such as, or modelled on, PISA items could provide students with an impoverished experience of modelling and leave them inadequately prepared to engage in this important mathematical practice.

Keywords: Modelling, problem solving processes, lesson study, PISA.

INTRODUCTION

> *"The formulation of a problem is often more essential than its solution"*
> (Einstein & Infeld, 1938, p. 92)

Cai and Howson (2013) argue that there is evidence of some convergence of mathematics curricula around the world due to the TIMSS and PISA series of international comparative studies. In particular, as a result of the PISA series, there has been a noticeable increase in interest in mathematical modelling and problem solving. In this article, therefore, we focus on these important aspects of mathematics in schools. We consider this a particularly pertinent time to raise issues in relation to the PISA conceptualisation of problem solving and the validity of the framework that is used to define the domain of mathematics and the test items that result.

At the heart of our concern, and research, has been developing greater understanding of how, in classroom learning, students might develop a mathematical literacy that will better prepare them to be able to apply mathematics effectively in modelling problems so that they are able to make sense of situations that arise from a range of different contexts. There has been considerable theorising and research in areas that might inform our concerns. For example, in relation to mathematical literacy see Steen (2001), for mathematical modelling see the 14th ICMI Study (Blum, Galbraith, Henn, & Niss, 2007) and for problem solving see Schoenfeld (1992). However, as a mathematics education community, our detailed understanding of teachers' classroom practices and students' actions in problem solving and mathematical modelling is much less well developed than our understanding of conceptual development. We report here results from the first year of our ongoing research in relation to the teaching of problem solving and modelling.

CONCEPTUALISATIONS OF PROBLEM SOLVING, MODELLING AND MATHEMATICAL PROCESSES

Acknowledging the important influence that the PISA series of international assessments play in informing the development of curricula, and by implication teaching and learning, around the world, we consider the PISA definition of mathematical literacy as an important starting point in understanding acknowledged conceptualisations of the field:

> Mathematical literacy is an individual's capacity to formulate, employ, and interpret mathematics in a variety of contexts. It includes reasoning mathematically and using mathematical concepts, procedures, facts and tools to describe, explain and predict phenomena. It assists individuals to recognise the role that mathematics plays in the world and to make the well-founded judgments

and decisions needed by constructive, engaged and reflective citizens. (OECD, 2013, p. 25)

Fundamental to the goal of PISA is a quest to measure the ability of students to be able to use mathematics to make sense of different contexts that have relevance and authenticity. This has implications for the age appropriateness of problems/tasks used. In developing a framework or vision of mathematical literacy in practice PISA has at its core a modelling cycle (Figure 1). Such cycles are well known (for example, see Blum & Leiß, 2007; Kaiser & Sriraman, 2006; Maaß, 2006; etc.). Although there are many variations both in the detail of the conceptualisation of the practice and its diagrammatic representation, the main the PISA diagram captures the essence of all.

Here the important processes as one moves from a contextual to a mathematical world and back again are:

- formulating – in which relevant mathematics that can lead to a solution, or sense-making, of the problem is identified. An appropriate mathematical structure and representation(s) are developed by making simplifying assumptions and identifying variables.
- employing – involves mathematical reasoning that draws on a range of concepts, procedures, facts and tools to provide a mathematical solution.
- interpreting and evaluating – involves making sense, and considering the validity, of the mathematical results/solution obtained in terms of the context in which the problem situation arises.

The cyclical representation of this overall process provides for the expectation that a refinement, or complete rethink, of the mathematical structure representing the real world situation may be desired, or even necessary. It is also important to bear in mind that progression around the cycle is not necessarily entirely one way, as there may be the need to refine thinking at any stage as the potential effects of decisions being taken become apparent and need modification as one proceeds.

The PISA framework, as in Figure 1, draws our attention to how problems may arise in a range of different contexts that can be classified as being *personal*, *societal*, *occupational* or *scientific*. Also of major importance are the mathematical content domains that in problem solving and modelling interact in symbiotic relationship with the problem-solving/modelling processes: PISA identifies these as being *quantity*, *uncertainty and data*, *change and relationships* and *shape and space*.

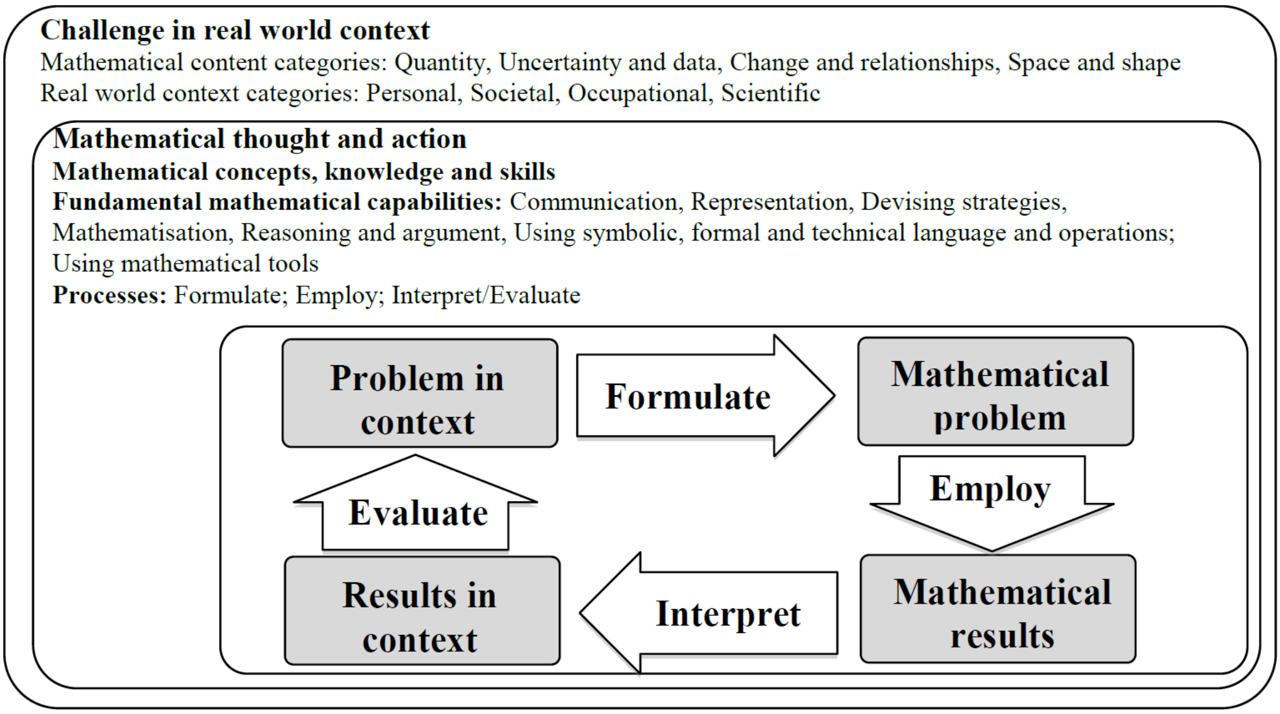

Figure 1: "A model of mathematical literacy in practice" (OECD, 2013)

In developing assessment items, it is acknowledged that it is not necessary that students engage with the whole modelling cycle: particular items may focus on only parts of modelling as a mathematical practice. This reflects the way in which adults engage with mathematics in practice, for example, in the workplace (Wake, 2014), where it is more usual to work with, or develop further, the mathematical models of others rather than start from scratch.

METHODOLOGY

Fundamental to the research project that informs this paper is a concept of professional learning that is focused on practitioner enquiry into teaching, learning and classroom practice. The project aims, therefore, to develop and research professional learning communities in which teachers work together and learn from each other, informed by 'knowledgeable others', who have a role of stimulating the community by drawing on a range of expertise that is research-informed. An adaptation of the Japanese lesson-study model (Fernandez & Yoshida, 2004) has been used and continues to evolve. This involves a community of teachers and a 'knowledgeable other' collaborating in a cyclical process that involves planning a 'research lesson', joint observation of the lesson and critical reflection in a detailed post-lesson discussion (Wake, Foster, & Swan, 2013). Lesson Study is perhaps particularly attractive, as it has the potential to meet the requirements that we know facilitate effective professional learning (Joubert & Sutherland, 2009); namely, that it is:

- sustained over substantial periods of time;
- collaborative within mathematics departments/teams;
- informed by outside expertise;
- evidence-based/research-informed;
- attentive to the development of the mathematics itself.

Here we draw on our research which has involved 3–4 teachers at each of nine schools organised in two geographically located clusters (of 5 and 4 schools), with teachers collaborating and involved in research lessons across their cluster. We adopted a case-study methodology in order to obtain rich, contextual data. This data consists of video recordings of the planning meetings, research lessons and post-lesson discussions, researcher records of students' working in research lessons, and audio recordings of interviews with teachers and other participants.

In this paper we present, as indicative of the outcomes we observed across the 30 research lessons that have been carried out within the project to date, examples from the work of two students that encapsulate their mathematical activity and learning in relation to mathematical modelling.

CASE STUDY

The task and lesson

The research lesson was with a class of 13 to 14 year-olds with little, but some, experience of working on problem-solving/modelling tasks. The students had worked on the task in the lesson prior to the research lesson, providing the teacher with insight into the

110 years on
This photograph was taken about 110 years ago.
The girl on the left was about the same age as you. As she got older, she had children, grandchildren, great grandchildren and so on.
Now, 110 years later, all this girl's descendants are meeting for a family party.
How many descendants would you expect there to be altogether?

Twentieth Century facts

At the beginning of the 20th century the average number of children per family was 3.5. By the end of the century this number had fallen to 1.7	In 1900, life expectancy of new born children was 45 years for boys and 49 years for girls. By the end of the century it was 75 years for boys and 80 years for girls.

Figure 2: Task '110 years on'. (Source: Bowland Maths Assessment tasks: http://www.bowlandmaths.org.uk/)

different ways in which they were beginning to understand the context and problem and the ways in which they were formulating a mathematical model of the problem. The inquiry focus of the lesson-study group in this particular research lesson was to better understand how mathematical representations may assist structuring and supporting mathematical thinking.

The chosen task is one from a collection of assessment tasks to be found at http://www.bowlandmaths.org.uk/. These differ from PISA tasks in that they are open-ended modelling tasks; albeit with guidance for teachers about how they might observe progression in each of the process skills such as formulating, employing and so on. In this way they are much less structured than PISA tasks leaving students with considerably more scope to explore the context. Due to restrictions of space here, we illustrate student outcomes by reference to the work of only two students, these being chosen to provide some evidence of the diversity in student thinking in this particular lesson.

Student A

Student A presented a list of key information that he considered relevant to the problem and also a list of assumptions which included the quantified factors presented in the formulation of the task. He also listed other factors that are not quantified in any way but are factors that could affect his solution. None of this is illustrated here due to space limitations. Student A's visualisation (Figure 3) of the situation effectively includes a timeline showing key years following the taking of the photograph. For example, 1903 is taken as the year in which the girl in the photograph is 13 years old. He assumed that after 3 years, in 1906, the girl married and after another 4 years, at age 20 she gave birth to 4 children. Throughout the period Student A assumed that people marry at age 16 and have children at age 20. He attempted to take account of the information that the average number of children per family was initially 3.5 by rounding to give 4 children in the first generation and then allocating a total of 14 children in the next generation (that is, that each of the girl's four children have 3.5 children). A similar logic underpinned his calculations to give the number of children in the next generation, although it is unclear how subsequent values in his diagram were calculated. Finally the student made some decisions about who from the early generations would have died in advance of the party.

Student B

Student B's representation of the situation (Figure 4) appears to show *fewer* descendants in each subsequent generation, which is contrary to what we would expect. On closer inspection of the diagram other features appear equally strange: for example, Student B distinguishes between males and females in the diagram, using a different marker for each. This leads to brothers and sisters, as well as sisters and sisters or brothers and brothers, being the parents of offspring. The calculations presented by Student B (not illus-

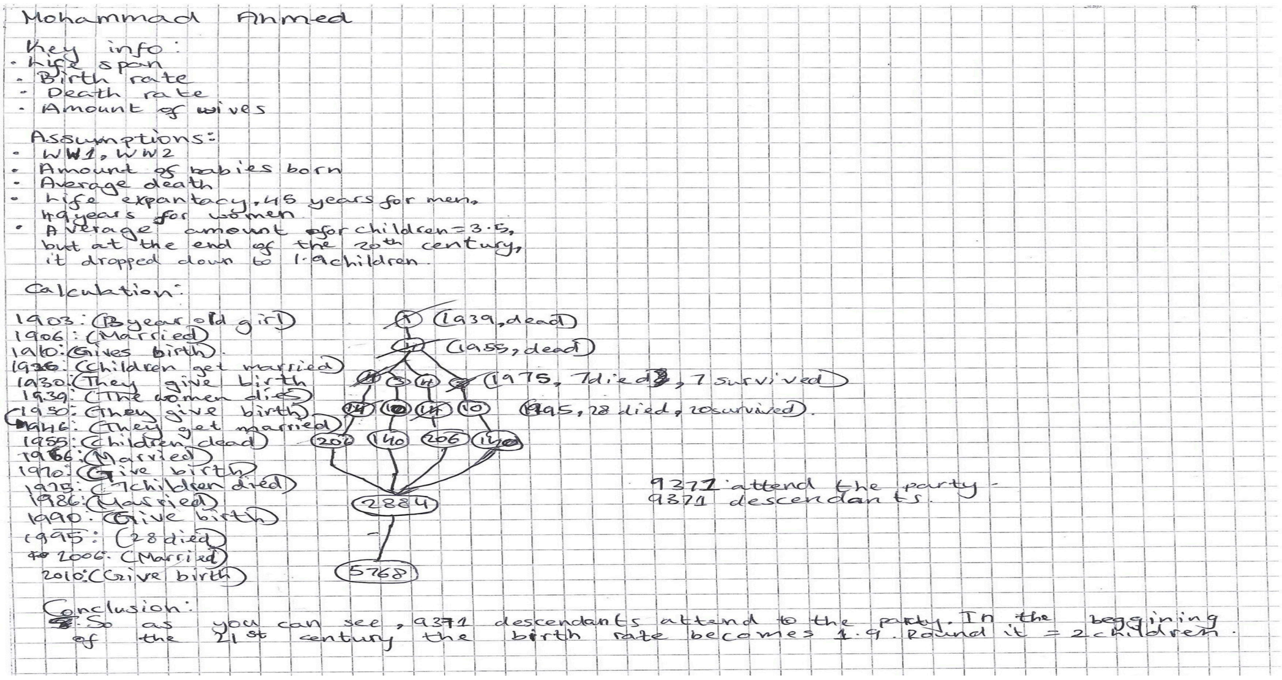

Figure 3: Extract from the response to the task '110 years on' by Student A

trated) provide insight into some of the thinking that underpins his diagram. It appears that Student B fell into the trap of selecting values given in the posing of the task and operating with these to calculate values he believed he needed to make progress. For example, he divided the information that there is a total time of 110 years between the photograph and the party by the average number of children per family (3.5) to calculate that altogether there should be 32 children. He also calculated that the girl in the photograph had 9 children by dividing 110 by 13 (the girl's age at the time of the photograph).

ANALYSIS AND DISCUSSION

As can be seen from the examples of the work of the two students illustrated here, the students not only arrived at very different solutions, they have very different understandings of the context/situation. Indeed, it appears that student B did not have an appropriate understanding of the situation at all. This was also true of some of the other students in the class, as evidenced by their representations and calculations. Of course we would expect varied approaches by students working on a modelling task, but here it is clear that some of the models being *formulated* were invalid.

Our experience across, and analysis of data from, lessons confirms that this is a common occurrence and leads us to contend that there are essential aspects of both problem solving and modelling that are under-emphasised in school practices when compared to similar practices in out-of-school settings. Crucially, in the process of *formulating*, the difficulty associated with understanding a complex context, and how this needs to be simplified so that it can be represented mathematically, is underestimated. This process requires an understanding of how a range of mathematics (concepts, procedures, facts and tools) might best be marshalled to provide a mathematical structure to represent the problem context/situation. Such understanding is important and needs to inform the simplification of the context/situation. Pollack (1969), Borromeo Ferri (2006) and Treilibs (1979), among others, draw attention to this important aspect of mathematical modelling. Across our case studies we note that students have particular difficulties with this crucial first step in modelling.

This leads us to emphasise that the mathematical model being developed to provide a mathematical structure that maps to a *simplified* structure of the reality it represents. In the initial phase of developing a mathematical model, this simplification of reality to provide what is in effect a model of reality or 'real model' is not necessarily a simple matter. The structure that is proposed has to be a realistic representation, capturing essential elements of what might in fact be a complex situation, *and* it has to be such that the modeller can use mathematics that they know and are comfortable to work with. Borromeo Ferri (2006) discusses how

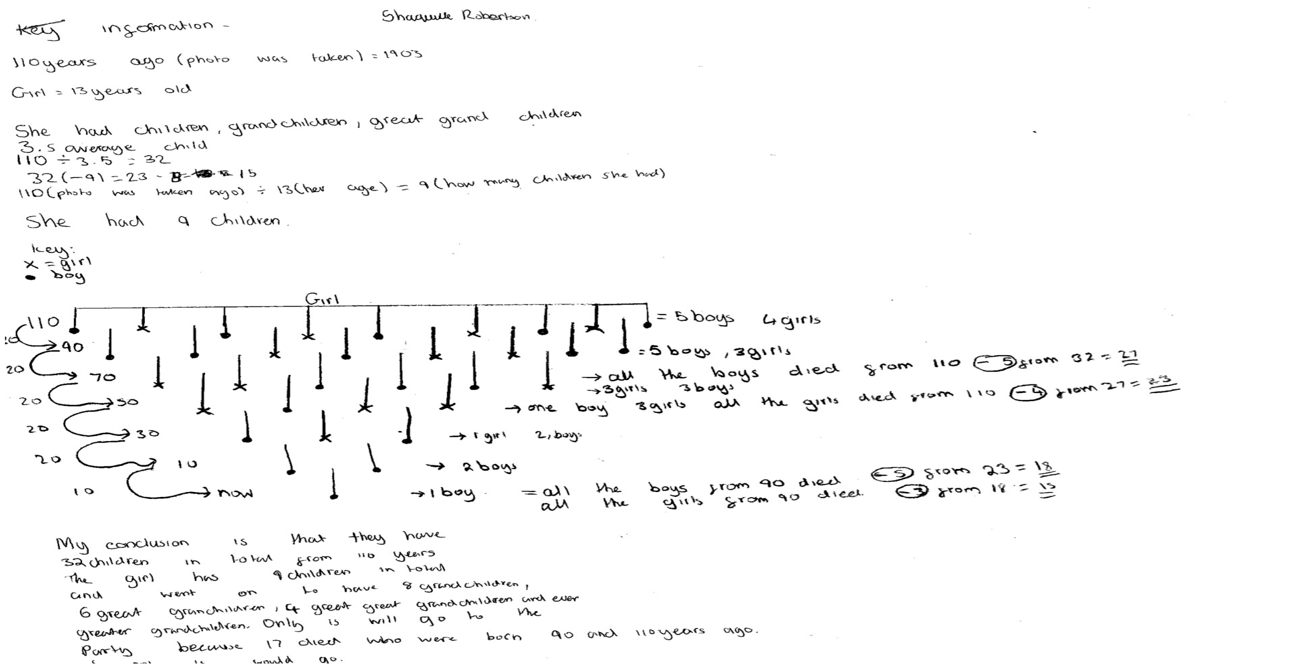

Figure 4: Response to the task '110 years on' by Student B

different researchers have attempted to characterise this early stage in the modelling cycle and identifies the terms 'situation model', 'mental representation of the situation' and 'real model' as being of significance here. Integral to this stage of mathematical modelling is the development of an understanding of the task: this should not necessarily be assumed as unproblematic. Blomhøj and Højgaard Jensen (2003) in their description of the modelling process and associated schema identify early processes as involving 'formulation of task' and 'systematisation', with the latter relating to making sense of the reality of the problem situation. Treilibs (1979) breaks down the formulation phase into subtasks, such as: modelling the situation by making simplifying assumptions, identifying relevant variables, generating relationships, and so on. Whatever terms we use to describe these initial steps towards being able to work mathematically, we have found that for many students the formulating stage can prove problematic and generate a lot of questions and discussions before a mathematical model can be developed.

Our consideration of this issue and how we might present tasks that involve students in effective mathematical modelling practices has raised the question of distinguishing between problem solving and modelling. We consider that mathematical models are mathematical structures that map to, or represent, a simplification of a real context, and as such they are useful when they have repeated use so as to consider variation of (a) factor(s) in the reality. For example, in the students' response to the task illustrated in this article assumptions made about the age at which people have children could be varied and the impact on results considered. In relation to this aspect of a mathematical model, we recognise that there are canonical models, such as exponential functions, inverse square laws, etc. that can, with adaptation, be used across numerous contexts and situations. In such cases, features of the mathematical model relate to factors and structure of the reality. For example, the growth of a population can be considered exponential when the rate of growth is proportional to the size, P, of the population, with the value of k in the equation $P=P_0e^{kt}$ being related to the time it takes the population to double in size. In mathematics teaching we are concerned with such adaptations as well as with models that are bespoke to particular contexts and situations, such as in the task presented in this article.

In either a canonical model or a bespoke model, change of an identified factor in the reality results in change of a variable in the mathematical structure (model), and vice versa: that is, varying factors in the mathematical model has implications for the reality it represents. This, we use to distinguish between solving a problem using mathematics (which also has a mathematical structure that maps to a simplified reality) and modelling. In the case of problem solving, there is a single solution, albeit dependent on decisions taken to simplify the reality (which may eventually be modified/refined); on the other hand, in the case of modelling, the expectation is that there will be variation of important factors and repeated use of the model. We consider drawing attention to this characteristic of a mathematical model as having importance as a potential pedagogical vehicle that can be used to focus students' attention on the aspects of modelling that we identify as being under-emphasised in school mathematics. These aspects are (i) the simplification of reality and (ii) the development of a mathematical structure that represents, or maps onto, the simplified reality, with each of these needing to be informed by detailed understanding of the implications and potential of each other.

In the examples of student working that we present here we note that it is clear that the students' representations, and by implication their simplification of reality, do not adequately capture the essence of the situation in order to allow them to successfully arrive at a valid solution. In this particular lesson the variation in student approach to the problem and consequently their understanding was perhaps the most significant and immediate observation made by the observers of the lesson. Although developing a family tree was the most typical approach each student's manifestation of this suggested at least minor differences in their understanding of the context leading to significant differences in the assumptions being made, and consequently variables and fixed values decided upon. Some students took very different approaches with at least one student providing an entirely textual solution with no apparent diagrammatic visualisation or calculations evident. This variation in understanding resulted in solutions that were also very different with the number of descendants varying from values that were less than fifty to values greater than 1000. The focus for the students appears to have been on arriving at a single solution rather than developing an appropriate mathematical structure for the situation. This is particularly starkly visible in the work of Student B. It seems likely that a pedagogical approach that focused on developing a model that could have repeated application, allowing for variation of a key factor, such as the time between generations, has the potential to force this issue in the classroom. In considering the design of tasks that might be appropriate to bring to the surface the important aspects of modelling that we have identified, we have found that introducing the requirement for students to work towards a product, such as an explanation to a particular audience about the effects of varying a particular factor in the reality, is potentially helpful in generating awareness of this aspect of modelling/using models. For example, in the case of '110 years on' we suggest that students might be required to write advice and explain to a caterer possible maximum and minimum numbers of guests at the party.

We suggest that greater emphasis should be given to model development in mathematics lessons; this seems crucial if we are to support student learning of effective modelling. We note that this appears under-emphasised in the PISA organising framework for the mathematics domain and, as a consequence, and importantly, in their assessment items (OECD, 2013). We therefore urge that there needs to be careful thought about how best to support students' learning in curricula based on PISA's conceptualisation of the mathematics domain. As it currently stands, we view that teaching towards a PISA notion of problem-solving/modelling may not support the mathematically literate students we seek. We also recommend further research in this area of modelling as a classroom practice in mathematics so that we are better informed about student learning, and what it means to make progress in learning, in this important area.

Identifying ways to improve student performance on context-based mathematics tasks

Ariyadi Wijaya[1], Marja van den Heuvel-Panhuizen[2,3] and Michiel Doorman[2]

3 Faculty of Social and Behavioural Sciences, Utrecht, Netherlands

This paper reports the Context-based Mathematics Tasks Indonesia (CoMTI) project that was aimed at getting a better insight into Indonesian students' low performance on context-based tasks and identifying ways to improve it. The project addressed three main issues: (1) Indonesian students' difficulties when solving context-based tasks; (2) possible reasons for students' difficulties; and (3) offering students opportunity-to-learn and testing its effect on student performance. These issues were investigated in four consecutive studies. The studies revealed that the students' difficulties are related to students' opportunity-to-learn.

Keywords: Context-based mathematics tasks, modelling, low achievement, Indonesian students, opportunity-to-learn.

BACKGROUND OF THE STUDY

The ability to apply mathematics is considered as a core goal of mathematics education around the world (see, e.g., Eurydice, 2011; NCTM, 2000). This goal is similar to what in the Programme for International Student Assessment (PISA) is called mathematical literacy, which refers to students' ability "to identify, and understand, the role that mathematics plays in the world, to make well-founded judgments and to use and engage with mathematics in ways that meet the needs of that individual's life as a constructive, concerned, and reflective citizen" (OECD, 2003, p. 24). To develop students' ability to apply mathematics, it is recommended to offer students mathematics problems situated in real-world contexts (De Lange, 2003; NCTM, 2000). In PISA study problems with real-world contexts are used to assess mathematical literacy (OECD, 2003).In this paper such problems are called context-based tasks and defined as tasks that are situated in real-world settings and provide elements or information that need to be organized and modelled mathematically.

Similar to many other countries, Indonesia also places a premium on applying mathematics as a core goal of mathematics education and pays attention to the use of context-based tasks (Pusat Kurikulum, 2003). Nevertheless, there is an apparent discrepancy between this goal and student achievement. The PISA results showed that Indonesian students perform low on context-based tasks. More than three quarters of Indonesian students did not reach the baseline Level 2, which means they could only answer tasks that have familiar contexts and present all relevant information (OECD, 2010). The low performance of Indonesian students on context-based tasks prompted an establishment of a project called "Context-based Mathematics Tasks Indonesia" (CoMTI), which was aimed at getting a better insight into Indonesian students' low performance on context-based tasks and identifying ways to improve student performance.

KEY IDEAS FROM LITERATURE

Solving context-based mathematics tasks

Solving mathematics problem situated in real-world contexts, which in this paper are called context-based tasks, requires interplay between the real world and mathematics, which is often described as a modelling process. According to Blum and Leiss (2007) the process of modelling is considered to be carried out in seven steps. The first step is establishing a 'situation model' to understand the real-world problem. Second, developing the situation model into a 'real model' through the process of simplifying and structuring. Third, constructing a 'mathematical model' by mathematizing the real model. The fourth step is carrying out mathematical procedure to get a mathematical solution. In the fifth and sixth steps, the mathematical solution is interpreted and, then, validated in terms of the real-world problem. The final step is communicating the real-world solution. This modelling process is similar to what is called 'mathematization' in PISA studies (OECD, 2003). Mathematization involves: understanding the problem situated in reality; organizing the real-world problem according to mathematical concepts and identifying the relevant mathematics; transforming the real-world problem into a mathematical problem which represents the situation; solving the mathematical problem; and interpreting the mathematical solution in terms of the real situation.

Opportunity-to-learn

A so called 'opportunity-to-learn' is often used to find an explanation for students' mathematics performance. In the First International Mathematics Study opportunity-to-learn was defined as "whether or not [...] students have had the opportunity to study a particular topic or learn how to solve a particular type of problem" (Husén, 1967, pp. 162–163). This definition was further specified by Brewer and Stasz (1996) who distinguished three aspects for measuring opportunity-to-learn. First, *curriculum content*, which refers to the scope of the topics offered to students. Second, *teaching strategies* that are used by teachers to present the topics and to engage students. Third, *learning materials*, such as textbooks, which are used to teach the students.

THE COMTI PROJECT

Although there are different ways used in different countries to improve educational achievement, improving Indonesian students' performance cannot be simply done by applying an educational practice that is used in other countries because, according to Pearson (2014), what works in one particular country will not necessarily give the same result in other countries. Careful thought about what is missing in current educational practices and what might be needed by students is necessary. Therefore, in order to identify possible ways to improve Indonesian students' performance the CoMTI project focused on three interrelated issues regarding context-based tasks in Indonesia. First, *what* difficulties are experienced by students when solving context-based tasks. Second, *why* students have difficulties, for which we investigated opportunity-to-learn to solve context-based tasks offered in Indonesian textbooks and in teachers' teaching practices. Lastly, to study *how* student performance can be improved, we offered students opportunity-to-learn to solve context-based tasks and test its effects on students' performance. These three issues were investigated in four studies, which are described in the following sub-sections.

Indonesian students' difficulties in solving context-based tasks [Study 1]

The first study of the CoMTI project was aimed at getting a better insight into the low performance of Indonesian students on context-based tasks. In this study the difficulties experienced by Indonesian students when solving context-based tasks were examined through an analysis of students' errors. This approach was chosen because students' errors provide access to students' reasoning and are considered as a powerful source to diagnose learning difficulties (Borasi, 1987). With respect to analysing students' difficulties in solving mathematical word problems, Newman (1977) developed a model that is known as Newman Error Analysis. Newman proposed five categories of errors, i.e. reading (error in simple recognition of words), comprehension (error in understanding the meaning of a problem), transformation (error in transforming a word problem into an appropriate mathematical problem), process skills (error in performing mathematical procedures), and encoding (error in representing the mathematical solution into written form).

Method

A total of 362 students from 11 schools in the Province of Yogyakarta, Indonesia participated in a so called CoMTI test. The test items were selected from the released PISA mathematics tasks. After the CoMTI test, an error analysis was carried out on the basis of students' incorrect responses to investigate the difficulties experienced by students. For this purpose, an analysis framework was developed based on Newman's error categories that were associated with the stages of modelling process and PISA mathematization. The analysis framework comprised four types of errors: comprehension, transformation, mathematical processing, and encoding. Newman's reading error was not used in our framework because this error category refers to a technical aspect and does not match to modelling process or PISA's mathematization.

Results and discussion
The error analysis revealed that of 1718 errors made by the students 38% were comprehension errors, 42% were transformation errors, 17% were mathematical processing errors, and 3% were encoding errors [1]. A closer examination of the comprehension and transformation errors disclosed that a half of the comprehension errors were errors in selecting relevant information. We also found that two thirds of the transformation errors were errors in selecting mathematical procedures required to solve the tasks.

The results of the error analysis indicate that Indonesian students mostly experienced difficulties in comprehending a context-based task and in transforming it into a mathematical problem. In addition to these specific results, this study showed how analysing students' difficulties can be a crucial preliminary step in the process of improving student performance because it sheds light on key aspects of solving context-based tasks that need to be developed. The findings of this study suggest that improving the task comprehension of Indonesian students requires a focus not only on students' language competence, but also on the ability to select relevant information. Furthermore, the ability to identify the required procedure or concept was found to be another key competence that needs to be improved.

Opportunity-to-learn to solve context-based tasks offered in Indonesian mathematics textbooks [Study 2]
The next step in the CoMTI project was identifying possible explanations for students' difficulties. Several studies have shown that student performance is often influenced by textbooks. Tornroos (2005) found a relation between student achievement on a test and the amount of textbook content related to the test items. The method used in a textbook to help students understand the content is also an important aspect influencing student performance. As found by Xin (2007), students tend to solve word problems by using the solution strategies suggested in the textbooks. Another aspect of a textbook that has an influence on student performance is the cognitive demands of the tasks. What competences students will master depends on the cognitive demands of mathematics tasks they are engage in.

Considering the important influence of textbooks on student performance, in the second study of the CoMTI project we investigated the opportunity-to-learn context-based tasks offered in Indonesian textbooks. Three issues were addressed in this study: (1) the amount of exposure to context-based tasks in Indonesian textbooks, (2) the characteristics of the context-based tasks in the textbooks, and (3) the relation between the characteristics of textbook tasks and students' errors.

Method
Three mathematics textbooks that were used in the schools participating in the first study of the CoMTI project were analysed. For this purpose, we developed an analysis framework that focused on three task characteristics. First, the type of context for which we used three types of context: relevant and essential context, camouflage context, and no context. Second, the type of information provided in a task: matching information, missing information, and superfluous information. Third, the cognitive demands of a task: reproduction, connection, and reflection tasks.

Results and discussion
The textbook analysis revealed insufficient number of context-based tasks in Indonesian mathematics textbooks [2]. Only 10% of tasks in the textbooks were tasks that used either camouflage or relevant and essential context. Of these tasks, three quarters used camouflage context, i.e. the context can be ignored in the solving process, and explicitly implied the required mathematical procedures. This finding indicates that Indonesian textbooks do not offer students enough opportunity-to-learn to identify mathematical procedure that is required to solve a context-based task, which might explain the high number of transformation errors made by students. An in-depth analysis of the task characteristics revealed that of 276 context-based tasks in the three textbooks 88% provided only the information that is needed to solve the tasks (matching information). This result signifies a lack of opportunities for students to learn to select relevant information, which might contribute to students' comprehension errors, in particular errors in selecting information. Lastly, regarding the cognitive demands, of all context-based tasks in the textbooks almost no

reflection tasks, i.e. tasks that require complex reasoning and a construction of original mathematical approaches.

Opportunity-to-learn to solve context-based tasks offered by Indonesian teachers' teaching practices [Study 3]

Several studies (e.g., Eurydice, 2011; Grouws & Cebulla, 2000) showed that student performance is affected by the teaching strategies used by teachers. How teachers teach mathematics and engage their students influences how well students learn. With respect to the teaching of context-based tasks, Antonius, Haines, Jensen, Niss, and Burkhardt (2007) argued that it requires more than an 'explanation-example-exercise' ritual because such directive approach does not offer students opportunity to develop strategic competences that are necessary to solve context-based tasks. Instead of using direct teaching, teachers should use a teaching approach in which they take a consultative role and give students opportunities to actively build new knowledge and reflect on their learning process (Antonius et al., 2007; Blum, 2011).

The purpose of this third study was to investigate the opportunity-to-learn (OTL) to solve context-based tasks offered in teachers' teaching practices. For this purpose, we investigated the teaching approach that was used by teachers to help students learn to solve context-based tasks. Teachers' beliefs were also investigated because they often influence teachers' teaching practices (see, e.g. Wilkins, 2008). Lastly, we investigate whether there was a relationship between the OTL to solve context-based tasks offered by teachers and the errors made by students when solving such tasks.

Method

A teacher survey and a series of classroom observations were used in this study. The survey was aimed at investigating teachers' beliefs and teachers' reported practices regarding the characteristics of context-based tasks offered to students. The classroom observations were carried out to investigate the teaching approaches used by teachers to help their students learn to solve context-based tasks.

Twenty-seven teachers from the schools involved in the first study of the CoMTI project participated in the teacher survey and four of them participated in the classroom observations.

Results and discussion

The survey data showed that the teachers tended to perceive context-based tasks merely as plain word problems. They believed that the mathematical procedure required to solve a context-based task should be given explicitly. Furthermore, the teachers also did not consider missing and superfluous information as an important characteristic of a context-based task. In agreement with these beliefs, the teachers reported that they frequently offered their students context-based tasks that have explicit procedures, but rarely gave context-based tasks that provide superfluous or missing information. Such practice might explain students' difficulties in identifying the required procedures and in selecting relevant information.

The classroom observations revealed that the teachers mainly used directive teaching approach in which they tell the students what a context-based task is about, translate the task into a mathematical problem, and explain what mathematical procedure to be carried out. In such teaching students were not encouraged to actively carry out and reflect on the stages of solving context-based tasks. This directive teaching approach was mostly used in the comprehension and transformation stages. Consultative teaching in which students were actively engaged in the process of solving context-based tasks was barely used by the teachers. Moreover, this teaching approach was mostly observed in the mathematical processing stage; a stage in which students do not have to deal with the context of a task.

Correspondences were indicated between teachers' teaching practices and students' difficulties. A lack of opportunities for students to paraphrase a context-based task might be related to students' difficulty in comprehending the task because, as pointed out by Kletzien (2009), paraphrasing helps students understand the text of a task. Moreover, teachers' direct advice regarding the procedures to be carried out might correspond to students' transformation errors because it might discourage students from thinking about the mathematics concepts addressed in the task.

Effects of opportunity-to-learn on Indonesian students' performance in context-based tasks [Study 4]

For teaching context-based tasks it is recommended to use teaching practice that emphasizes on guiding students to construct new knowledge actively and independently by using their prior knowledge and experiences (Antonius et al., 2007; Blum, 2011), which in the CoMTI project is called 'consultative teaching'. Blum (2011) found that students who learned through such teaching approach made a better progress regarding their modeling competence in comparison to students who were taught with directive teaching. In addition to teaching practices, it is also important to give students tasks that have superfluous and missing information and do not provide explicit suggestions about the required procedures (Maass, 2007).

The second and the third studies of the CoMTI project revealed a lack of opportunity-to-learn offered in Indonesian textbooks and in teachers' teaching practices. Therefore, in the final study of the project an intervention that offers students opportunity-to-learn to solve context-based tasks was developed. The effects of opportunity-to-learn on students' performance in solving context-based tasks were examined from the perspectives of students' score gains and students' errors.

Method

A field experiment with a pretest-posttest control-group design was used in this study, which involved a total of 299 students (144 students were in the experimental group and 155 students in the control group) from six schools.

An intervention program comprising a set of context-based tasks and a consultative teaching approach was used in the experimental group. The context-based tasks used in the intervention had three important characteristics: relevant and essential context, superfluous or missing information, and not explicit suggestion about the required mathematical procedures. The consultative teaching used metacognitive prompts, which included self-addressed questions and verbal prompts or instructions to help students focus attention on particular aspects of the solving process such as asking students to paraphrase a task and to underline relevant information.

Results [3] and discussion

A univariate ANOVA with the gain score (posttest score minus pretest score) as dependent variable and intervention as a fixed factor was carried out to investigate the effect of the intervention. Contrary to our expectations, the difference in gain scores between the students in the experimental group ($M_{experimental}$ = 0.11, $SD_{experimental}$ = 0.99) and the students in the control group ($M_{control}$ = -0.09, $SD_{control}$ = 0.95) was only marginally significant and the effect of the intervention was small ($p = .068$; $\eta_p^2 = .011$). Nevertheless, a closer examination of the effect of the intervention on students' errors revealed a significant difference between the experimental group and the control group for the decrease in the total number of errors (χ^2 (1, n = 4127) = 4.149, $p = .042$). This finding reflects a positive influence of the opportunity-to-learn on reducing students' errors. Students who received the opportunity-to-learn could better understand the instruction for a context-based task and had improved performance in selecting relevant information. With respect to transforming a real-world problem into a mathematical problem in general no influence of the opportunity-to-learn was found. However, a positive influence was found for context-based tasks addressing graphs – i.e. the topic taught during the intervention period – in which students who got the opportunity-to-learn were better able to give a mathematical interpretation of a graph. Reflecting upon this finding and referring to Howson (2010), it can be learned that to improve students' ability to identify the required procedure it is essential to provide not only context-based tasks that are related to the topic being taught, but also context-based tasks that address other topics.

FINAL REMARKS

In general, the results of the CoMTI study suggest two important ways to identify and to improve student performance; i.e. diagnosing students' difficulties and identifying opportunity-to-learn offered to students. By connecting students' difficulties with opportunity-to-learn, we could identify what was missing in the educational process. Our results show that textbooks and teaching practices are key aspects to improve students' performance on context-based tasks.

In the appendix we provide the summary of the findings of the four studies in the CoMTI project and show how the results of the four studies are interrelated.

APPENDIX: THE RESULTS OF THE COMTI PROJECT

STUDENTS' DIFFICULTIES (*Study 1*)

Analysis of Indonesian students' errors when solving context-based tasks

The most dominant error types:
- **comprehension** errors; in particular, errors in selecting relevant information.
- **transformation** errors; in particular, errors identifying the required mathematical procedures.

POSSIBLE REASONS FOR STUDENTS' DIFFICULTIES: OTLS AS A KEY CONCEPT (*Study 2* and *Study 3*)

Analysis of Indonesian mathematics textbooks

Exposure of the context-based tasks:
- Only about 10% of all tasks were context-based.

Characteristics of the context-based tasks:
- most of the tasks used *camouflage contexts* and provide explicit indications about the required mathematical procedures.
- most of the tasks provide *matching information*, i.e. only the information that is needed to solve the tasks.
- almost no *reflection tasks*, i.e. tasks with highest cognitive demands which require constructing original mathematical approaches and communicating complex arguments and complex reasoning.

An investigation into Indonesian mathematics teachers' teaching practices

Teachers' report about the **characteristics of context-based tasks** offered to students:
- most of the teachers frequently give tasks with *explicit procedures*
- most of the teachers frequently give tasks with *matching information*
- a half of the teachers never or rarely give tasks with *superfluous information*
- a half of the teachers never or rarely tasks with *missing information*.

Teachers' **teaching approach**:
Over all stages of solving context-based tasks:
- *No instruction* was given in 42% of all questions discussed in the lessons.
- *Directive teaching* was applied in 47% of all questions discussed in the lessons.
- *Consultative teaching* was applied in only 12% of all questions discussed in the lessons.

Specified for the stages of solving context-based tasks:
- Directive teaching was most frequently applied in the comprehension and the transformation stages.
- Consultative teaching was mostly applied in the mathematical processing stage.
- Almost no attention was paid to the encoding stage.

OTL AND STUDENT PERFORMANCE (*Study 4*)

Offering students opportunity-to-learn (OTL)		**Effects of the OTL on students' performance**
Context-based tasks:	**Consultative teaching approach with metacognitive prompts:**	
- Context-based tasks with missing or superfluous information.	- Paraphrasing: asking students to formulate a task in their own words. - Underlining all information and circling only the relevant information - Self- questioning; e.g. *"Do we have enough information to solve the task?"*	A positive effect of the OTL on students' task comprehension was found: - Students could understand better the instruction of the task - Students' ability to select relevant information improved
- Context-based tasks with a relevant context that requires modeling - Context-based tasks with non-explicit procedure	- Self-questioning; e.g. *"What are possible strategies to solve the task?"*	- In general no effect of the OTL on students' ability to transform a real-world problem into a mathematical problem. However, a positive effect was found for tasks addressing an interpretation of a graph, which in fact was related to the topic taught during the intervention. - This finding leads to a recommendation to offer students 'mixed exercises', i.e. a set of context-based tasks that address various topics.

'Literature' on mathematical modelling from a teacher perspective: A textbook's portrayal

Anders Wolfsberg

University of Copenhagen, Faculty of Science, Copenhagen, Denmark, rnp123@alumni.ku.dk

In this paper, it is proposed to reformulate the question of whether modelling as depicted in academic literature is insufficiently implemented in school. Rather, the question proposed is: what form of modelling is actually portrayed in textbooks and curricula – understood as teachers' 'literature' on mathematical modelling?

For illustration, a case is offered wherein perspectives on modelling are traced from academic literature, through curriculum, and an upper secondary textbook, all taken from a Danish context. It is discussed how the textbook's portrayal of mathematical modelling deviates from that in academic literature. Further, it is suggested that this deviation – this gap – may be closed by fitting the version of modelling to be implemented better to the institutional structure of upper secondary school.

Keywords: Mathematical modelling, textbook portrayal, connecting research to practice.

INTRODUCTION AND DISPOSITION

Large scale implementation of mathematical modelling (hereinafter modelling) activities in mathematics education is a visionary project that has been under way for the past several decades. According to many researchers it is still present in mathematics classrooms to a degree far from satisfactory (Barquero, Bosch, & Gascón, 2010).

The aim of this paper is to understand better the causes and consequences of the apparent gap between research on modelling, and modelling as taught in practice.

One may take the position that researchers have a particular 'vision' of a subject to implement in practice – their version of modelling. Observing that it is not satisfactorily implemented, one is led to the question: 'what are the obstacles hindering its implementation?' This paper proposes a change of perspective.

Instead, the viewpoint taken is that a subject known as mathematical modelling exists in the upper secondary school institution, one that is different from the subject conceived of in academic research. Hence, it is integral to find out what this subject is, how it relates to academic perspectives, and why it takes the form it does. This might guide the way in conceiving of a version of modelling that is better fit to be implemented in teaching-in-practice in school classrooms.

A case is presented wherein a particular notion of mathematical modelling is traced from academic literature, throughout curriculum documents to a textbook's portrayal. All three samples constituting the case are taken from a Danish context.

The case is taken as point of departure for a discussion of the differences between two versions of modelling: that which is portrayed in academic literature, and that portrayed in textbooks and curricula – 'literature' implemented in secondary school.

DIDACTIC TRANSPOSITION

Theory of Didactic Transposition (TDT) is a theoretical framework developed by Yves Chevallard. TDT describes the transition of scholastic knowledge produced in universities throughout the educational system, e.g., curriculum and textbooks, to teaching situations. The mathematics being taught is not the same as that being produced in research institutions. Indeed, academic knowledge naturally undergoes changes when transposed through curriculum into textbooks (Winsløw, 2011).

The *external* transposition process takes place in what is called the 'noosphere' where 'scholarly knowledge' is transformed into 'knowledge to be taught', to be found in, e.g., curriculum and textbooks.

> The first step [the external transposition] corresponds to the study of the *formation* of the 'teaching text' (...) and highlights the conditions and constraints under which the 'knowledge to be taught' is constituted (...) (Bosch & Gascón, 2006, p. 56)

The *internal* transposition describes how teachers adapt and implement the knowledge into the very teaching situation (Winsløw, 2011).

Didactic knowledge such as that on *teaching mathematical modelling and promoting modelling competency* is produced in communities of mathematics and educational science researchers. However, the knowledge emerges in curriculum and textbooks (often by the work of others) in a transposed form more or less dissimilar to that envisioned by educational researchers.

Thus, in a TDT view, incoherencies between knowledge of (some) researchers, and that portrayed in textbooks, and applied by teachers, is a naturally occurring phenomenon. Indeed, constructing a so-called *epistemological reference model* (hereinafter reference model) of knowledge on a given topic in all levels of the didactic transposition allows for analysing these incoherencies (Winsløw, 2011).

METHOD OF ANALYSIS

The case study consists of three samples of 'knowledge on mathematical modelling': one from academic literature, one from curriculum, and one from a textbook. The contents of these samples are analysed qualitatively. In view of TDT this method corresponds to constructing a three-level reference model for 'knowledge on modelling' – a view of modelling in three different 'spheres' of the educational system. Hence, only the external transposition is analysed in this case.

All three samples are taken from a Danish context but are of international relevance. Thus, the scope on literature focuses on Danish researchers who work with mathematical modelling and the concept of modelling competency as used and developed by Mogens Niss. Niss has had significant influence on the wording of Danish mathematics curriculum via the KOM project on mathematical competencies (Blomhøj & Kjeldsen, 2010). Furthermore, interpretations of the modelling subject such as that of Niss are widely used in international literature on modelling (see, e.g., Niss, Blum, & Galbraith, 2007). The textbook is one of the most widely used in Danish upper secondary mathematics teaching.

In the following three sections, views on mathematical modelling as portrayed in academic literature, curriculum, and textbook are extracted.

Inspiration has been drawn from Julie and Mudaly (2007), who identify two categories for tendencies in didactical research on teaching modelling: 'modelling as vehicle' and 'modelling as content'. In a modelling as vehicle perspective, modelling is conceived of as providing motivation and support for learning of other mathematical subjects. As content, modelling is conceived of as a topic in itself.

In the following analysis and extraction of academic views, and curriculum and textbook descriptions, the focus is set on the category of modelling as content. Thus, content is sampled that describes modelling as educational content, not as a way of teaching. What is excluded are views on how modelling could or should be taught.

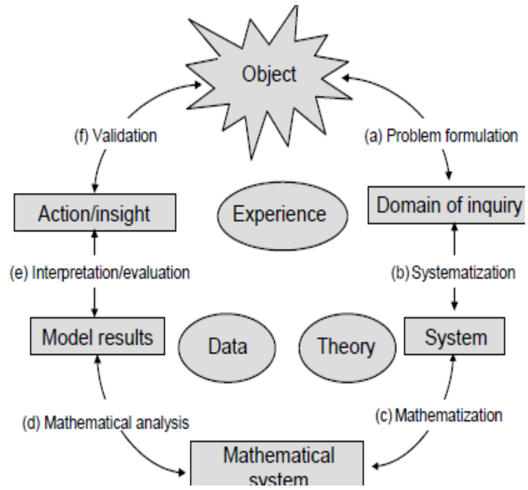
ACADEMIC VIEW ON MODELLING

Models and modelling

Niss (1989) defines a mathematical model as a triplet (A,f,M) of three domains denoting an extra-mathematical domain, A, a mathematical domain, M, and then a mapping, f, between the two. The domains must be understood abstractly as "collections of relationships, phenomena, questions (and possible answers) and such-like" (Niss, 1989, p. 28).

Niss identifies modelling with model construction, and in defining the concept, he characterises the process that signifies general model construction processes. We find an equivalent characterisation of the modelling process in Blomhøj & Kjeldsen (2010, pp. 3–5), illustrated in Figure 1 – the modelling cycle.

The process is illustrated cyclically since the object to be modelled often is redefined progressively. Between the sub-processes are double-headed arrows to indi-



a) Formulation of a task (more or less explicit) that is related to a perceived reality and influenced by the modeller's interests. Through this process the object of the modelling process is constructed. The object can be reconstructed as a result of the modelling process. However, it is the object and the formulated task that guides the identification and construction of a domain of inquiry.
b) Selection and construction of the relevant objects, relations etc. from the domain of inquiry, and idealisation of these, in order to make a mathematical representation possible.
c) Transformation and translation of selected objects and relations from their initial mode of appearance to mathematics by further abstraction and idealisation.
d) Using mathematical methods to achieve mathematical results and conclusions.
e) Interpretation of these as results and conclusions regarding the system or th initiating domain of inquiry.
f) Evaluating the validity of the model by comparison with data (observed or predicted) and/or with already established knowledge (theoretically based c shared/personal experience based)

Figure 1: Left: the modelling cycle/process. Right: the six sub-processes (Blomhøj & Kjeldsen, 2010, p. 4)

cate that activity in any one sub-process influences the entire model in either direction simultaneously. The sources of information for the model are shown in the three ellipses.

Niss (1989) points out, on the nature of models, that "Models are designed to model *something* – not to be confused with something *unique*." (p. 31).

Modelling competency

The modelling competency is one of eight mathematical competencies identified by Niss in the KOM Project which are characteristic to mathematical activity. Mathematical competency is described as "someone's insightful readiness to act in response to the challenges of a given situation" (Blomhøj & Jensen, 2007, p. 47). Specifically, the modelling competency is characterised as:

> A person's insightful readiness to autonomously carrying through all aspects of a mathematical modelling process in a certain context and to reflect on the modelling process and the use of the model (Blomhøj & Kjeldsen, 2010, p. 3)

Thus, "insightful" and "reflect on" indicates that, for teaching purposes, abilities beyond mere mechanical skills are sought in students. The student must be able to construct models, and "autonomously" at that. Furthermore, it is emphasised that the student in this regard be able to consider a model and the process of constructing it *holistically*, not simply as separate algorithmic steps. Finally, the student must be capable of reflecting on "the use of the model", which can be understood as having capabilities for both *internal* and *external* reflections:

> Internal reflections add meaning and quality to the sub-processes involved in a mathematical modelling process, (...) the external reflections address the role and function of the model in actual or potential applications. (Blomhøj & Kjeldsen, 2011, p. 1)

Purposes

In (Blomhøj, 2009, p. 6) the main purposes for teaching and learning mathematical modelling, as given by the above definitions, are divided into three categories. Below these are described in a shortened, partly reformulated, but content preserving form:

- *Proficiency:* To learn modelling, it being a subject of the mathematical discipline and to provide motivation and support for learning of other mathematical topics.

- *Applications:* To apply mathematics in dealing with the challenges of private and professional life.

- *Cultivation:* To strengthen students' competences as critical and insightful participants of a highly technologically developed democratic society.

MODELLING AS PORTRAYED IN CURRICULUM

In this section references to modelling and models in Danish curriculum for mathematics Stx A, B and C levels are explained (Danish Ministry of Education [DME], 2013, Bilag 35–37). The levels A, B, and C refer to upper secondary mathematics education. A level is the highest.

Under "disciplinary goals" (DME, 2013, Bilag 35, 2.1) models and modelling are mentioned several times. Exact quotes are not given here, but are presented in synthesised form in Table 1 illustrating the results of the analysis.

The curriculum subsection "Supplementary material" proposes teaching modelling on B level, and differential equation models on A level. This supplementary material must "provide perspective and depth to the central material" (DME, 2013, Bilag 35, 2.3).

Under "Interaction with other disciplines" it is pointed out that material must be included so that the student can understand "the significance of considering and discussing the preconditions for any mathematical description of reality, and the validity of results obtained hereby" (DME, 2013, Bilag 35, 3.4).

MODELLING IN THE TEXTBOOK

The B level mathematics textbook "Gyldendals Gymnasiematematik Grundbog 2B" (Clausen, Schomacker, & Tolnø, 2007b) contains the chapter "Models" (Danish: "Modeller") of 37 pages, wherein modelling and models are treated.

The entire textbook series, this book included, introduces models when treating a diversity of other subjects (variable correlations, functions, etc.). Many of the examples given there are revisited in the analysed section, focusing now on their specific qualities as models and the construction of these by modelling. In the following, Clausen and colleagues (2007b) is referenced whenever only page numbers are stated in parenthesis.

The textbook chapter commences with a motivational text giving a number of examples of models (nine pages). Thereafter follows the theory on modelling (two pages). It is emphasised that "The mathematical model describes a real-world situation" (p. 91) that "may have limited range" (p. 91), and that it can "give insight into, and overview of, the real-world situation that is described" (p. 91).

A simplified version of the modelling cycle is shown illustrating the sub-processes "Translation to mathematics", "mathematical treatment" and "translation to reality". These steps are presented in a non-cyclic, algorithmic manner, connected by single-headed arrows (p. 91).

Throughout the succeeding two pages, examples and exercises – by references to the exercise book (Clausen, Schomacker, & Tolnø, 2007a, pp. 27–33) – are given on model analysis. In particular, emphasis is put on identifying variables and parameters, respectively, and on their range: "Consequently, (...), x must take values between 200 and 1200" (p. 92).

The succeeding 21 pages contain more examples and exercises, now with emphasis on constructing models – modelling. All six sub-processes from Figure 1 are visited in linear succession in nearly every example. With several examples it is clarified that a model can be generalised: "Considering an alternative thickness for the paper sheet (...)" (p. 92), and "It is easy to generalise the model to considering alternative widths of the canal (...)" (p. 98). However, no examples or exercises are given wherein a point is made of progressively redefining real-world situations to be modelled. The approach is algorithmic rather than holistic.

The exercises focus on the student activity of extracting and interpreting information from a model, as well as constructing models. As with the examples, no exercises are given wherein the student must assess or reflect on the quality or validity of a model.

The remaining three pages of the chapter consist of a text considering existing "professional" models, and how their construction and use depend on applicants' interests. For example: "An oil company and an environmental organisation will hardly construct and interpret a model in the same way." (p. 116).

WHAT IS MODELLING? THREE POINTS OF REFERENCE

In this section the content extracted in the above three sections is organised and illustrated in Table 1. The table is organised so that distinct aspects of modelling may be viewed comparatively in terms of their depiction in each of the three levels of the educational system analysed.

Firstly, extracts from the analysis have been sorted under either purposes of *applications* and *proficiency*, or, under the purpose *cultivation* (see "Academic view on modelling" above). Secondly, four colours; purple, red, green, and blue highlight the four main comparable aspects of modelling that I wish to emphasise. These four points focus on portrayals of the modelling cycle (purple), the modelling process (blue), internal critical reflections (red), and external critical reflections (green).

DISCUSSION

This discussion sets out first to explore what versions of modelling are portrayed in the specific case elaborated above. This is done relative to the scope on academic literature on modelling that the case presents. Subsequently, possible causes for the gap between modelling in academic literature and textbooks are discussed. Lastly, it is suggested that a version of modelling better fit for implementation might be conceived of by considering the institutional structure of secondary school.

Lack of holistic and critical perspectives

In the textbook only examples and exercises are given where models are considered as results of following certain mathematical calculations in linear order (see blue and purple coloured text in Table 1). This approach is predominantly algorithmic as it never invites students (and teacher) to consider the model *holistically*: perspective is in every example and exercise confined to sub-processes of the modelling process.

Note that a holistic understanding of the modelling process was emphasised in literature (as presented in the case) for being essential in developing *autonomous* competencies. This is so since autonomy is understood as deriving from seeing both what is to be done to solve a problem, and why. An algorithmic viewpoint hence confines students and teacher to considering what step to do next, not what it means for the model in its entirety. As a consequence, the form of modelling portrayed in the textbook does not promote well autonomous competences.

Also, *critical* competences are underemphasised (see red and green coloured text in Table 1). In the textbook, assessment of a model's validity and range amounts merely to examining ranges of variables and parameters. This is a devaluing interpretation of the curriculum statement on understanding the "range of models". Indeed, consider the notion of *critical reflections* in the scope of the case on academic literature. In this view, "range of models" is understood as what the model in its entirety explains, its descriptive power and its limitations, not simply the range of variables used in it.

A text example is offered in the textbook describing how an oil company and an environmental organisation might interpret a model differently. Assessing others' use of models, which academic literature emphasises as part of modelling competency, is therefore somewhat an element of the modelling subject por-

	Literature	Curriculum	Textbook
Purpose declarations	-Applications - Proficiency	- Knowledge of math's usability in formulating and treating problems from other disciplines	No indication
Specific points of note	- Complex modelling cycle with double-headed arrows - Holistic perspective on modelling process - Internal critical reflections on models and model construction	- Skills in constructing and using models (geometrical, statistical, simulations) - Knowledge of basic properties of models and modelling - Reflection on idealisations and range of models	- Linear modelling cycle with single-headed arrows - Iterative modelling process. No examples or exercises displaying a holistic perspective - Examples and exercises on range of variables in models
Purpose declarations	- Cultivation	- Knowledge of mathematics' interaction with culture, science, technology	No indication
Specific points of note	- External critical reflections	- Reflection on assumptions and validity of mathematical descriptions (under "interaction with other disciplines")	- Text example of an oil company and an environmental organisations' different interpretations of a model

Table 1: A case of 'mathematical modelling' in three levels of the educational system

trayed in the textbook. Yet, no techniques to making these critical model assessments are offered.

Hereby, model criticism seems but a matter of examining ranges of functions and variables, not assessing its significance for the real-world situation it is supposed to describe. Thus, the *cultivation* purposes of academic literature, and the corresponding purpose declarations of the curriculum are underemphasised, if present at all, in the textbook. That is, the use and role of models in decision making is hardly part of the modelling subject portrayed in the textbook.

A fragmented version of modelling

The lack of holistic and critical perspectives in the textbooks indicate an overall conception of modelling as a *mathematical* technique to solve mathematically stated problems, not real-world problems. This may seem natural as it is a topic presented in a mathematics textbook. Yet, it is worthwhile to ponder the consequences of portraying this mathematics-centred version of modelling.

In the scope on academic literature presented in the case, holistic and critical perspectives are integral aspects of the modelling process and competency. These aspects, however, necessitate an approach to modelling that goes beyond mathematical algorithms and concepts. When transposing the subject into teaching material for mathematics class proper, we might suspect that the subject that results becomes centred on the mathematics. That is, aspects that go beyond that discipline become underrepresented. We saw in the above that this suspicion seems justified in the case studied.

Under which subject, then, do the holistic and critical aspects of modelling sort, if not under the subject known as modelling in mathematics textbooks?

The curriculum phrasing indicates a hint. Note that it is stated in Table 1 (in green) that reflections on assumptions and validity of mathematical descriptions sort under 'interaction with other disciplines'. Thus, it seems reasonable to assume that these aspects of modelling are considered content to be taught in interdisciplinary work.

Hence, it is reasonable to suggest that modelling in upper secondary are in fact two subjects: a mainly mathematical one found in mathematics textbooks, and one pertaining to extra-mathematical aspects found in interdisciplinary teaching material. This might seem reasonable as the teacher can use different material – different literature – when teaching modelling.

Yet, assuming that modelling should be a subject that in its very nature aims to *connect* the mathematical and the extra-mathematical, this fragmentation is problematic. Indeed, reflecting on the extra-mathematical situation that one aims to model, constructing a suitable model, and then assessing its validity is a process of *connecting* mathematical and the extra-mathematical domains.

However, this situation is only problematic when seen relative to academic perspectives on modelling. Modelling as a subject seems to find its own form in practice, one that fits the institutional structure, e.g., with subjects divided in disciplines and activities considered to be either mathematical or interdisciplinary. Understanding better this version of modelling-in-practice, and the processes that determine the form it takes is what this paper has aimed at.

CONCLUSION AND PERSPECTIVES

This study set out to investigate the gap between research on modelling and its degree of implementation in school. Rather than viewing the gap as an issue, it was considered a *condition* of connecting research to practice.

From this viewpoint, the question was not which obstacles lay in the way of implementing modelling in practice, and how they may be overcome. Rather, it was to understand how, and why, the subject of modelling takes the form it does in textbooks and curriculum.

Departing from a specific case, it was discussed how modelling as portrayed in textbooks and curricula differs from modelling as envisioned by researchers. In particular, it was indicated that this subject, modelling-in-practice, is fragmented into two subjects. One to be taught in mathematics class proper focusing on the mathematical work in modelling activities, and one aimed at interdisciplinary work focusing on critical reflections and holistic aspects of the modelling process.

It was argued that this fragmentation is a natural consequence of the division of activities common in secondary school, between mathematical and interdisciplinary activities. Taking this situation to be a condition rather than an issue (a viewpoint that must also be taken!), it is reasonable to ask whether the version of modelling to be implemented must be reshaped into a form more fit to the common secondary school structure. Indeed, could research provide a version of modelling that in distinct ways targets mathematics class proper, interdisciplinary work, as well as activities that bridge the two?

To be sure, researchers must attempt to implement the version of modelling that they see fit, and ensure that the teaching institution is changed accordingly to accommodate this subject. Yet, the point made in this paper is that investigating the version of modelling that actually occurs in teaching materials, one might see that the particular vision of modelling one has could be fitted better to the institutional structure of school.

The Fraunhofer MINT-EC Math Talents Programme

Martin Bracke, Patrick Capraro, Jana Kreckler and Andreas Roth

University of Kaiserslautern, KOMMS, Kaiserslautern, Germany, roth@mathematik.uni-kl.de

Fraunhofer MINT-EC Talents supports talented, selected students from ages 16 to 18 and encourages them to develop their own scientific research interests and projects. Those projects are suggested and designed by the students as part of their independent work. It is important, that each project contains theoretical mathematical work alongside technical aspects like the control and construction of electric devices. Members of KOMMS support them by providing mathematical and technical expert knowledge and soft skill training during several workshops and by offering infrastructure for communication and computing.

Keywords: STEM, talent, secondary education, workshops.

SETUP

The programme is a cooperation between KOMMS (Competence Centre for Mathematical Modelling in STEM Projects at Schools, http://komms.uni-kl.de), the ITWM (Fraunhofer Institute for Industrial Mathematics, http://www.itwm.fraunhofer.de), and MINT-EC (Association of Mathematical and Technical Excellence Centres at Schools, http://www.mint-ec.de). MINT-EC certifies secondary schools (Gymnasia), which exhibit a distinctive profile in STEM disciplines. Talented students at ages 16 are selected from these schools, and get the opportunity to work on mathematical-technical projects together during several workshops, parallel to their standard secondary education. The project does not have to end with their final exam; given the quality of the developments made in the two-year course, participation at competitions like “Jugend forscht” (“Youth researches” – a German youth science competition, http://www.jugend-forscht.de) is possible and desired. The number of project groups and their participants is determined in an initial workshop. We make sure, that the challenges of each topic include the necessity of mathematical modelling as well as the actual implementation of software and construction of devices. It is important, that the students themselves decide how to approach their projects and which resources are needed to proceed. The supervisors, who are KOMMS personnel, can then offer support from their experience with modelling and solution of real-world problems. Fraunhofer ITWM provides financial support to purchase necessary hardware components, offers infrastructure for communication via the myTalent portal and also pays for accommodation and transport during workshops. Due to a sponsoring agreement with MathWorks, the students in the current programme have the opportunity to work with the Matlab and Simulink Student Suite. This tool provides enough abstraction from the hardware layer, so the students can focus more on mathematical challenges and have to deal with less implementation issues. During the workshops, the supervisors or external experts offer compact courses for skills in several programming languages or for different types of hardware, if needed. The poster includes a graphical representation of the activities belonging to the MINT Talents programme and displays the involved parties and their tasks.

PROJECT EXAMPLES

Some project examples are explained with concise statements and pictures.

Playing billiards with electronic assistance

A computer software shall help a billiard player to decide which ball is the easiest to play next. A camera is used to capture the development of the game, hence it is necessary to get acquainted with basic methods of image processing. A mathematical model has to be established to rank different possible moves. As an extension, the software should be able to screen the players' skills in order to generate a profile and to give personalised suggestions.

Automatic steering of model quadcopters
A quadcopter model aircraft is supposed to navigate autonomously in a specified region and to recognise certain objects. Mathematical methods for image processing and strategies for autonomous navigation have to be developed. A swarm model can also include more than one aircraft.

GOALS

Students should emerge from the programme as self-confident young individuals, who will be able to do excellent research in the future. Acquiring expertise in project-oriented work is also the basis for putting their own ideas into market some day. But most importantly, the students learn to work with applied mathematics intuitively and produce visible results from a science, which is often considered to be of an abstract and not application-oriented type. This experience is in general not achieved by means of classic school teaching. The workshop character of the programme additionally teaches a variety of soft skills, which can come in handy in the future academic or job-related lives of the students.

A didactic problem around the elementary differential calculus and functional modelling

Catarina Lucas[1], Josep Gascón[2] and Cecilio Fonseca[1]

1 University of Vigo, Department of Applied Mathematics I, Pontevedra, Spain, catarinalucas.mail@gmail.com, cfonseca@uvigo.es

2 Autonomous University of Barcelona, Faculty of Sciences, Department of Mathematics, Barcelona, Spain, gascon@mat.uab.cat

This work is part of a PhD thesis in the field of the Anthropological Theory of the Didactic: "Se propone un modelo epistemológico de referencia (MER) del cálculo diferencial elemental (CDE) alternativo al modelo dominante en el sistema escolar." It proposes an alternative reference epistemological model to the dominant model of elementary differential calculus (EDC) for Secondary school systems. We assume that its rationale arises in the context of functional modelling (FM).

Keywords: Calculus, modeling, anthropological theory of the didactic, dimensions of a didactical problem.

The didactic problem approached will be here characterized by three fundamental dimensions: *epistemological*, *economic* and *ecological* (Gascón, 2011):

EPISTEMOLOGICAL DIMENSION

What is the rationale of EDC in the transition secondary school-university?

How to interpret and describe EDC linked to FM?

The *Activity Diagram* of the FM constitutes the basis for answering these questions (Figure 1).

ECONOMIC DIMENSION

How is EDC organized and managed in the Portuguese educational system? What is the rationale currently assigned to it? Which were the transpositives changes (Chevallard, 1985) suffered by its role in the FM activity to pass from the scientific community to the education system?

Some answers to these questions emerged from an historical evolution analysis of the EDC role in the Portuguese curriculum and the potential relationship FM-EDC. So, we characterized the EDC 'official' rationale in secondary-university as a way to study isolated functions with a weak connection to FM.

ECOLOGICAL DIMENSION

What conditions are needed to develop functional modelling in the transition secondary-university? *Dimensión ecológica:*What role could play the EDC to establish these conditions? What restrictions could hinder its development?

To partially answer these issues a *study and research path* (Chevallard, 2009) was designed and experimented, on the basis of a part of the proposed reference epistemological model.

Learning the concept of family of functions through the modelling process using tablets

Miriam Ortega and Luis Puig

University of Valencia, Faculty of Education, Valencia, Spain, miriam.ortega@uv.es, luis.puig@uv.es

In this study, we present a teaching situation to work on the modelling process using real data taken in classroom with tablets. The situation allowed us to work on the concept of the quadratic function with a group of 11th grade students and take into account the hypothesis that the qualitative analysis of the phenomenon, the knowledge of the qualitative properties of the families of functions and the meaning of the parameters are crucial elements for the management and control of the modelling process. We observed they are key elements to choose the function used as a model and to check its adequacy throughout the modelling process. Some student's conceptions on height and time were found and analysed.

Keywords: Modelling process, functions, real data, tablet, problem solving.

INTRODUCTION

We present the design and some results of a pilot study on the teaching of the concept of family of functions through a modelling process. In the teaching situation, real data are taken in classroom using the possibilities given by apps for *iPads*®, and data are processed using free apps. In particular, the situation studied is the bounce of a ball dropped from a certain height, restricting the model to a single bounce, i. e., since the moment it touches the ground for the first time until it touches it again.

The teaching situation takes also into account the hypothesis that the qualitative analysis of the phenomenon, the knowledge of the qualitative properties of the families of functions and the meaning of the parameters are crucial elements for the management and control of the modelling process, and includes this metacognitive element in the design of the materials, as we have done in a previous study (Puig & Monzó, 2013).

This teaching model was explored with a group of 11th grade students with the following aims: (a) Check the influence of the qualitative analysis in the management and control of the process and (b) Explore the behaviour and the previous ideas of the students.

MATERIALS AND METHODS

Our study is globally organised by the theoretical and methodological framework of the Local Theoretical Models (Filloy, Rojano, & Puig, 2008).

The pilot study was made in a natural group of 11th grade science students in València, Spain. They hadn't worked on the modelling process before, but they have been taught with a problem solving methodology.

The teaching experiment was carried on in two sessions and a set of interviews. In the first session, the students were given a worksheet with a set of questions that begins by asking to draw a sketch of the graph they expected to find when making the experiment, in order to explicitly include in the teaching the control of the modelling process by the qualitative analysis. After that, they represented and recorded the phenomenon studied using *Video Physics*®. In the second session, they introduced the data obtained from this app in *Data Analysis*® to choose the function which fits better, and they answered some other questions related to the phenomenon represented using *Free GraCalc*®, which is a graphing calculator. In the interviews they were asked about their answers recorded in the worksheets, and were given some hints to get over the difficulties observed.

The results of the research were obtained from two sources. On the one hand, the data from the two worksheets and from the tablets were analysed by doing a rational reconstruction of the problem solving process. On the other hand, the data from the interviews were analysed in detail to get more information about the answers' origin and the students' conceptions.

SOME RESULTS AND CONCLUSIONS

Our study supports the hypothesis that the qualitative analysis of the phenomenon, the knowledge about the meaning of the parameters and the qualitative properties of the families are decisive elements in the control and management of the modelling process. Specially, they are key elements to choose the function used as a model and to check its adequacy throughout the modelling process.

Regarding students' conceptions, we have found a deeply rooted idea that the height can't take negative values, and the idea that time is absolute.

ACKNOWLEDGEMENT

This is a result of a research program (EDU2012-35638) and a PhD grant (BES-2013-063826) both of them funded by the Ministerio de Economía y Competitividad (Spain).

TWG07

Mathematical potential, creativity and talent

Introduction to the papers of TWG07: Mathematical potential, creativity and talent

Roza Leikin[1], Alexander Karp[2], Demetra Pitta-Pantazi[3] and Florence Mihaela Singer[4]

1 University of Haifa, Haifa, Israel, rozal@construct.haifa.ac.il
2 USA/Russia, apk16@columbia.edu
3 Cyprus, dpitta@ucy.ac.cy
4 Romania, mikisinger@gmail.com

This was the third CERME at which Thematic Working Group (TWG) "Mathematical potential, creativity and talent" took place. One of the central goals of this TWG was to raise attention of the mathematics education community to the field of mathematical potential, creativity and talent, and to promote empirical and theoretical research that will contribute to the development of our understanding in the field. In 2011, 25 participants from 14 countries discussed 15 contributions. This time (2015), 35 participants took part in the TWG discussions about 24 contributions by researchers and practitioners from 15 countries from different parts of the world. The TWG facilitated communication between educational researchers, mathematics educators and research mathematicians focusing on the nature and nurture of mathematical creativity in all students and high mathematical ability in particular individuals.

Following the debates at TWG07 at CERME7 and CERME8, we continued an international exchange of ideas related to the research into the identification of mathematical talent, the didactics of teaching highly able students as well as the promotion of creativity in all students.

Four main topics framed the TWG discussion: Topic 1: Creativity – definitions, identification, development; Topic 2: Mathematical tasks for different levels of abilities and expertise; Topic 3: High mathematical abilities: Characteristics and components; Topic 4: Teacher preparation: teaching for creativity, teaching the gifted. In order to disseminate the ideas of different participants, each session started with small group work followed by a whole group discussion. Thus, the TWG concentrated on the exchange of the ideas rather than on individual presentations.

Topic 1: Creativity – definitions, identification, development

During two sessions devoted to Topic 1, the discussion focused on the relationship between general creativity and mathematical creativity following the study of Kattou, Christou and Pitta-Pantazi. The researchers demonstrated that mathematical creativity exists as a distinct type of creativity and concluded that no predictions can be made on general creativity based on mathematical creativity and vice versa. Bronislaw Czarnocha suggested that "bisociation and simultaneity of attention" could serve a useful theoretical framework (based on Arthur Koestler's ideas expressed in his monograph "Act of creation") for the analysis of creativity and argued that mental flexibility is not related at all to creative processing. In contrast to this study, Rott analysed heuristics and mental flexibility in the problem solving processes of regular and gifted fifth and sixth graders. The study of Desli and Zioga directed the attention of the group's participants to the creativity embedded in primary school mathematical tasks which are useful for educating teachers in the management of creativity in their classes. The authors argued that prospective teachers mostly connect mathematical creativity to arousing student interest whereas in-service teachers connect it to book-oriented problem posing indicating their narrow and blurred perceptions.

While Winkler and Brandl suggested process-based analysis of mathematically gifted pupils in a regular class at the primary school level, Karakok, Savic, Tang and El Turkey suggested a model for the analysis of mathematicians' views on undergraduate students' creativity that addresses flexibility as one of the central characteristics of creativity. They suggested the following rubric for mathematical creativity: Creative thinking, risk-taking, innovating thinking, connecting and transforming, originality and aesthetics of the solutions. Based on the work of Monstad, participants discussed mathematical practices involved in mathematical creativity. Émin, Essonnier, Filho, Mercat and Trgalova analysed didactical contract negotiation and technology assigned to creativity. They suggested additional ways of fostering mathematical creativity through the implementation of electronic books.

Obviously the studies varied in their definitions of creativity, research methodologies, target populations and the ways in which creativity was evaluated and the proportion between cognitive and social characteristics addressed. No agreement among the researchers was achieved on the definitions of creativity and the relationships between creativity and ability grouping. This variety of views stressed the importance of further research in the field.

Topic 2: Mathematical tasks for different levels of abilities and expertise

Task design and use is a core issue in research in mathematics education. In the context of the TWG "Mathematical potential, creativity and talent" the design of mathematical tasks for the identification and development of mathematical potential and creativity attracted the attention of all participants. Leikin and Elgrably analysed integrative investigation geometry tasks as a tool for the development and evaluation of creativity for pre-service mathematics teachers. They argue that problem solving expertise influences mental flexibility which is reflected in the richness of discovered properties as well as investigation strategies. Pitta-Pantazi, Christou, Kattou, Sophocleous and Pittalis suggest a system of mathematical competences for the evaluation of the mathematical challenge embedded in the mathematical tasks: Digital, social, communication in mother tongue, learning to learn and sense of initiative. Study participants found "digital competence" and "learning to learn the most difficult aspects to incorporate in their mathematical tasks". Palha, Schuitema, van Boxtel and Peetsma discussed the effect of high versus low guidance structured tasks on mathematical creativity. The study extended the previous research on mathematical creativity by accounting for the relationship between the learning environment and creativity and by providing a way to operationalize fluency and flexibility in conceptual mathematical terms. Safuanov, Atanasyan and Ovsyannikova argued that open-ended exploratory learning in the mathematics classroom is an effective tool for the development of knowledge and creativity, while Schindler and Joklitschke suggested criteria for designing tasks according to students' capabilities with special attention to mathematically talented students. Singer, Pelczer and Voica explored behaviours of 10 to 16 year old high achievers during a problem modification process. The researchers studied the relationship between students' creative approaches and the quality of the mathematics problems they generated, and concluded that these children either show low amplitude driven creativity, or, when they try to be more creative, they fail to pose consistent problems that make use of deep structures of mathematical concepts and strategies. Mellroth presented the Kangaroo Mathematical Competition as a very effective tool for the popularisation of mathematics among students with a wide range of mathematical abilities. In turn, Bureš and Nováková explored developing students' culture of problem solving via heuristic solving strategies. The participants discussed the construct of heuristic strategies.

Mathematical investigations, challenging problem solving and problem posing were the most common tasks considered by the TWG07 participants. The tasks were considered in different contexts: Development of creativity in students and teachers, assessing creativity, and teacher education. The participants raised the following questions for further investigation: What is done in teacher education internationally in order to assist prospective teachers to develop creativity? What are textbooks doing to develop creativity in different countries? Can "problems from the scientific studies" be used in regular classes?

Topic 3: High mathematical abilities: Characteristics and components

High abilities in mathematics is an ill-defined concept. There was no agreement between the group participants on who are the students with high ability in mathematics. Baruch-Paz, Leikin and Leikin analysed cognitive characteristics (with a focus on Speed of Information Processing) among students with superior mathematical performance. This research involved 190 students from four groups of 16–18 years old participants varying in levels of general giftedness and excellence in mathematics. The researchers demonstrated that the differences between the groups are task dependent; that is, between-group differences vary among different cognitive skills. They argued that excellence in school mathematics differs from mathematical giftedness. In contrast to the previous study that focused on the basic cognitive traits as related to mathematical abilities, Benölken's study explored emotional factors, namely, he investigated the impact of interest in Mathematics on the identification of girls' mathematical talent. In this study, the impact of mathematical interest and attitudes were used in order to identify girls' mathematical talent. Boys showed a stronger interest in mathematics compared to girls among those who were not identified as mathematically talented. Motivational factors were shown to be critical for the identification of mathematical talent.

Nordheimer and Brandl presented challenges facing the identification of mathematical giftedness in students with hearing impairment. The researchers claimed that for teachers, it is vital to recognise their pupils' diverging abilities effectively in order to meet their respective learning requirements. They compared empirically the possibilities of identifying mathematical giftedness of 3rd/4th graders by combining written tests and by process-based analyses of lessons. Szabo examined the interaction of mathematical abilities and the role of mathematical memory in students with high achievements in mathematics. The study demonstrated that mathematical memory has a critical role in the choice of problem-solving methods. The study showed that if the initially selected methods do not lead to the desired outcome, the students find it very difficult to modify them. The study confirms some qualitative differences in problem solving between high-achievers who are not essentially mathematically gifted and mathematically gifted students. However, the inflexibility of the participants could also be explained by two main functions of the cerebral cortex, where working memory operates. Winkler and Brandl argued that with heterogeneity at schools growing, individualisation of education has become more important than ever. For teachers, it is vital to recognise their pupils' diverging abilities effectively in order to meet the pupils' respective learning requirements. The researchers presented a project aiming at showing ways to identify and characterise mathematically gifted pupils during regular lessons.

An interesting discussion developed during this session. Just as at the first two sessions devoted to the studying nature and nurture of mathematical creativity, the researchers did not agree on who the mathematically gifted are, or what are the indicators of high mathematical abilities. Moreover, one of the participants in the group argued that "such a thing as giftedness does not exist". After the discussion, it was clear that more attention should be paid, through systematic research to the following questions: Can giftedness be developed or is it an innate trait? How can mathematical giftedness be determined? Are school achievements predictors of mathematical giftedness? Is mathematical creativity a part of mathematical giftedness?

Topic 4: Teacher preparation: Teaching for creativity, teaching the gifted

It is clear to every mathematics educator that teachers' expertise, knowledge and skills determine the quality of mathematics teaching. This is equally true when teaching the gifted or when goals of teaching mathematics include the development of creativity in all students. Karp and Busev devoted their study to people who taught highly gifted schoolchildren and developed educational materials for them. They claimed that teaching the highly gifted requires the teachers' creativity the development of which can be provoked and supported by the social environment. To exemplify their ideas, researchers discussed two prominent Russian figures in the advanced course of mathematics. In contrast, Birkeland analysed mathematical reasoning of pre-service teachers through the distinction between imitative and creative reasoning. This study reveals variety of the types of students' mathematical reasoning and indicates that if their reasoning is not imitative it is perhaps not creative either. Safuanov's work is devoted to different ways of teaching students in pedagogical universities to solve various types of non-routine mathematical problems, while Sinitsky's work aimed to highlight the different aspects of promoting creativity from the point of view of an educator involved in the professional development of pre-service teachers. Challenging the prospective teachers with open-ended mathematical problems provided data on their beliefs and behaviour concerning creativity and creativity encouragement in the classroom.

Overall, participants agreed that the development of teachers' understanding of the special characteristics of gifted students is essential for teaching the gifted, and that the development of teachers' creativity in mathematics teaching is essential for the development of teachers' overall creativity.

The impact of mathematics interest and attitudes as determinants in order to identify girls' mathematical talent

Ralf Benölken

University of Münster, Münster, Germany, rben@wwu.de

In proportion, girls often are decidedly underrepresented in support programs that aim at mathematically talented primary school children. Thus, it is of interest to ascertain aspects that might make possible a more differentiated identification and support. In the following article, a questionnaire study will be presented which can clarify the significance of mathematics interest and attitudes as determinants for the identification of mathematical talent: Boys and girls who were identified to be mathematically talented, and boys who were not showed a stronger mathematics interest (in and beyond the classroom) and more advantageous mathematics attitudes compared to girls who were not identified to be mathematically talented.

Keywords: Mathematical talent, mathematical giftedness, interest, attitudes, gender.

INTRODUCTION AND RATIONALE

In Germany just like in other western European countries, girls are in proportion decidedly underrepresented in programs that foster mathematical talent (Benölken, 2011). This phenomenon contradicts the consensus on the fact that both sexes have equal potentials across all academic domains (Endepohls-Ulpe, 2012). When it comes to primary school children, aspects such as gender stereotyping of mathematical occupational fields cannot really act as possible explanations, especially because there cannot be found any gender-specific differences in mathematical competencies at this age (Lindberg, Hyde, Petersen, & Linn, 2010). In addition, studies have indicated a decline of such differences at subsequent ages for many years (Hyde, Lindberg, Linn, Ellis, & Williams, 2008). This is why it is of interest to look for aspects that improve the identification of girls' mathematical talent (see [1]). With a holistic approach, diagnostics should be organized as a process considering both cognitive and co-cognitive, e.g. motivational, parameters as determinants in order to identify talents. For instance, girls and boys who were identified to be mathematically talented ("imt") as well as boys who were not ("n-imt"), often show more advantageous self-concepts and attributions in mathematics than n-imt girls (Benölken, 2014). Findings like these raise the question how other motivational factors can be characterized in view of these groups. In this article, the significance of both mathematics interest and attitudes as determinants for the identification of mathematical talent at primary school age will be examined by a questionnaire study. Its aim is to investigate boys' and girls' frequent characteristics as to these factors by a comparison of the four groups mentioned above. Based on literature reviews, hypotheses on the characteristics in question will be deduced that correspond to the questions of the study. Afterwards, the design and the results of the study will be reported.

BACKGROUND

Theoretical frameworks

Mathematics interest: The conception of interest applied in the study refers to Prenzel, Krapp and Schiefele (1986): Interest is seen as a result of an interaction between a person and an object that – along with adjuvant conditions – might cause to focus on a long-term preoccupation with this specific object. This relation is characterized by (1) value-related, (2) affective and (3) cognitive aspects. Additionally, in accordance with current approaches on a multidimensional structure of interests, a distinction between subject-, context- and topic-related interest was considered (Krapp, 2010). The first two dimensions were summarized in the term of "mathematics interest in the classroom" because it cannot be expected that primary school children differ between activities and contexts applied in classrooms (Hellmich, 2006). The third one is referred to by the term "mathematics interest beyond the classroom".

Mathematics attitudes: The construct of "attitudes" focuses on an evaluation of objects which an individual imagines or perceives in his or her environment. Attitudes can be explicitly and consciously accessed, or they can emerge implicitly and spontaneously – in both cases influencing an individual's behavior (Bohner, 2003). The conception of attitudes applied in the study refers to the classical operationalization consisting of (1) cognitive, (2) affective and value-related as well as (3) behavior-related components (Aronson, Wilson, & Akert, 2004).

Brief literature reviews

Preliminary notes: Research on both mathematics interest and attitudes mostly focuses either on children at middle school age or on gender-specific differences without regarding specific aspects of giftedness or talent. Studies which investigated mathematics interest or attitudes in the context of exceeding abilities mostly refer to "giftedness" as a "g-factor-concept" implying standardized diagnostics. Thus, their results cannot be transferred automatically to "mathematical talents" regarding domain-specific criteria and implying long-term process diagnostics (see [1]). The findings collectively show, however, the significance of both factors as determinants for the identification of girls' mathematical potentials. Therefore, they are suited to provide a basis for the intended deduction of hypotheses.

Mathematics interest: Primary school children often have a lot of interests like sports, TV, computer games or reading (Pruisken, 2005). Furthermore, gender-specific differences can already be found at this early age (Hoberg & Rost, 2000): horseback riding, animals or reading seem to be "typical" interests of girls; football, technics or computer "typical" interests of boys (Fölling-Albers, 1995). Boys more often show stronger mathematics interest – even at primary school age and both in and beyond the classroom; girls interest in language or literature (Hellmich, 2006; Pruisken, 2005). Though gifted children show the same differences, they do not have any extraordinary interests compared to non-gifted children. However, gifted children generally seem to be more interested in both mathematics and languages or literature (Pruisken, 2005). In contrast to non-gifted girls, gifted girls have more interests which are supposed to be "typical" interests of boys, and they have a larger spectrum of interests than gifted boys (Kerr, 2000). Regarding specific mathematical talents (in the sense of [1]), girls (irrespective of the identification of talent) more often show a larger spectrum of interests than boys (Benölken, 2014). The majority of primary school children does not differ between mathematics interest in the classroom and beyond the classroom (Hellmich, 2006). However, current studies do not focus on gender- or giftedness- respectively talent-specific aspects in this context. Furthermore, there are only very few studies with a focus on ability-related mathematics interest. Their findings indicate, that the mathematics interest of students with lower achievements exceeds that one of higher achievers (Frenzel, Goetz, Pekrun, & Watt, 2010), but these studies do not focus on gifted or talented students. Finally, an often reported phenomenon is a decline in mathematics interest in the years of adolescence (Fredricks & Eccles, 2002), which is of little importance when conducting studies with primary school children.

Mathematics attitudes: Boys show advantageous mathematics attitudes more often than girls (Hyde, Fennema, Ryan, Frost, & Hopp, 1990). As to the cognitive aspect, studies primarily focus on individuals' assessments of usefulness and difficulty of mathematics. There seem to be no gender- or talent-specific differences between imt and n-imt children regarding usefulness (Benölken, 2011), but some studies indicate that mathematically gifted boys and girls as well as non-gifted boys ascribe mathematics a lower level of difficulty compared to non-gifted girls (Wieczerkowski & Jansen, 1990). Finally, there are findings on gender stereotypes: The older girls are the more they ascribe mathematics to males (Newton & Newton, 1998), which seems to be less important at primary school age, since such differences mostly appear from an age of ten onwards. Concerning the affective aspect, results on gender- or giftedness-specific differences of individuals' intrinsic values (such as enjoying mathematical task solving) seem to play the most important role: Similar to characteristics of the assessment of mathematics' difficulty, some studies show that mathematically gifted boys and girls as well as non-gifted boys show a higher intrinsic value doing mathematics compared to non-gifted girls (Wieczerkowski & Jansen, 1990). On the other hand, studies indicate that boys in general ascribe a higher intrinsic value to mathematics than girls (Bos, Wendt, Köller, & Selter, 2012). As to the behavior-related aspect, boys seem to engage in mathematics beyond mathematical school lessons more often than girls (Schiepe-Tiska & Schmidtner, 2013).

THE STUDY

Questions

The study was designed to answer the question how mathematics interest and attitudes can be characterized with the regarded groups. The following hypotheses were deduced from the theoretical findings: (1a) Imt girls and boys as well as n-imt boys show a stronger mathematics interest in the classroom than n-imt girls. (1b) Imt girls and boys as well as n-imt boys show a stronger mathematics interest beyond the classroom than n-imt girls. (2) Imt girls and boys as well as n-imt boys show more advantageous mathematics attitudes than n-imt girls.

Design

The study adds to previous research on the significance of motivational factors as determinants for the identification of mathematical talent using questionnaires that are appropriate to primary school children, and that can be completed within a short time (e.g., Benölken, 2011; 2014). Operationalizations of mathematics interest in and beyond the classroom as well as of attitudes were tested within pilot studies.

Sample and procedure

The sample contains N=162 children of the third and fourth grade (71 girls, 91 boys). The subsample of imt children is n=83 (32 girls, 51 boys). Children who are assessed as "imt" take part in a project that fosters mathematical talent at the University of Münster called "math for small pundits". They were chosen by long-term process-diagnostics that are a synthesis of standardized and non-standardized tools (see [1]; Benölken, 2014). The sample contains n=79 n-imt primary school children (39 girls, 40 boys) from common classes. The probands were questioned during the school year of 2014/2015. All procedures of questioning were consistent: The children were told how to fill in the questionnaire. In this context, possible differences between mathematics interest in and beyond the classroom were emphasized (see [2]). The children completed the questionnaire on their own without any time limit (no one took more than ten minutes and no one refused to fill in the questionnaire).

Method

Apart from declaring sex, the questionnaire was anonymized. The phrasing of all items (following styles of common operationalizations in each case) was formulated in German. In order to measure mathematics interest in the classroom by a value-related, an affective and a cognitive aspect, the following instruction was given: "This is about mathematics in the classroom. Mark with a cross a statement that you think fits best to you: (1) Mathematics in the classroom is really important to me. (2) I always look forward to mathematics in the classroom. (3) I am interested in mathematics in the classroom." An analog instruction was composed to collect data about mathematics interest beyond the classroom: "This is about mathematics beyond the classroom. Mark with a cross a statement that you think fits best to you: (1) Mathematics is really important to me. (2) I always look forward to doing mathematics. (3) I am interested in mathematics." In order to measure attitudes by cognitive, affective and behavior-related aspects, the following instruction was given: "Mark with a cross a statement that you think fits best to you: (1) Mathematical tasks are sometimes too difficult. (2) I enjoy doing mathematics. (3) I engage in mathematics beyond mathematical school lessons." To evaluate the items, in each case a four-step Likert-scale was offered ("that's not correct", "that's almost not correct", "that's almost correct", "that's correct"; instead, the children could choose "I don't know").

Evaluation

Statements about all items except the one relating to cognitive attitudes were translated into numbers from 1 ("that's not correct") to 4 ("that's correct"). As to the cognitive attitude-item, the assignment was turned around: "that's not correct", e.g., was translated into 4 and "that's correct" into 1, because statements that focus on a low level of difficulty reflect advantageous characteristics of attitudes. Regarding the mathematics-interest-in-the-classroom-scale, the coefficient of correlation as defined by Pearson between the included items moves in a range from .366 to .475 (with $p<.01$ in each case) and the internal consistency is only just acceptable (Cronbachs α=.680). As to the mathematics-interest-beyond-the-classroom-scale the coefficient of correlation as defined by Pearson between the included items is in a range from .378 to .576

(with $p<.01$ in each case) and the internal consistency is between acceptable and good (Cronbachs α=.731). Finally, the coefficient of correlation as defined by Pearson between the included attitudes items moves in a range from .334 to .617 (with $p<.01$ in each case) and the internal consistency is between acceptable and good, too (Cronbachs α=.710). In all cases, the items have been combined to one scale with mean values. Data have been evaluated by an analysis of variance with two factors ("talent" and "sex") to find significant differences between the four groups. In addition to that, η^2-values have been calculated to see the possible importance of both the factors and their interaction by their effect size. The requirements of the statistical procedure need the independence of subsamples and a normal distribution of the regarded trait within the groups amongst homogeneity of variance: The subsamples are obviously independent because of the distinction between sex and talent-identification. As a consequence of a graphical analysis of the distributions-histograms and the corresponding quantile-quantile-plots, the data are leptokurtic, but sufficiently similar to normal distributions (Hatzinger & Nagel, 2009). The requirement of homogeneity of variance is statistically firm as a result of Levene-testings.

RESULTS

Mathematics interest

Regarding *mathematics interest in the classroom*, the averages of imt boys and girls are relatively similar, while the value of n-imt boys is slightly larger and the value of n-imt girls is slightly lower (Table 1). There is no significant main effect on talent ($F(1,158)<.001$, $p=.990$, $\eta^2<.001$), but there can be found a significant main effect on sex ($F(1,158)=12.795$, $p<.001$, $\eta^2=.075$) as well as a significant effect of interaction ($F(1,158)=4.139$, $p=.044$, $\eta^2=.026$). As indicated by η^2-values, sex (medium effect of 7,5%) plays a bigger part to explain variance than the interaction (medium effect of 2.6%). Thus, the boys' groups, especially the n-imt boys, show a stronger mathematics interest in the classroom compared to the girls' groups, but as indicated by the significant effect of interaction, imt girls are more similar to the boys' groups than to the n-imt girls, who show a lower mathematics interest in the classroom on average compared to all other groups. Therefore, the statistical evaluation confirms hypothesis 1a in principle.

As to *mathematics interest beyond the classroom*, the averages of imt children and n-imt boys are very similar and exceed the value of n-imt girls (Table 1). There are significant main effects on talent ($F(1,157)=10.579$, $p=.001$, $\eta^2=.063$) and sex ($F(1,157)=8.435$, $p=.004$, $\eta^2=.051$) just as there is a significant effect of interaction ($F(1,157)=7.579$, $p=.007$, $\eta^2=.046$). As indicated by η^2-values, talent (medium effect of 6,3%) and sex (medium effect of 5.1%) play a similar role to explain variance. Thus, imt children and n-imt boys show similar characteristics of mathematics interest beyond the classroom which is stronger compared to n-imt girls, i.e. hypothesis 1b is confirmed. In addition, a descriptive data analysis of all groups' mean values regarding both mathematics interest in and beyond the classroom indicates that only imt children seem to differ between these dimensions, since the values of n-imt boys and girls are quite similar in each case, while imt children's mathematics interest beyond the classroom is stronger than in the classroom.

Mathematics attitudes

As to mathematics attitudes, the mean values of imt boys, imt girls and n-imt boys are relatively similar, even though the value of imt boys is slightly larger than the values of imt girls and n-imt boys. The value of n-imt girls is clearly lower in comparison to all other groups (Table 2). There are significant main effects on both talent ($F(1,158)=29.023$, $p<.001$, $\eta^2=.155$) and sex ($F(1,158)=21.550$, $p<.001$, $\eta^2=.120$). Finally, there is a

	mathematics interest in the classroom		mathematics interest beyond the classroom	
	boys	girls	boys	girls
imt children	3.07 (.83)	2.89 (.51)	3.39 (.70)	3.37 (.48)
	n=51	n=32	n=51	n=32
n-imt children	3.30 (.76)	2.65 (.72)	3.33 (.79)	2.74 (.55)
	n=40	n=39	n=40	n=38

Table 1: Averages (standard deviations) of mathematics interest-statements

significant effect of interaction ($F(1,158)=7.597$, $p=.007$, $\eta^2=.046$). As indicated by η^2-values, talent (strong effect of 15,5%) and sex (medium effect of 12.0%) play a similar role to explain variance, even though the talent effect is stronger. Thus, attitudes of imt children are more advantageous compared to n-imt children, but n-imt boys merely differ a little from the imt children. The statistical evaluation confirms hypothesis 2.

DISCUSSION

Synopsis: In this article, the significance of both mathematics interest – by a distinction between in and beyond the classroom – and attitudes as determinants for the identification of mathematical talent at primary school age was investigated by a comparison of frequent characteristics with boys and girls who were identified to be mathematically talented (imt) as well as with boys and girls who were not (n-imt). Based on a review of existing empirical evidence, hypotheses on the mentioned characteristics were deduced: It has to be expected that imt children and n-imt boys show a stronger mathematics interest and more advantageous attitudes than n-imt girls. The hypotheses were investigated by a questionnaire study. The statistical results confirm the assumptions in principle: First, the boys' groups, especially n-imt boys, show a stronger mathematics interest in the classroom compared to the girls' groups, while imt girls are more similar to the boys' groups than to n-imt girls, who show a lower mathematics interest regarding this aspect than all other groups (similar to Pruisken, 2005). Second, imt children and n-imt boys show a stronger mathematics interest beyond the classroom than n-imt girls. In addition, only imt children seem to differ between mathematics interest in and beyond the classroom showing stronger interest beyond the classroom, while n-imt children on average took similar stances in both cases (which could explain the results of Hellmich, 2006). Finally, attitudes of imt children are more advantageous compared to n-imt children, but n-imt boys merely differ a little (similar to Wieczerkowski & Jansen, 1990).

A deeper interpretation of the results indicates that all groups show a relatively strong mathematics interest and advantageous attitudes, even though the values of n-imt girls are lower compared to the other groups in each case. Regarding the significance of mathematics interest and attitudes for the identification of talent, the results insinuate that both a particularly strong mathematics interest (in and beyond the classroom) and advantageous attitudes can be found – independent of the identification of talent – more often with boys, while girls who have been identified to be mathematically talented are very similar to these groups. An observable stronger mathematics interest, especially in the classroom, and more advantageous attitudes might cause more efficient diagnostics of boys' talents, because they might tend to a strong preoccupation with mathematics, or teachers might perceive their potentials primarily. By contrast, both lower mathematics interest, especially in the classroom, and disadvantageous attitudes might lead to the fact that children do not develop a stronger preoccupation with mathematics and, e.g., turn to different interests. This might also apply to children who have a high potential that might be more difficult to identify. Though the findings are not suitable to predict how mathematics interest and attitudes can be characterized with mathematically talented but not identified girls, they imply the following thesis: Disadvantageous characteristics of mathematics interest and attitudes are important aspects effecting a more infrequent identification of high potentials with girls. In addition, interest and attitudes have to be seen in a strong interdependence with other motivational factors as well as with influences of socialization or gender-specific preferences in solving tasks (Benölken, 2011, 2014).

As to *limitations of the study and directions for future research*, within the imt group the underrepresentation of girls has to be discussed: Because of the rare

	boys	girls
imt children	3.32 (.58)	3.11 (.60)
	n=51	n=32
n-imt children	3.03 (.78)	2.23 (.76)
	n=40	n=39

Table 2: Averages (standard deviations) of mathematics attitudes-statements

identification of mathematical talent with girls, it takes a long time to compose suitable subsamples (in particular, by process diagnostics). Nevertheless, despite the relative imbalance within the imt group, the size of all subsamples is sufficient in principle, even though follow-up studies should enlarge all subsamples and ensure a balance. The diagnostics procedures of talent identification that are used to compose the imt subsample have been established for many years. Thus, "imt" children most probably are rightly assessed in that way. In addition, there might be motivational effects caused by their participation in "math for small pundits" that cannot be found with children who have high potentials, but who are not taking part in such a program. Finally, the subsample of n-imt children is nothing more than an insufficient image of population. Thus, the sample's representativeness has to be seen as limited. The questionnaire was adequate to the aims of the study in principle. It is suited for a pragmatic use in classrooms because its design is appropriate to children, and it can be completed in a short time. However, mathematics interest and attitudes are strongly reduced in their conceptions, and the evaluation depends on very simple measurements. The external validity of the findings cannot be judged because tools that evidentially regard criteria of quality were not applied (in favor of the appropriateness to young children) and because the imt sample is very specifically composed. In sum, the study has obvious limitations, and it rather has an explorative character. Despite the significant results, subsequent studies might focus on a deeper clarification using established tools.

As to a survey of exemplary *practical consequences*, first, any gender stereotyping of mathematics should be avoided. Second, the development of mathematics interest and advantageous attitudes seems to play an important role for girls in order to support their potentials to emerge. In this context, e.g., task-fields that are composed to foster girls especially – without stereotyping – might be useful (Benölken, 2013). The distinction between mathematics interest in and beyond the classroom that was observed with imt children indicates the significance of a challenging education, e.g., by using enrichment tasks in common classes (Fuchs & Käpnick, 2009).

ENDNOTES

1. According to Fuchs and Käpnick (2009), "mathematical talent" is seen as an above-average potential regarding the criteria of Käpnick (1998), i.e., remembering mathematical facts, sensitivity and fantasy, structuring and transferring structures or reversing thoughts. This potential is characterized by individual determinants and a dynamic development depending on inter- and intrapersonal influences in interdependence with personality traits supporting the talent.

2. As to the distinction between the interest dimensions, the questionnaire instructions contained the following elucidation (translated from German): "I would like to know how you like mathematics in and beyond the classroom. 'Mathematics in the classroom' focuses on everything you do in mathematical school lessons. 'Mathematics beyond the classroom' focuses on, e.g., mathematical activities or themes in your life beyond mathematical school lessons or even outside the school."

Pre-service teachers' mathematical reasoning

Alv Birkeland

UiT The Arctic University of Norway, Tromsø, Norway, alv.birkeland@uit.no

The focus of this study is the mathematical reasoning of pre-service teachers. One class of pre-service teachers preparing to teach from grade 5 to 10 was organized in small groups where they worked on certain mathematical exercises. While working on these exercises the students were video and audio recorded. The dialogues of each group constitute the unit of analysis. The research framework used in this study distinguishes between imitative and creative reasoning. This distinction is based on the idea that rote learning is imitative, while the opposite kind of reasoning is creative. However, this study reveals some of the variety of the students' mathematical reasoning and indicates that if their reasoning is not imitative it is perhaps not creative either.

Keywords: Pre-service teachers, imitative reasoning, non-imitative reasoning, creative mathematical reasoning, creativity.

INTRODUCTION

To foster creativity among students in general, it would probably be useful to have teachers that could engage students in creative mathematical work. Therefore it might be of interest to study the mathematical work of pre-service teachers. Thus knowledge about pre-service teachers' mathematical reasoning would be useful. To know if some of their reasoning could be characterized as creative or not would be valuable. Such knowledge would perhaps make it possible to prepare pre-service teachers better for their future work. This is what motivates this study.

Skovsmose (2001) distinguishes between the exercise paradigm and landscapes of investigations. Within the exercise paradigm the textbook is central for classroom practice. The relevance of the exercises is not part of the mathematics lesson, and there is one and only one correct answer to each exercise. In contrast to the exercise paradigm, landscapes of investigations is an investigative approach where students are involved in processes of exploration and explanation. Skovsmose makes the point that traditional mathematics education often falls within the exercise paradigm. If students' work with mathematical exercises falls within the exercise paradigm and essentially involves copying the solutions they find in the textbook, their reasoning can hardly be characterized as creative. To copy or imitate solutions from the textbook would be what Lithner (2008) labels as imitative reasoning. He denotes the opposite kind of reasoning as creative reasoning. Haylock (1987) is concerned with creativity in school mathematics and makes the point that overcoming certain kinds of fixations is essential. He calls overcoming fixations "flexibility". Sriraman (2009) has investigated the work of research mathematicians and defines creativity to be the ability to produce novel or original work. The novelty of students would normally be at a personal level only, which is called relative creativity by Leikin and Pitta-Pantazi (2013). To copy the solutions in the textbook might be a normal procedure for students of mathematics except perhaps for students at an advanced or graduate level (Lithner, 2004). An undergraduate textbook giving several examples of solutions to the mathematical exercises in the book, is perhaps asking the students to reason imitatively (Lithner, 2008) rather than to engage them in an investigative approach (Skovsmose, 2001). However if the students cannot find a solution in the textbook to copy, the situation is different. To find a solution to an exercise would then probably require relative creativity (Leikin & Pitta-Pantazi, 2013).

One class of pre-service teachers, preparing to teach students from grade 5 to 10, participated in a study of creative mathematical reasoning. The participating students were not selected for any kind of mathematical giftedness or excellence. The class was organized in small groups and given some mathematical exercises to work on. The number of students in each group varied from two to four. The topic was basically number theory and the exercises were part of a course. The students were recorded on video and audio, and transcripts of the students' dialogues were prepared and analyzed. It was hoped that the dialogues of the students would reflect the actual mathematical reasoning of the students, and perhaps reveal more than what their written works only would have done. This led to the following research question:

Is Lithner's (2008) distinction between imitative and creative reasoning sufficient to analyze pre-service teachers' mathematical reasoning, or can some of their reasoning be neither imitative nor creative?

REVIEW OF THE LITERATURE

In a review of the literature mainly from English speaking countries, Haylock (1987) is concerned with creative thinking in school mathematics. The review indicates that both overcoming fixations and the ability for divergent production are essential components in any assessment of mathematical creativity. One aspect of creative reasoning that would be relevant for mathematical work would thus be to overcome fixations or rigidity. Haylock suggests two key aspects of fixations or rigidity in mathematical reasoning. One is called content-universe fixation where the reasoning is unnecessarily restricted to an insufficient range of elements that may be used or related to the mathematical situation. The other kind of fixation is called algorithmic fixation, where the reasoning continually adheres to an initially successful algorithm even when this becomes less than optimal. The counterpart of fixation or rigidity is called flexibility. In divergent production tests the common element is that the subject is given a mathematical situation with many responses. The creativity of the responses in such tests is conventionally assessed by evaluating them in terms of the number of responses (fluency), the number of categories of responses (flexibility) and originality (the statistical infrequency of the responses). The opposite of divergent thinking is convergent thinking where the subject is supposed to find a single solution to a given problem.

Sriraman (2009) investigated the work of five creative mathematicians. The study indicated that in general, the mathematicians' creative process followed the four stage Gestalt model of preparation-incubation-illumination-verification (Wallas, 1926) as indicated by Hadamard (1954). According to this model the creative process starts with a period of preparation where in spite of hard work over a period of time apparently no results are achieved. In a period of incubation the problem is left aside and partly forgotten. However, even though the problem is put aside for some time, it is not completely forgotten and it is thought that the mind is occupied with the problem, but in a subconscious way. Later in a moment of illumination an idea comes up which possibly solves the problem. This idea may seem to come more or less out of the blue. Therefore the moment of illumination is also seen as a result of the work of the subconscious mind. Finally, it is necessary to verify the solution. Incubation and illumination may be the work of the subconscious mind. However, both preparation and verification obviously take place in a fully conscious way.

Leikin and Pitta-Pantazi (2013) reveal that the relationship between creativity and giftedness is complex. Some researchers claim that creativity is one form of giftedness, whereas others feel that creativity is an essential part of giftedness, and still other researchers suggest that creativity and giftedness are two independent characteristics of human beings. A distinction is made between relative and absolute creativity. Creativity is relative if the creativity is at a personal level only, as opposed to absolute creativity where creativity is regarded as novel to the professional community. Students' ability to produce solutions to mathematical exercises that are new to the students only would typically be relative creativity, whereas new mathematical discoveries such as those awarded the Abel Prize would be seen as the result of absolute creativity. Researchers have different focuses on where the creativity lies. The focus is either on the creative person, the creative process, the creative product or the creative environment. Research studies that focus on the creative person deal with individuals' cognitive and personality traits. Other research studies focus on the way creative work is produced such as the four stage Gestalt model of Wallas (1926). Research studies that focus on product concentrate on ideas translated into tangible forms. Researchers that focus on environment concentrate on where the creative person acts. In educational settings this could be the educational environment where the creative activity takes place and where the creativity is studied.

Lithner (2004) gives a detailed description of how exercises in undergraduate calculus textbooks may be solved by mathematically superficial strategies. A distinction is made between intrinsic and surface mathematical properties of the components involved in the reasoning. An intrinsic mathematical property is central to the problem as opposed to a surface property which has little or no relevance to the problem (Haavold, 2013). When considering surface mathematical properties it is not necessary to understand the central mathematical ideas and analyze the consequences of their properties. Bergqvist (2007) has classified tasks and task solutions from all introductory calculus courses at four Swedish universities during the academic year of 2003/2004. The analysis shows that about 70% of the tasks do not require creative reasoning. All exams except one were possible to pass without the use of creative reasoning of any kind. In one quarter of the cases it was possible to pass exams with distinction without using creative reasoning of any kind. Lithner (2008) has introduced a research framework for creative and imitative reasoning. The basic idea behind this framework is that rote learning reasoning is imitative while the opposite type of reasoning is creative. The characteristic for imitative reasoning is that the reasoning individual is copying solutions e.g. by looking at a textbook example or remembering a textbook algorithm. The opposite kind of reasoning is called creative mathematically-founded reasoning. This kind of reasoning is characterized by novelty, plausibility and that the reasoning is mathematically founded.

The research framework introduced by Lithner based on empirical data is applied in this study. This framework identifies two types of mathematical reasoning called imitative reasoning (IR) and creative mathematically-founded reasoning (CMR). More precisely imitative reasoning is based on imitating or copying a line of reasoning laid out step by step for the student. On the other hand, the characteristics of creative mathematically-founded reasoning are (Lithner, 2008, p. 266):

1) Novelty. A new (to the reasoner) reasoning sequence is created, or a forgotten one is re-created.

2) Plausibility. There are arguments supporting the strategy choice and/or strategy implementation motivating why the conclusions are true or plausible.

3) Mathematical foundation. The arguments are anchored in intrinsic mathematical properties of the components involved in the reasoning.

The components involved in the reasoning could be objects such as numbers, functions and matrices, (Haavold, 2013). According to Haavold the notion of plausibility in this framework is inspired by Polya (1954). Polya makes the point that there are two kinds of mathematical reasoning. There is demonstrative reasoning and there is plausible reasoning. Demonstrative reasoning is what mathematical proofs are made of, whereas the reasoning used to solve a mathematical problem or find a proof is plausible. According to Polya, the result of the mathematician's creative work is demonstrative reasoning. However, to find a solution to a mathematical problem plausible reasoning is used.

METHODOLOGY

The design of this study was to divide one class of pre-service teachers into small groups and give them some mathematical exercises. The video and audio recordings of the work of each group constitute the data of the study. The exercises were selected from the course. Thus the mathematical work of the teaching experiment would also be relevant for the students. The students were in fact preparing for their exam doing the exercises. It was not expected that the students would solve the exercises using imitative reasoning only. The reason for this was that although the students were given an idea on how to get started, they were not given a complete solution. The episode from the video recording was chosen because it indicates that when pre-service teachers' reasoning is not imitative, it is perhaps not creative either. Similar mathematical reasoning was found in many of the groups involved in the study. However, one example was chosen for this paper to show what was found.

The term commognition has been coined by Sfard (2008) meaning a combination of communication and cognition. This means that interpersonal communication and individual thinking are two facets of the same phenomenon. Thinking is defined by Sfard as the individualized version of interpersonal communication. In this paper we view reasoning as a form of thinking. Thus we study the mathematical reasoning of each individual by studying the interpersonal communication of each group. Therefore the unit of analysis is the dialogue of each group. The idea behind this approach is that the dialogue of each group would perhaps reveal more mathematical reasoning than the written works only would have done.

The analysis was based on the research framework of Lithner (2008), which makes the distinction between imitative and creative reasoning. However, the analysis of the dialogues indicated that some of the students' reasoning was not compatible with Lithner's distinction. The analysis indicated that if the students' reasoning was not imitative it was perhaps not creative either. Therefore it became interesting to analyze the students' reasoning if it was neither imitative nor creative and find a way to characterize it. Hence, in order to analyze pre-service teachers' mathematical reasoning a new distinction of reasoning was introduced. In addition, new categories were introduced.

ANALYSIS

One of the problems the students worked on was the sequence (a_n) starting with the terms 0,4,10,18,28,40... The students were asked to find an expression for a_n. Let us start by looking at the dialogue of one of the groups with three students. The instructor made the students familiar with the idea that they could write down the differences between consecutive terms of the sequence to get a set of equations that could be added. The video shows that when the dialogue begins the students have written down the following equations:

$$a_2 - a_1 = 4 = 2 \times 2$$
$$a_3 - a_2 = 6 = 2 \times 6$$
$$a_4 - a_3 = 8 = 2 \times 4$$
$$\ldots$$
$$a_n - a_{n-1} = 2n$$

Adding these equations, the students arrived at the equation:

$$a_n - a_1 = 2 \times 2 + 2 \times 3 + 2 \times 4 + \ldots + 2n$$

Thus the students did what one would expect if they were to follow the line of reasoning given to them by the instructor. Therefore their reasoning was probably imitative so far (Lithner, 2008). We enter the dialogue with the following episode from the video. The numbered transcription of the episode is given with some comments.

Episode:

1. Katherine: And then we can write 2 outside,
2. Elizabeth: And a_1 is zero, we don't need it, we can simply skip it.

Following this dialogue the students have written down the equation:

$$a_n = 2(2 + 3 + 4 + \ldots + n)$$

In lines 1 and 2 Katherine and Elizabeth use formulations such as "we can write 2 outside" or "we can simply skip it" as opposed to formulations such as "what do we have to do here?" or "what are we supposed to do here?" This could mean that the students make their own choices about what to do, rather than asking themselves what they are supposed to do which would be characteristic for imitative reasoning. If the students make their own choices then their reasoning would not be imitative. The dialogue of the episode continues as follows:

3. Jennifer: We are now looking for the triangular numbers.
4. Elizabeth: Hm.
5. Katherine: No, plus n, the sum of the n first positive integers, so it is really the triangular numbers we are looking for, but can we...?
6. Jennifer: We are missing 1.
7. Katherine: We are missing 1, yes if we add...
8. Elizabeth: Add 1 to each side.
9. Katherine: We have to add 2...2...2 times 1... to both sides, because we have the number 2...Yes, if we try that, add 2 times 1, then you get a_n plus 2 times 1 equals 2, and then we get 1 plus 2 plus 3 plus 4...plus n.
10. Elizabeth: Yes, we do.
11. Katherine: Yes.
12. Jennifer: Can we just add like that?
13. Katherine: Yes we may add to both sides.
14. Jennifer: Yes, and then we just have to...

Finally, the video recording shows that the students arrive at the following equation:

$$a_n + 2 \times 1 = 2(1 + 2 + 3 + \ldots + n)$$

As the students are familiar with triangular numbers, the exercise is now resolved.

Jennifer continues the dialogue in line 3 by making the point that they are looking for the triangular numbers. After having agreed that they should look for the triangular numbers, Jennifer begins a line of reasoning in line 6 by observing that they are missing the number 1. She is obviously referring to the fact that the sum within the brackets should have started with the number 1. Katherine suggests in line 7 that they should add something. This is followed up in line 8 by Elizabeth saying that they should add 1 to each side of the equation. However, in line 9 Katherine introduces a different idea saying that they should add 2 times 1 to each side of the equation. Thus the students change their point of view while reasoning, which would not be typical for imitative reasoning. Instead, changing point of view characterizes flexible reasoning (Haylock, 1997). The formulation "Yes, if we try that" used by Katherine in line 9 further indicates that the students are trying out their own ideas rather than following step by step a given line of reasoning, and thus that their reasoning is not imitative (Lithner, 2008). Hence, their reasoning should not be characterized as imitative but, rather, as flexible.

When Katherine introduces her idea in line 9 she shows little uncertainty. In fact she says: "Yes, if we try that, add 2 times 1, then (...)" thus perhaps showing some confidence. Elizabeth easily accepts the idea of Katherine in line 10. Only Jennifer hesitates a little in line 12 (Birkeland, 2013) but accepts the idea in line 14. Thus the idea they use is introduced rather smoothly. This would hardly be the case if the idea was new to the group. Therefore nothing indicates that the idea has novelty to the group. If the students' reasoning is based on a relational understanding (Skemp, 1978) of the components involved, then it is reasonable to assume that it is mathematically founded (Lithner, 2008). This would indicate that the reasoning of the group is mathematically founded, has flexibility (Haylock, 1987) but no novelty or originality.

DISCUSSION

The first part of the students' reasoning was to write down the differences between consecutive terms of the given sequence to get a set of equations that could be added. The students were made familiar with this idea by the instructor. Therefore the first part of their reasoning was probably imitative (Lithner, 2008).

The second part of the students' reasoning was not laid out step by step for them. The instructor did not give them any hints. The students tried out certain ideas they had and finally chose their own line of reasoning. If their reasoning was based on their own choices then it should not be characterized as imitative. Assuming that their reasoning was based on relational understanding (Skemp, 1978) it was probably both plausible and mathematically founded. Further, nothing indicated that their reasoning had novelty. However, their reasoning was found to have flexibility. Probably the students were working flexibly with familiar lines of reasoning.

One may argue that flexible reasoning is part of creative reasoning. However, if creativity is the ability to produce novel or original work (Sriraman, 2009), then flexibility alone is not sufficient for the reasoning to be creative. Therefore the students' reasoning should perhaps not be characterized as novel or creative. Consequently the first part of the students' reasoning could be said to be imitative, however the last part of their reasoning would be neither imitative nor creative as defined by Lithner (2008).

The episode chosen for this paper was quite typical for the mathematical reasoning of most of the groups involved in the study. It appears that they all followed the line of reasoning given to them by the instructor on how to get started. Therefore, for all groups the first part should be characterized as imitative reasoning. However, having started each group followed their own line of mathematical reasoning, varying slightly from one group to another. The reasoning of all the groups except for one should not be characterized as imitative. Their reasoning had flexibility but nothing indicated novelty. Only one group continued with imitative reasoning. The video shows that this group found an earlier example to compare with. The group appears to have found similarities between the two examples. However, the similarities should be characterized as surface similarities. Therefore their mathematical reasoning should be characterized as superficial reasoning.

Hence, according to this study, an analysis of the mathematical reasoning of pre-service teachers should be based on a distinction between imitative reasoning (IR) and non-imitative reasoning (NIR). Imitative reasoning is defined by Lithner (2008) as the kind of reasoning where each element of the reasoning is laid out step by step for the reasoning subject. Non-imitative reasoning is introduced in this paper as the kind of mathematical reasoning which is not imitative.

It is quite possible that the imitative reasoning of the first part was based on a relational understanding (Skemp, 1978). However, if the reasoning is based on surface property considerations (Lithner, 2008) only, it should be characterized as superficial reasoning (SR).

This study indicates that imitative reasoning may be mathematically founded or plausible (IMR). However, imitative reasoning may also be based on surface property considerations only (SR). Hence, imitative mathematical reasoning may or may not be mathematically founded or plausible.

Non-imitative reasoning (NIR) can hardly be based on surface property considerations only because that kind of reasoning would always involve some elements of copying. If plausible reasoning (Polya, 1954) is about supporting conjectures, then plausible reasoning would not be imitative reasoning. Therefore plausible reasoning could be an example of non-imitative reasoning (NIR). The kind of non-imitative reasoning found in this study is characterized by the fact that it is plausible and mathematically founded (Lithner, 2008), has flexibility (Haylock, 1987) but no novelty. This kind of non-imitative reasoning is called flexible mathematically founded reasoning (FMR) in this study.

FINAL REMARKS

This study shows that to analyze the mathematical reasoning of pre-service teachers, it might be useful to base the analysis on a distinction between imitative and non-imitative mathematical reasoning (NIR) rather than imitative and creative reasoning (Lithner, 2008). Imitative reasoning includes both superficial reasoning and imitative mathematically-founded reasoning (IMR). Non-imitative reasoning (NIR) includes both flexible reasoning (FMR) and creative mathematically-founded reasoning (CMR). Thus non-imitative reasoning may or may not involve novelty. If novelty is essential to the concept of creativity as defined by Sriraman (2009) then non-imitative reasoning would include mathematical reasoning that is neither imitative nor creative. Hence, to analyze pre-service teachers' mathematical reasoning, Lithner's (2008) distinction between imitative and creative reasoning might not be sufficient. Some of the students' reasoning might be neither imitative nor creative.

Developing students' culture of problem solving via heuristic solving strategies

Jiří Bureš and Hana Nováková

Charles University in Prague, Faculty of Education, Prague, Czech Republic, jiri.bures@pedf.cuni.cz

The goal of our long-term project presented in this paper is to develop students' culture of problem solving based on using heuristic solving strategies. In this paper, we describe the method of implementation of the strategies in class preceded by a detailed a priori analysis and followed by an a posteriori analysis and a comparison between the teacher's expectations and the reality in the class. We focus on the variables of a problem to be treated in class that may influence the role and use of the problem in developing students' creativity and their culture of problem solving.

Keywords: Problem solving, word problems, heuristic solving strategies, creativity, a priori analysis.

INTRODUCTION

Problem solving is generally acknowledged as one of the key features of mathematical education. The role and the use of problem solving tasks vary with different learning situation. Our observations and some studies (Novotná, 2000) show that, in secondary schools in the Czech Republic, problem solving is generally used as a tool for applying basic mathematical concepts, such as linear equations or systems of linear equations. Teachers often show an algorithmic way to solve a class of problems and students are lead to identify and to use this method to solve other problems. This approach to problem solving in school mathematics can create an illusion of students' good abilities to solve various problems; however, it does not fulfil the potential of word problems to promote creativity and ability to solve non-standard or real-world problems.

The research presented in this paper is focused on the culture of word problem solving based on a different perspective and way of using word problems and solving strategies in school mathematics. One of the main goals of the research is to investigate heuristic solving strategies and problem types that support students' ability to apply the acquired knowledge and skills in various situations to work creatively in mathematics. According to Silver (1997) or Kopka (2010, Foreword), we believe that solving carefully selected problems may help to develop and cultivate students' creativity. By students' creativity in problem solving, we understand the ability of finding non-standard ways of solution as well as the ability to find more than one method of solving a problem.

The key concept of our research is the culture of solving mathematical problems, which is understood as a structure of internal factors that influence a pupil's performance and success in problem solving. Based on the four categories of skills needed to have success in mathematics (Schoenfeld, 1985), the culture consists of four components: intelligence, creativity, ability to use existing knowledge and reading comprehension skills (Eisenmann, Novotná, & Přibyl, 2014).

The main research activities were: designing problem solving situations based on problems encouraging the students to use non-standard solving strategies, a detailed a priori analysis of these problems and using these problems and strategies in different classes. The implementation of the situations in class was preceded and followed by psychological screening, by testing the ability to use existing knowledge and by evaluation by the teacher of mathematics (see, for example, Eisenmann, Novotná, & Přibyl, 2014). The psychological screening consisted of a test of intelligence for the category of age 12–18, the test of ability of reading with comprehension and the Christensen-Guilford test of creativity measuring fluency, flexibility, originality and elaboration.

In this paper, we focus on the method of designing a problem-solving situation based on a detailed a priori analysis used in the research. The realization of a problem-solving situation in class is preceded by the *a priori* analysis and followed by the *a posteriori* analysis. The objective of the a priori analysis is to give, in advance, a detailed description of a teaching unit and to predict as accurately as possible the course of this unit, students' and teacher's attitudes and reactions, solving strategies and knowledge prerequisite for the use of the solving strategies (Brousseau, 1998; Novotná, Nováková, 2014). In the a posteriori analysis, the a priori analysis is compared with the experience of the realization of the situation in the class. The comparison is based on the observation of a video sequence from the lesson and on the discussion with the teacher. Recommended changes arise from this comparison.

The problem solving situation described in the paper is one of many situations during the period where the teacher teaches the students to use various solving strategies. In order to promote creativity in problem solving, four heuristic solving strategies were treated in the class in this situation. Two strategies were presented by the students (Direct method – graphical representation – solution drawing and Direct method without graphical representation) for Problem 1 and the second strategy was generalized and used to solve Problem 2. After solving both problems, the use of the strategy of analogy for solving a general problem was discussed in the classroom.

We used the following problems in the situation:

Problem 1. We have to dispose 24 stakes around a square ground. How many stakes at most can we dispose on each side of the ground if there has to be the same number of stakes on all sides?

Problem 2. We have to dispose c stakes around a square ground (c is a number divisible by 4). How many stakes at most can we dispose on each side of the ground if there has to be the same number of stakes on all sides?

Problem 2 represents in fact a set of problems created from Problem 1 by changing the variable of the number of stakes. The set of problems issued from changing a variable of the given problem is called a cluster of problems and represents a possibility to motivate the students to use various solving strategies.

A PRIORI ANALYSIS OF PROBLEM 1

The main purpose of this paragraph is to describe in detail the a priori analysis of Problem 1. Most of the characteristics of Problem 2 are similar, with the exception of the solving strategies. Since the problems are given to the students together as a cluster of problems, we believe that the solution of Problem 1 will precede the solution of Problem 2. If Problem 2 is posed to the students separately, the solving strategies will probably start with a specification of the number of stakes if the student is not able to solve the general problem.

The a priori analysis of Problem 1 is described below.

Nature of the assignment

Knowledge prerequisite to grasping the problem: general expressions (stake, around a ground, side of a ground), mathematical expressions (square, at most, the same)

Potential problems in comprehension of the assignment: We think that younger students might have a problem with the expression "at most" in the formulation of the question. It would be better to use the word "maximally". We also think that the formulation "How many stakes at most can we dispose on each side of the ground" is not exact and we propose to reformulate it as "How many stakes can one see..."

Thematic unit

Word problems (possible resolution with a linear equation or without an equation)

Goal of the problem

Goal for the students: to find the maximal number of stakes that one can see on one side of the garden

Didactical goal for the teacher: to find out if the students are able to represent the situation in a picture, to identify their solving strategies and to make a generalization of the problem with the students

Time needed for the solution of the problem

We estimate 10 minutes for the solution of the problem.

Class management

Individual work or work in pairs or groups. Homework or work in class.

Aids
paper, pen, squared paper

Cognitive didactic variables
(squares) The ground might have another form (triangle, irregular ground etc.).

(24) The choice of the number is crucial for choosing a solving strategy. With a small number like 4, the problem can be presented to young students; however, with a big number like for example 444, students cannot use graphical representation and the difficulty of the problem rises significantly.

(same) We can modify the problem by giving a given difference of the number of stakes on each side of the ground.

Formulation variables
There are the following formulation variables: (dispose), (stakes), (on each side), (number), (how many).

Students' reactions and attitudes
We suppose that the problem may be interesting for the students because of its real-life context. We think that they might have some problems with understanding the formulation of the problem.

Teacher's reactions
We suppose that the problem may be interesting for teachers because of its real-life context and its potential of modification and generalization.

Correct solving strategies
1) Systematic experimentation

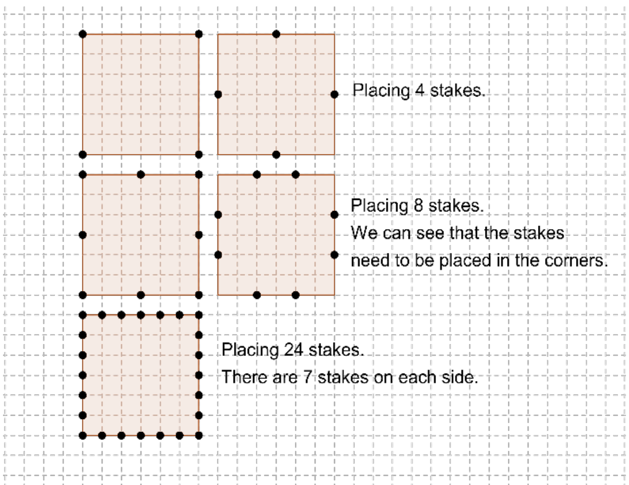

Figure 1: Systematic experimentation

Systematic experimentation leads us to a graphical representation of the situation. It leads to the fact that there must be a stake in each corner to get the maximum number of stakes on each side. Since we dispose of 24 stakes, there are 7 stakes on each side.

Knowledge needed: square and its properties, addition of natural numbers

Possible difficulties: lack of system in the experimentation, clarity of the drawing, idea of placement of stakes in the corners

2) Direct method – graphical representation – solution drawing

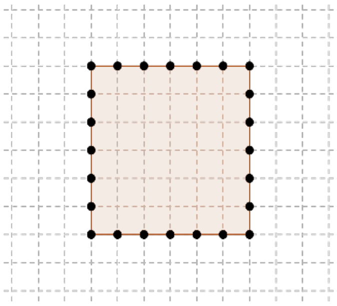

Figure 2: Direct method – graphical representation – solution drawing

There are 7 stakes on each side.

Knowledge needed: square and its properties, addition of natural numbers

Possible difficulties: lack of system in the experimentation, clarity of the drawing, idea of placement of the stakes in the corners

3) Analogy

We simplify the solution of the problem by choosing a smaller number of stakes (for example 4 or 8 stakes) and we solve the analogical problem. The choice of 4 stakes or 8 stakes leads to the idea of placing the stakes in the corners of the ground.
A stake placed in the corner counts for two sides. By increasing the number of stakes to 24, we find the solution – 7 stakes on each side.

Knowledge needed: square and its properties, addition of natural numbers

Possible difficulties: choice of numbers creating an insolvable problem, clarity of the drawing, idea of placement of stakes in the corners

4) Direct method without graphical representation

A direct way of solving the problem is based on the idea that placing a stake in the corner makes it being counted for two sides. When we place 4 stakes in four corners, we have 20 stakes left. Since 20 can be divided by 4, we can dispose 5 stakes on each side, which gives totally 7 stakes on each side.

Knowledge needed: square and its properties, addition of natural numbers

Possible difficulties: idea of placement of stakes in the corners, numerical error

Incorrect solving strategies

1) Arithmetical way

There are 24 stakes to place on 4 sides of a square, so there are 6 stakes on each side.

2) Solution drawing

The pupil places 6 stakes on each side of the ground and leaves the corners free.

The a priori analysis of Problem 2 is based on the analysis of Problem 1. In our opinion, students will first use the same solving strategies based on a concrete number of stakes and then they will generalize the results. We suppose that the time needed for solving the problem might be longer.

REALIZATION OF THE SITUATION IN THE CLASS

In this part we describe a problem-solving situation from June 2013 in the class of students aged 15 or 16 in a grammar school in Prague, Czech Republic. The class is composed of students selected during the entrance exams. There are some very gifted students, but there is also a big difference among the students in their performance in Mathematics. In the years 2012–2014, this class participated on the long-term research mentioned in the introduction. The students dealt regularly with problems using different heuristic problem solving strategies.

The situation was based on the problems described in the previous section and its goal was to learn how to grasp a general problem by solving a simplified problem with specified variables. The description of the situation is based on a video sequence and on the observations of the teacher. There were 18 students in the class. First, they were given 10 minutes to prepare the solution of the problems. They could work individually or in pairs and they could use only paper and pen or pencil to solve the problems. Then, some volunteers presented their way of solving the problems to the others. The presentation was always followed by a whole class discussion about the methods and results.

Student 1 presented her way of solving the problem based on a graphical representation of the square and the stakes. She found the correct solution and presented also the idea of dividing 24 by four as a wrong idea, without explanation. The correct argument (the expression "at most" from the assignment) appeared in the following whole class discussion. Most of the students used the same solving strategy based on a graphical representation.

Student 2 presented her solution based on the idea of placing a stake in each corner of the ground and the same number of stakes on each side. Since there are 2 stakes at the corners and 5 on the side, the total number of stakes on a side is 7. Only three students used the same solving strategy.

16 students found the correct answer, 2 students answered 6 stakes. Since there were not any other solving strategies used for the Problem 1, the next students presented their solution to Problem 2.

Student 3 showed the following method: The number of stakes is divisible by 4, so we divide it by 4 and then, we add 1 to the result because of the stake at the corner that counts two times. The general formula is $n : 4 + 1$.

Student 4 showed another formula: $(n - 4):4 + 2$ with a commentary that the result is the same as for the formula of Student 3.

There were 13 students who found the first or the second formula and 5 students who did not find any general formula. Student 5 showed that both formulas are equivalent by rewriting the second formula as the first one.

A POSTERIORI ANALYSIS AND COMPARISON

The a posteriori analysis and comparison will focus on some characteristics of the situation that appear to us as the most important.

Nature of the assignment

The students did not have problems understanding the assignment. Nevertheless, there appeared a difference among students in realizing the importance of the expression "at most" at the moment when they had to explain why 6 is not a correct solution. During the discussion, they used both expressions "at most" and "maximally". In our opinion, younger students might have more problems with these expressions.

Goal of the problems

Goal for the students: The students were mostly able to find the maximal number of stakes in Problem 1; however, the generalization of the formula presented a difficulty for some students.

Didactical goal for the teacher: The students were able to represent the situation by a picture. For some of them, the graphical representation was not necessary to find the solution and it was probably replaced by a mental representation. The teacher could also identify students' solving strategies. The generalization of the problem appeared only in the number of stakes. Due to lack of time, the teacher did not deal with the other possible generalizations of the problem, as for example a change of the form of the ground or a given difference between the number of stakes on each side.

Time needed for the solution, class management, aids

We supposed 10 minutes for the Problem 1 would be needed. Most students were able to solve both problems in less than 10 minutes. Some of them worked individually but most of them worked in pairs using a paper and a pen.

Cognitive didactical and formulation variables

(24) The choice of the number 24 for the stakes permitted the students to use graphical representation as a solving strategy. As most of the students found the solution very quickly and then considered the problem an easy one, we believe that the choice of a higher number (72, for example) could provoke more reflection than the given number, in particular for students aged 15 or 16. Problem 1 was suitable for showing different solving strategies; however, it was not a challenge for the more gifted students or for all the students having the idea of placing the stakes at the corners. Problem 2 was more challenging for the students.

As the assignment was understood by all students, we did not identify any importance of the formulation variables in the solution of Problem 1. However, we believe that omitting the information „*c* is a number divisible by 4" in the assignment of Problem 2 could provoke more reflection and also more errors in solution of the problem.

Students' reactions and attitudes

Problem 1 was interesting for students with average results in Mathematics because it was easy for them. Problem 2 was more interesting for the more gifted students. Nevertheless, some students with average results were satisfied with finding a solution to both problems, which could improve their self-confidence and attitude to problem solving.

Correct solving strategies

15 students used the Direct method – graphical representation – solution drawing. Some students drew the complete solution, some of them only the corners and one side of the ground. 3 students used the Direct method without graphical representation. We did not notice any solution using systematic experimentation, but a non-systematic experimentation appeared in most of the solutions using graphical representation.

Incorrect solving strategies

Incorrect solving strategies appeared only in two cases. These students did not realize the fact that a stake placed at the corner of the ground counts for both sides.

The comparison between the a priori and the a posteriori analysis shows that most of characteristics of the situation described in the a priori analysis appeared in the class. In our opinion, there could be more reflection on the choice of didactical variable (number of stakes) with respect to the age of the students. The a posteriori analysis shows that the number 24 was suitable for promoting the use of both principal solving strategies, the reflection upon the generalization of the problem might be provoked by giving a number of stakes that did not allow a graphical representation. For this reason, we suggest replacing the number 24 by another number, for example 72, and we believe that the students will be lead to use the graphical representation for a smaller number of stakes by the constraints of the milieu and not by the fact that it is easy to represent.

One of the goals of the situation was to make a generalization of the problem with the students. Even though there was enough time to solve both problems, there was not any time and enough support for the teacher. In our opinion, the cluster of problems suitable for generalization should contain also problems dealing with other variables, for example:

Problem 3. We have to dispose c stakes around a *pentagonal* ground. How many stakes at most can we dispose on each side of the ground if there has to be the same number of stakes on all sides?

CONCLUSION

The methodology described in the paper was used for various word problems and solving strategies (see, for example, Břehovský et al., 2013; Eisenmann, Novotná, & Přibyl, 2014). The results of the research show that number of using of two solving strategies, *Systematic experimentation* and *Adding of an auxiliary element*, increased significantly. The analysis of the psychological screening show that the indicators of creativity increased in an important way, in particular the fluency and the flexibility. The didactical situation based on the use of various solving strategies seems to be a suitable environment to enhance the development of these key features of creativity. A question about the way how the problems-solving activities can promote also the originality and the elaboration arises immediately from these results. The role of the key features of a problem solving situation in development of fluency and flexibility gives also an implication for future research.

The most important changes appeared in the attitudes of the students towards problem solving. We could observe half of them make an increasing effort to solve a problem despite the fact that they didn't know how to solve it at the beginning. The participating teachers became more tolerant to different students' solving strategies. Furthermore, there is a list of problems and solving strategies prepared to use by teachers promoting students' creativity in problem solving.

ACKNOWLEDGEMENT

Looking for creativity in primary school mathematical tasks

Despina Desli and Marianthi Zioga

Aristotle University of Thessaloniki, Faculty of Education, School of Primary Education, Thessaloniki, Greece, ddesli@eled.auth.gr

The purpose of this study is to explore the features that primary school teachers consider appropriate when choosing tasks intended to promote mathematical creativity. 26 prospective and 48 in-service teachers completed a questionnaire whereby they were asked to choose a mathematical task and explain why it fosters mathematical creativity. Interviews were also conducted with 2 prospective and 2 in-service teachers to further investigate their perceptions of creativity in mathematics as well as issues related to teaching mathematics using creative problems. Disparate views were revealed between the two groups: prospective teachers mostly connect mathematical creativity to arousing student interest whereas in-service teachers connect it to book-oriented problem posing indicating their narrow and blurred perceptions. Outcomes highlight the need for educating teachers about creativity in mathematics.

Keywords: Mathematical creativity, teachers, primary school.

INTRODUCTION

Creativity, traditionally linked to art and literature, has been characterized as an individual activity intended to produce something new (Bolden, Harries, & Newton, 2010). Creativity has also recently been associated with mathematics, it being the ability to create new mathematical insights and ideas (Sriraman, 2009). Similar to this idea, the ability to combine previously known concepts or discover unknown relations between mathematical facts and employ non-algorithmic decision-making can be considered as a creative act of doing mathematics (Ervynck, 1991). Divergent thinking in problem solving is also associated with mathematical creativity (Haylock, 1997; Chamberlin & Moon, 2005). It allows one to analyze a problem from different perspectives without applying one fixed answer, identify patterns, differences and similarities and choose an appropriate method for tackling it. Although there are many definitions of mathematical creativity, in general, two common trends describe it - the generation of new mathematical knowledge and flexible problem solving abilities (Kwon, Park, & Park, 2006).

Even though the importance of facilitating mathematical creativity in educational settings has been well established, there is a clear need to study the choices teachers make in terms of tasks that could develop children's creativity in mathematics. The present study focuses on the features they consider necessary for mathematical creativity and the reasons for these choices.

RESEARCH BACKGROUND

Mathematical creativity is often assessed on the basis of the four indices of creativity proposed by Torrance (as cited in Silver, 1997) and Guilford (as cited in Klavir & Hershkovitz, 2008). These indices include: a) fluency, referring to the number of correct responses that the student produces, b) flexibility, referring to the number of different mathematical concepts and ideas that the student discovers, usually breaking away from stereotypes, c) elaboration, indicating the complexity of mathematical thinking, as the student integrates different pieces of mathematical knowledge, and d) originality, illuminating the extent that the student's ideas are insightful, new and lead to unexpected and unconventional solutions.

Studies of mathematical creativity have revealed that students' creative mathematical thinking and indices of mathematical creativity could be encouraged by providing divergent product tasks. Klavir and Hershkovitz (2008), for example, suggested tools for teachers to analyze and evaluate the work of fifth-grade students when dealing with an open-ended problem. These tools referred to indices of mathematical creativity as well as levels of complexity in mathematical knowledge. Their results led them to suggest that open-ended problems tend to distance us from the stereotype that there is only one solution to any given problem and recognized their value as an assessment tool for both teachers and students. Kwon and colleagues (2006) also found that divergent thinking in mathematics could be cultivated through an open-ended approach: in their study with seventh-grade students, open-ended problems were found more cognitively challenging, because they allowed for multiple interpretations and solutions and offered students the opportunity to solve problems using their actual skills. As Mann (2006) suggests, solving these types of problems let the students take the first steps towards mathematical creativity.

The encouragement for promoting children's mathematical creativity in the classroom is advocated in mathematics curricula worldwide that regard it as a desirable outcome of mathematical education. Given the fact that mathematical creativity is also considered as a dynamic faculty that can be improved and enriched or, conversely, decline (Leikin, 2009), great attention has recently been paid to how teachers perceive creativity in mathematics. Bolden and colleagues (2010) found that pre-service teachers in UK hold narrow conceptions regarding creativity in mathematics: these conceptions are mainly associated with the use of resources and technology and, while attempting to create a 'fun' environment, they 'teach creatively' rather than 'teach for creativity'. Their great difficulty in recognizing creativity in teaching mathematics and also in identifying ways of encouraging it in the classroom was also observed. More positive results were revealed in Chiu's study (2009), which found that in-service teachers profess a greater preference for creative problems, compared to non-creative problems for teaching fractions: a liberal approach was proposed as the most appropriate method for teaching creative problems with emphasis on the children's imaginative and diverse solutions. Secondary classroom teachers, however, identified both opportunities and constraints in posing more challenging mathematical tasks, especially those related to changes to their pedagogies and assessment of student work (Sullivan & Mornane, 2014).

However, a key component of mathematical creativity is how teachers select and use appropriate tasks which enhance children's creativity in terms of school mathematics. In her study, Levenson (2013) investigated general trends that prospective and in-service teachers attribute to tasks that may occasion mathematical creativity. Of these trends, the most common one was the implication that creativity pertains to being different and unusual. The responses of participants also focused on the cognitive demands of the chosen tasks, as well as their affective aspect. Interestingly, with regards to the latter, teachers took into consideration possible feelings which a task may elicit from students.

These studies suggest that excluding the teachers as important factors in determining the use of creative mathematics problems in the classroom could lead to an incomplete understanding of the situation. Thus, investigating teachers' perspectives of creativity in primary mathematics, by asking them to choose such tasks is important, in order to understand the knowledge they hold that could influence their interpretation of creativity in the curriculum and what they do in their teaching. Specifically, this study attempted to examine the following questions: a) Which task characteristics do prospective and in-service primary school teachers associate with the promotion of mathematical creativity?, b) Are there any discrepancies between the task characteristics identified by prospective teachers and in-service teachers?, and c) How they envision creativity being taught in the mathematics classroom?

METHOD

Participants. Twenty-six prospective teachers and forty-eight in-service teachers participated in the study. At the time of the study, prospective teachers, who were in their last year of an elementary teaching education programme at a large-sized university in Thessaloniki, participated in a course on teaching mathematics that was mainly focused on observing, planning and teaching mathematics in local primary schools. They were predominantly women (92%) with a mean age of 22 years and 2 months. In-service teachers, most of which were women (83%) with a mean teaching experience of 18 years, worked at several grades of state primary schools from various geographical regions of Northern Greece and their ages ranged from 26 to 58 years old. A small percentage of in-service teachers (15%) who took part in the study had completed postgraduate studies, but did not mention that they have attended specific training courses on creativity. All participants' selection was random and their participation was voluntary.

Instrument. Data were collected via a questionnaire and semi-structured interviews. The questionnaire used was based on Levenson's (2013) research tool and asked participants to: a) choose a task that they consider appropriate for promoting mathematical creativity. This task could be from either the state mathematics textbooks or any mathematics book or even one proposed by themselves., b) indicate their source, c) state the grade to which the task is targeted and whether it is intended for individual or group work, and d) describe why they consider the task they had chosen suitable for promoting mathematical creativity. All questions in the questionnaire were open-ended and no possible answers were provided. Additionally, no instruction about the term 'task' was given to participants who were free in their interpretation. However, the present study relies on Stein and Smith (1998), who clarified the multiple roles of tasks: these may be set up by teachers during their instruction as learning tasks, review tasks, practice and assessment tasks with the main purpose of developing a particular mathematical idea.

Follow-up interviews were conducted on the basis of the questions developed from the completed questionnaires. Thus, supplementary data were gathered, in order to verify that questionnaire responses were being interpreted as they were initially intended. Interview questions explored the participants' envision of creativity in mathematics and the use of creative problems in teaching mathematics in primary schools. In the present study the results of only two prospective and two in-service -randomly chosen- teachers are presented as these were the first interviewed and became part of a larger sample for the purposes of a later relevant study.

Procedure. The questionnaires were administered to prospective and in-service teachers during their classes, at the University and the schools, respectively, and they were collected after two weeks. The majority of those contacted returned the completed questionnaires, reaching 93% and 89% participation response rates for prospective and in-service teachers, respectively.

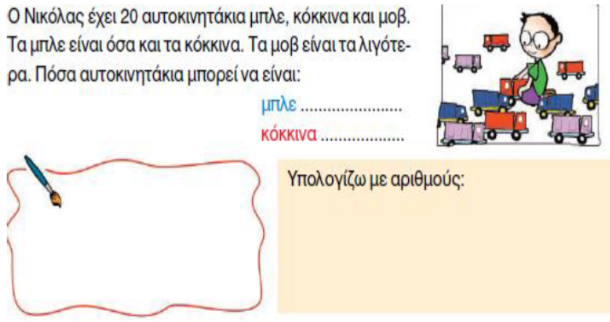
Interviews were conducted individually at a place convenient to interviewees, two weeks after they had completed the questionnaires, and lasted approximately 20 min.

RESULTS

The results are presented in two main sections. It is not possible to present all the tasks proposed by the participants in this paper, therefore only three are presented in the first section. In the second section we describe common trends in the responses of participants, drawn from answers to the questionnaire and the interviews, regarding the teaching of mathematics and learning with creative problems.

a. Tasks proposed by the participants. The majority of the tasks the participants chose were taken from the mathematics textbooks that are given to all students in the nation (85% and 83% for prospective and in-service teachers, respectively). Only one in-service teacher seized the opportunity to propose a task herself and handed in a task that was her own devising. Prospective teachers proposed about 40% of the tasks for individual work, whereas the rest of the chosen tasks were divided equally for either group work or both individual and group work. Great preference for tasks carried out individually (42%) – rather than for all students (38%) – was also observed by in-service teachers.

Katerina, a prospective teacher, chose the task shown in Figure 1, taken from a Grade 2 mathematics student book, and proposed that children could work on it individually. The task in question is special because it does not provide students with a familiar methodology for solving it. Katerina mentioned it in her response and explained why this task promoted mathematical creativity: '*it is a task that cannot be easily solved in the usual way. It doesn't use typical formulas ... children will experience the struggles of finding explanations and solutions... it leads to creative thinking*'. Even the opportunity to use a trial-and-error strategy when solving the problem was seen as conducive to mathematical creativity. For her, mathematical creativity was associated with breaking away from well-trodden paths. However, she did not mention the fact that there are several ways of solving this problem, a characteristic that raises flexibility as involved in creativity. Last, she put great emphasis on the story involved (toy cars) and believed that anything that motivates students to work – indicating mainly the problem story – can promote creativity.



Nikolas has a total of 20 blue, red and purple toy cars. Blue cars are as many as red ones, purple cars are less. How many are the blue and red cars? Compute with numbers.

Figure 1: Katerina's task

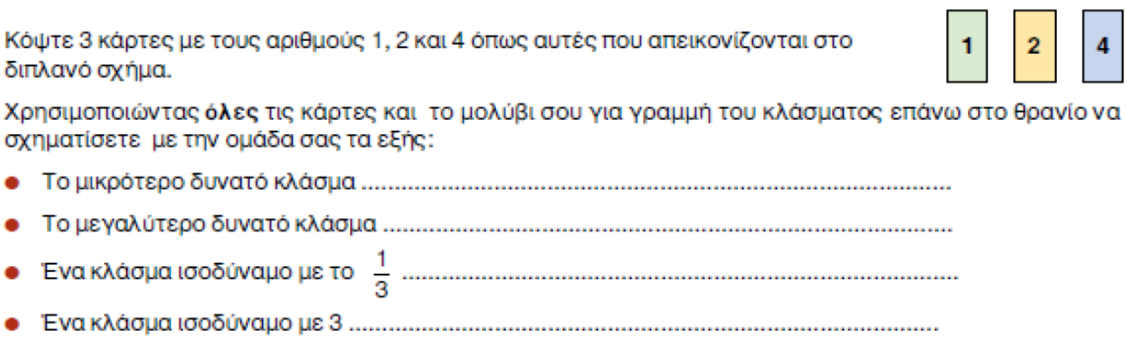
Make your own problems that suit the pictures.

Figure 2: Anna's task

The task in Figure 2 was proposed by Anna, an in-service teacher. It was taken from a Grade 1 mathematics workbook and it was meant for all students to solve. Anna mentioned three components she believes are promoted by the task. First, every child may phrase and create her own problem and, thus, may take an active part in solving it. In this sense, '*every child may bring her interests into mathematics and feel involved*'. Although this feature calls mostly on the emotional impact that a task may have on children, Anna raises the issue of the mathematical content involved. According to her, '*children may see addition or subtraction involved, insert numbers and perform calculations*'. This feature, though, is more reminiscent of a conventional problem that requires certain ordered steps to reach algorithmic answers. Third, she acknowledges that the fact that children can pose different problems leads them to different solutions that may encourage debates and contribute to a productive classroom discussion.

Figure 3 shows a prospective teacher's choice of a creative mathematical task, taken from a Grade 6 mathematics workbook. Maria's activity includes four mini questions -each of which is meant to have one and only one algorithmic solution- that do not require new ideas. It may be conducted in the classroom using pen and paper and by following steps in a specific order. However, this fact did not deter Maria from considering this task as one promoting creativity. Instead, she considered the fact that children are asked to act (e.g. by moving the cards), are presented with the mathematical knowledge and communicate their findings as important. The fact that some features are overestimated or others are ignored is often the case, as it happens with Maria's choice.

b. Participants' reasons for choosing tasks. Participants listed various reasons for choosing their task. Because they provided more than one reasons, these are analyzed on the basis of the number of participants (see Table 1). Attractive and entertaining stories (30,8%) involved in the task that may arouse children's interest and inquiry was one of the two most important elements for fostering mathematical creativity, according to prospective teachers. Creative mathemat-



Cut three cards and place numbers 1, 2 and 4 on them, as shown in the figure. Using all cards and marking a fraction line with your pencil, work in groups and make: the smallest possible fraction, the biggest possible fraction, a fraction equal to 1/3, a fraction equal to 3.

Figure 3: Maria's task

ical tasks were also those that allow children to make their own constructions (30,8%), placing emphasis on the children's active engagement in mathematical activities, as well as those that invite work between students and encourage cooperative learning (23%).

In-service teachers seem to relate creativity to the activity of problem-posing on the part of the children (37,5%) and the placement of the task in a real-life context (16,7%) that may offer opportunities for the flexible use and application of mathematics in everyday life. However, many in-service teachers insisted on more 'traditional' ideas: these tied creativity to solution methods provided from the start and presented in multiple steps following an hierarchical order (29,1%) and focused on algorithmic thinking and techniques (20,8%).

Both groups of participants mentioned creativity in terms of searching for new ways to cope with mathematical problems on the basis of their previous mathematical knowledge (23% and 8,4% for prospective and in-service teachers, respectively). Presenting children with unusual questions (quizzes were the most frequently mentioned) was connected to motivation for imagination and creativity (23% and 20,8% for the two groups). Interestingly, prospective teachers only seem to regard that difficult technical calculations are not necessarily required; they view mathematical creativity as not being constrained by precise methods or anticipated outcomes and support non-algorithmic thinking and computational estimation (8,5%). Last, seeing the same problem offering several different solutions as well as connections with other, less (or non-) mathematical, school subjects were also considered to elicit mathematical creativity.

DISCUSSION

The characteristics participants associated with mathematical creativity, as shown in the aspects they considered in choosing tasks, demonstrated predominantly that both prospective and in-service teachers identify creativity in primary mathematics classrooms. Based on the mathematical tasks they chose, however, it was revealed that identifying mathematical creativity was not an easy thing to do. Interviews further confirmed the participants' difficulties in being clear about planning and encouraging creativity in the classroom. Although they seem to believe that mathematics can be a subject that is offered for the promotion of creativity in children, however, they acknowledge constraints in the classroom, mainly related to the role of the teacher and the mathematical content.

There were some common ideas between the two participant groups, but the issue of mathematical creativity and how this can be fostered drew disparate views, which were probably influenced by their academic training. Prospective teachers mostly related mathematical creativity to arousing children's interest and

Elements of tasks that promote mathematical creativity	Prospective	In-service
	Teachers	
Story that arouses children's interest and inquiry	30,8%	8,4%
Problem-posing by children		37,5%
Children construct (e.g., draw, combine shapes)	30,8%	8,4%
The solution method is provided in multiple steps	15,4%	29,1%
Presenting with unusual questions	23%	20,8%
Connections between mathematical topics and everyday life	23%	16,7%
Use of manipulatives	23%	12,6%
Use and extension of previous knowledge	23%	8,4%
Children work together – Cooperative learning	23%	
Focus on algorithmic thinking and techniques	7,7%	20,8%
Large number of possible solutions to a problem	15,4%	8,4%
Focus on computational estimation	8,5%	
Connections with other school subjects	7,7%	4,2%
Other	3%	4,2%

Table 1: Characteristics identified for tasks that promote mathematical creativity by prospective and in-service teachers

motivation, mainly with the use of attractive stories or puzzles that keep them engaged in mathematics. This finding is in agreement with Bolden and colleagues' (2010) results that, for prospective teachers, creativity was bound up with the use of resources in order to create a 'fun' environment for children. Although this might be a desirable outcome, care is needed to avoid underestimating children's access to mathematical ideas. Prospective teachers also gave emphasis on children's own constructions when doing mathematics, use of materials and non-algorithmic thinking. It is encouraging to see prospective teachers moving away from a conservative view of mathematics with algorithmic calculations. This orientation that brings flexibility to the front was also observed in Bolden and colleagues' (2010) study. In general, prospective teachers recognize some of the aspects of creativity as do researchers (Klavir & Hershkovitz, 2008; Levenson, 2013; Kwon et al., 2006). Last, cooperative work was often considered necessary for the promotion of mathematical creativity; children working on a task may contribute insights, experiences and ideas building eventually to a solution brought forth by more than one student. The issue of collective mathematical creativity was originally raised by Levenson (2011) who deems it equally important as individual mathematical creativity.

In-service teachers, on the other hand, related mathematical creativity to children's problem posing. They explain that asking children to make up a problem provides them with the opportunity to feel involved and take an active role in solving their own problem. Other elements they considered as important referred to applying some algorithm learned in class and following strictly-defined steps towards a solution method. These were limited to rule-based applications and were relatively different from what researchers consider as mathematical creativity. Their choices of tasks, in general, were less imaginative without recognizing the essence of the problem to be solved, and indicated their narrow and blurred perceptions. Thus we wonder how easily a teacher may overestimate the more conservative aspects of teaching and discard the opportunities for mathematical creativity that a task might provide. Searching for the new in mathematics and expressing the unusual have also been considered by a few participants who highlighted novelty and placed emphasis on creativity in mathematics. These participants raised issues such as real-life connections to mathematics, connections with other school subjects and extension of previous knowledge. Unusualness as an element for creativity was strongly supported by the use of non-routine problems (e.g., quizzes), non-standard problems that involved unexpected and unfamiliar solutions (Yeo, 2009).

An additional finding of the study showed that although participants identified characteristics of mathematical creativity in general, these characteristics were not always revealed in the tasks they had chosen or did not fit well with their choices of tasks. For example, a few participants regarded multiple solution methods as a key element to creativity. Although searching for different solutions can definitely be seen as an aspect of both flexible thinking and fluency, its value is mediated, if an explicit direction to consider several different ways of solving the problem is given at the end of the task. The demand to solve a task using different methods may have the opposite effect on creativity. Similarly, in the search for a task that may foster children's mathematical creativity, the vast majority of the participants searched for tasks taken from standard classroom textbooks. This may be interpreted in two ways: participants are unwilling to look for tasks other than those provided, or, less pessimistically, participants may transform any task to a creative one, depending on how they themselves implement it in the classroom. Although attention to the nature of mathematical tasks that foster mathematical creativity is important, an equal level of it in the classroom processes associated with mathematical creativity is needed. We are aware that analyzing only the tasks chosen by the participants is an inadequate method for predicting if the lessons would run for the purpose of teaching for creativity. Further investigation of this topic is needed.

The findings from this study suggested that the awareness of prospective and in-service teachers in terms of choosing tasks that promote mathematical creativity was apparent, at least at its manifested level; however, encouraging creativity in primary mathematics classrooms can generally be an elusive accomplishment. There is a need for clarification on how the idea of mathematical creativity is implemented and referred to in a mathematics lesson. This leads to the need for providing teachers with opportunities to be educated in mathematics teaching for creativity.

Assigned to creativity: Didactical contract negotiation and technology

Valérie Émin, Nataly Essonnier, Pedro Lealdino Filho, Christian Mercat and Jana Trgalová

Université de Lyon, Université Claude Bernard Lyon 1, S2HEP EA4148, École Normale Supérieure de Lyon, Lyon, France, pedrolealdino@gmail.com

The mcSquared European project aims at studying Social Creativity among pedagogical resources designers and Creative Mathematical Thinking in their users, through technology, namely a creative e-book software infrastructure and resources called "c-book units". This article focuses on a study carried out in the framework of this project in France experimenting such a c-book unit and highlights a particular obstacle created by a didactical contract effect related to creativity in the French mathematics classroom: high achieving students perform well on content related to an official assignment but have difficulties engaging in unusual creative problems. The article concludes on possible ways to circumvent it in order to foster the unleashing of mathematical creativity in all students.

Keywords: C-book technology, creative mathematical thinking, didactical contract.

INTRODUCTION

Mathematicians profess that performing mathematics is a creative activity (Hadamard, 1954). While "capital C" creativity is clearly of the essence, can "small c" creativity (Csikszentmihalyi, 1996) be implemented in the classroom in a way to transpose professional activity as a learning tool? Technology supported inquiry based learning is a possible way to put students in situations where their creativity is needed and can be expressed (Blumenfeld et al., 1991). Yet, many obstacles pave its way (Edelson et al., 1999). Despite these obstacles, inquiry based learning is rather put in practice and somehow familiar to students in sciences; but it might not be so in mathematics. This article focuses on didactical contract effects that may deter its adoption, in a manner similar to (Brandl, 2011) in the realm of giftedness.

In this article, we first introduce the mcSquared European project [2] and its structure in Communities of Interest (CoI) (Fischer, 2001) aiming at designing electronic books for teaching mathematics enhancing Creative Mathematical Thinking (CMT). We then present the educational resource under consideration in the reported experiment, the "Velocity" c-book, designed by the French CoI. Then we describe and analyze the experimentation carried out in two Grade 9 classrooms, where 14–15 years old students were invited to work on the Velocity c-book math activities. This lead to a didactical contract clash that we describe, followed by an outline of possible remediation. We then conclude on possible ways to improve acceptability and devolution of activities aiming at promoting creativity in mathematics classroom.

THE MC SQUARED EUROPEAN PROJECT

The mcSquared project aims at designing and developing an intelligent computational environment, a new genre of authorable e-book, which we call 'the c-book' (c for creative), extending e-book technologies to include diverse dynamic widgets, an authorable data analytics engine and a tool supporting asynchronous collaborative design of pedagogical resources, which we call 'c-book units'. The c-book environment aims at stimulating and enhancing creative designs for fostering mathematical creativity in mathematics classes.

Creativity is studied in two complementary ways: Creative Mathematical Thinking (CMT) in students using technology and Social Creativity (SC) in the design of c-book units intended to enhance CMT in the users. The c-book units are produced by four different Communities of Interest (CoI), organised by consortium partners' countries (France, Greece, Spain and UK), bringing together stakeholders from different professional domains, such as publishers, game developers, math education researchers, school educators... The French CoI is composed of representatives of several Communities of Practice (CoP) (Wenger, 1998), mainly gathered around the IREM [3] in Lyon and in Grenoble, and a few individuals (Figure 1).

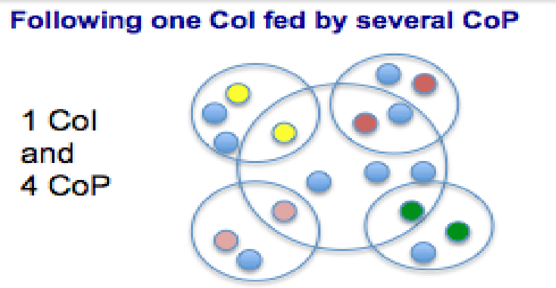

Figure 1: Several CoPs around a CoI

In this paper we only consider the creative mathematical thinking part of the project.

Creative mathematical thinking

Based on the existing literature review on creativity (Guilford, 1950; Kaufman & Sternberg, 2010), mathematical creativity (Sriraman, 2004, 2005; Leikin & Lev, 2007) and mathematical thinking (Tall, 2002; Blinder, 2013), we understand CMT as the combination of divergent and convergent thinking in mathematics.

Divergent thinking in mathematics is characterized by:

- fluency: number of solutions;
- flexibility: number of categories (representations and settings) of solutions;
- originality: statistical frequency of solutions;
- elaboration: depth and detail of solutions.

Convergent thinking is characterized by:

- mathematical correctness or conventional answers,
- use of cognitive processes to produce one or very few possible solutions.

Besides, CMT can be fostered by adequate feedback regarding its different dimensions: fluency, flexibility, originality/novelty, appropriateness and usefulness, provided by the c-book unit, teachers, fellow students... CMT is associated with an individual and relative to a given community, a given context, in which the process is envisioned to be used.

We can also integrate the social aspect of creativity in CMT dealing with motivation of participants, the issue of informal norms that promote cooperation and assistance, the social recognition of one's work value. The present article treats specifically this point and some obstacles that hinder creativity, namely didactical contract effects.

THE VELOCITY C-BOOK UNIT

First, a c-book unit is a digital pedagogical resource developed in a specific environment of the project, the c-book technology, viewable and editable in any modern Internet browser, organised in a set of pages which bundle together texts and communicating widgets from different origins enabling a great variety of affordances. They can be movie or sound players, 2D and 3D object viewers, but also constructionist bricks of software such as dynamic geometry software (Geogebra, Cinderella...), dynamic algebra software (epsilonwriter), programming environments (eSlate Logo TurtleWorlds, javaScript, cindyScript, GeogebraScript...), specialized visualization constructs ("widget factories", spreadsheets, graph of a function, algebraic expression editor, calculator...). These widgets can be saved and shared in a particular state, ranging from an empty canvas to a finished full-fledged "press and play" interactive resource, as well as half-baked micro-worlds (Kynigos, 2007) to be appropriated and worked upon by the students.

The idea of the Velocity c-book unit stems from the Community of Practice called TraAM (Mutualised Academic Works [4]) group in IREM Lyon, mainly composed of secondary mathematics teachers, focusing on the design of open-ended problems and problem-solving with technology. Their aim is to develop a shared repertoire of resources based on interesting use of ICT in the tackling of interdisciplinary open-ended problems in everyday life situations. They collaboratively design resources that they cross-experiment in their own classes. This CoP production takes place into a national framework coordinated by the ministry of education.

After a presentation and a quick *a priori* analysis of the c-book unit, we present the results of the experimentation carried out in two classes, with different average achievement levels in mathematics.

Learning goal

The Velocity c-book unit, aimed for Grade 9 students, has as the main learning goal the notion of speed as distance divided by time leading to the notion of derivation as a faraway objective.

The main targeted competency is modelling real world situations, but a series of sub-competences useful in this context and promoting creativity are also at stake: Understand a problem, engage in a research, show initiatives, be original; suggest answers, propose hypotheses or conjectures, formulate questions; prove that something is true or that it is false; communicate, orally or in a written form.

The idea behind this c-book unit is to let students gather information from the real world in order to analyse what they see with a "scientific eye", including the need to "be true to the data", reflecting the fact that real life does not provide you with polished data that makes sense at once: real data is full of glitches and does not follow exactly the model that you want to force on it. Specifically for this c-book unit, speed is the topical notion at work. Therefore an important goal is to make the students realize that position and time can be defined exactly only in theory but nevertheless, that a crude approximation is enough to be able to make science and take decisions based on it. We know from the start that this is a real change in didactical contract (Brousseau, 1988) for most of the students, used to be fed artificial exercises with a unique well defined answer to a question they know they can answer with readily available tools. This experiment focuses on the study of the devolution phase.

Description of the learning situation

The c-book unit comprises a series of four activities organized in 11 c-book pages (Table 1).

Each activity presents raw data of some sort and a very simple question that should engage the students in making sense of the data in order to answer these questions (see Table 1). Initiatives, which are manifold, have to be taken in order to overcome the limitations inherent to real world phenomena and reach definitive conclusions despite uncertainty. Being able to validate hypotheses such as "the car was driving too fast", or "the truck drove for more than 500 km", without knowing everything precisely is a goal that is attainable but requires mathematical creativity from the students. In what follows, we present in more details the Tunnel activity and its brief *a priori* analysis.

In this activity, students have to analyse videos taken from within a car while driving through a tunnel and try to figure out whether the speed limit is reached or not. They have to look for clues, such as the trails of lights or chevrons in order to estimate the car speed, by tabulating the timing and positions of these events, computing the average speed, dealing with imprecision and confidence intervals. Three different videos are provided (Figure 2), with computer adjusted speed profiles falling in three different scenarios showing two types of speed camera: a fixed speed camera and an average speed measuring camera, requiring the notions of instantaneous and average speed. In the first scenario, the car is not caught by any of the two speed cameras, in the second one it is caught only by the fixed speed camera, and in the third scenario it is caught only by the average speed measuring camera.

The total length of the tunnel is 1757 m. The students can identify chevrons and lights that are evenly spaced,

Activities	"widgets" used	Questions asked to students
Tunnel (3 pages)	Three videos taken from a car driving through a tunnel, Cinderella chronometer, GeoGebra	According to the video, will the car driver receive a fine for exceeding the speed limit in the tunnel?
Particles (4 pages)	Simulation of a particle in Cinderella, Graph2, GeoGebra, Microsoft Kinect	Dance your way as a function: graph the movement of a particle, and move to replicate a given graph.
Control (3 pages)	Picture of a paper disk used in trucks to monitor their speed along the day, Geogebra	According to the tachograph, what is the total distance driven by the truck driver that day?
Average speed (1 p)	GeoGebra	Give the average speed of a car in a given condition.

Table 1: Velocity c-book unit activities

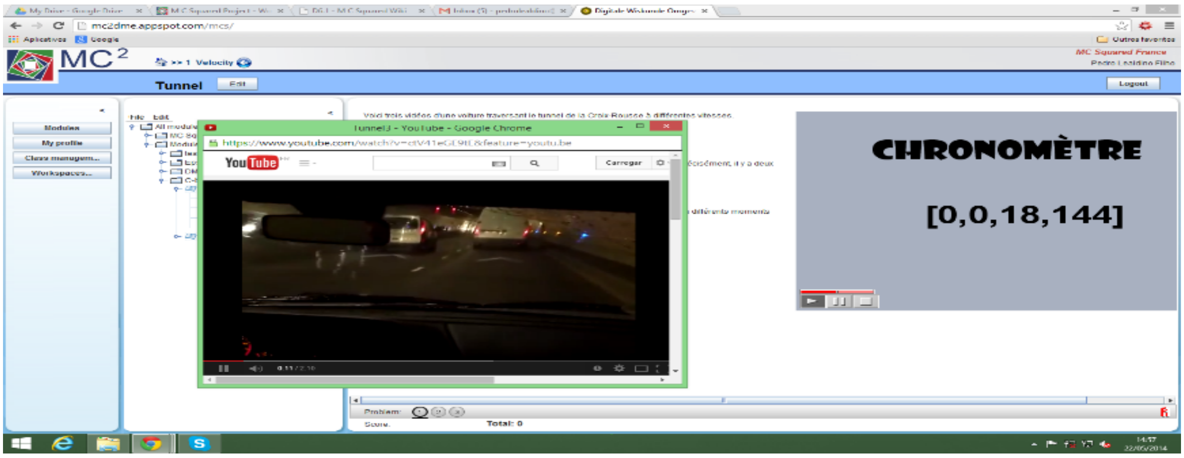

Figure 2: The tunnel activity

with a space prescribed in some official documents that can be found on the internet, or estimated with the number of such events and the total length. The position of the fixed speed camera should be found as well. Then a chronometer available on the c-book page can be used to record some events like the moment a chevron or a light disappear from the screen.

The expected students' behaviour is to search for the total length of the tunnel, to view the video and to measure with the embedded chronometer the total time from the beginning to the end and finally to infer the average speed for the first question.

Several issues are expected to be encountered. What about the format Hours : Minutes : Seconds . Milliseconds, how to work with this data in order to make some math? The students are supposed to paste the minutes and seconds in two columns and elaborate a formula that gives the total amount in seconds. Another issue is the accuracy of the data. When two students record the same events, the data can vary. How can they account for it? Shall they take the mean of the different values between students? Before that they have to agree on a starting time and a translation in time might be in order. Once this is done, they can begin to do some calculations, but they were already involved in mathematics: modelling a phenomenon, transforming it to observations which can be quantified, is part of mathematics. A more difficult problem is the comparison of data recording different events: especially the ones that record timings of chevrons and timings of lights: it is only after the plotting of both position graphs overtime that the comparison can be performed, because the discrete set of data for both events do not mingle that easily on the tables of numerical values. Only the graphical plot of position with respect to time (and not the rank of item!), which are both discrete sequences of the same integer rank, can show similarities. This is a difficult issue because plotting position against the item rank (the line number in the spreadsheet) is the obvious way to plot a sequence. And the item ranks of the chevrons and lights are related to the associated positions through a linear transformation (the respective distances between two occurrences). This requires a deep understanding of the notion of function of one variable: the position is a function of time but given as values in a sequence with given ranks and time itself is a function of the same rank. Therefore we can infer values of the position as a function of time and forget about the rank as an intermediate variable, artefact of our modelling.

Starting with the raw data, we produced different elaborate constructions and each page in the c-book unit unravels some possible new features, including widgets of many different kinds. We count on the orchestration of a teacher, knowing a good portion of what is feasible given the available technology and examples of implementations that are proposed in the c-book, to help the students leapfrog from one instrumented situation to another. But it is our hope that some students will eventually go beyond the proposed implementations, or in totally new unexpected directions to answer the first question.

THE EXPERIMENTATION

Although our objective was to design learning situations in which the use of the c-book unit could be autonomous by groups of students, the pilot study reported in this section is regulated by a teacher, in order not to "spoil the fun" and yet see progress. Moreover, mastering all the aspects of the powerful tools afforded by the c-book technology is not obvious. For the time being the transition from one page to a next one is not automatic and should be controlled by a teacher orchestrating the activity. The pedagogical context in which we conducted the experimentation was provided by a teacher with her students. Two Grade 9 classes (secondary 3rd in French school system, called therefore 3C and 3D in what follows) with 14–15 years old students participated in the study, working in groups of 3–4, equipped with computers and a beamer that could project the work of a given group. The two classes are very different, the first one is composed of students which perform well in mathematics and the second one of students that have difficulties coping with the core of the curriculum and who circumvent frontal confrontation with mathematics.

We report only on the "Tunnel" activity. Investigation on the average speed, different speed controls and some research on the tunnel was given as homework before the classroom session during which the students worked together on the activity.

3D class – lower achieving students

The students were relating the scenario to their own experience and discussed about the issue, it really meant something for them. After a few viewings of the video, they understood how to compute the average speed by measuring the time and the distance, having learnt how to do it themselves in similar situations. They addressed, discussed and solved the issues, difficult for them, of converting the ratio of a distance by a time from m/s to km/h, using proportionality and dealing with decimal representation of time instead of the usual hexadecimal HHMMSS representation. They showed progress in the direction of defining a protocol suitable to estimate the instantaneous speed (lights, marks on the road) but nobody came to a definite answer, only the average speed was computed and related to their own estimates based on their experience. The session was nevertheless felt as successful by all parties.

3C class – higher achieving students

When comparing the assigned videos between groups, the class, in a very homogeneous fashion, realized that it was the same one, tuned to fit special purposes. They answered at once without doing computations, sorting correctly the three videos into three different scenarios regarding the fine. They gave the answer they thought the teacher was expecting, minimizing their effort and failing to engage into the activity. When pressed, they correctly explained the measurements and computations that had to be done, both for the average and instantaneous speeds but nobody actually did them. What refrained them from doing anything is the obvious fact that only crude estimates were possible and that the answer had to be somehow unique, giving that an approximation would have been wrong and was not in order. The issue of giving error margins was debated. Incited once again to make measurements, they were forced to reluctantly take decisions, measure events, and give answers. They had to admit that, whereas their actual numbers were indeed different, the final conclusions were the same for each group on a given video. The expressed feeling was that of an abuse of power and a lousy work ethic on the part of the teacher who went beyond her right in asking such questions, that this was not mathematics and that nothing of that sort was ever asked at the junior high school final national exam "brevet des collèges". This students' behaviour can be interpreted as a reaction to the didactical contract break-up (Brousseau, 1988).

Remediation

A possible way out of this didactical contract clash was found by making explicit a list of competencies taken from the national curriculum. This list of competencies, one of the results of the EvaCoDICE project [5], is now introducing the c-book, in order to be self-evaluated throughout the activity. For example, students have to choose, for the competency labelled "Understand the problem, do some research, take initiatives, be original" an item in the following list:

— "I don't understand what we are looking for, I cannot begin",

— "I understand what we are looking for but I don't know how to begin, I don't have any good idea",

— "I understand what we are looking for, I am trying but I make mistakes in my research, I have some ideas",

— "I understand what we are looking for, I make some experiments, I have ideas".

Showing the students a table with the list of competencies reassured them in the fact that, whereas these are indeed never assessed at a national exam, they are nevertheless officially expected from them. But on the other hand, this remediation leads to a reinforcement of the didactical contract that only what is explicitly and officially required is to be used in the classroom. In a system where national assessments explicit the expectations for all partners of the educational system (students, teachers, parents...), and which sticks to technical and standardized tasks, promoting CMT is a real challenge when the achievement measured by these assessments does not correlate easily with CMT.

CONCLUSION

Fostering Creative Mathematical Thinking in the classroom needs a tailored "ecology" (Barquero, Serrano, & Serrano, 2010), a trained teacher, a rich *milieu* and a special didactical contract (Chevallard, 2012; Wozniak, 2012) to be negotiated: *it's alright to think! Make some guess! Explore!* Such competencies are seldom valued in the curriculum.

In the agenda for progress in math education, Schoenfeld (2011) states that "assessments that are consistent with [mathematically rich content and sense making activities]" is one of the conditions to achieve the goal of a "meaningful engagement with powerful mathematics for all children". This condition might be the most taxing in the didactical contract effect that was observed here: high achieving students tend to minimize their effort and see no direct interest in engaging into what they see as exceeding their job as a student. Teacher training has as well to address the evaluation of competencies.

It is all the more true with technology enhanced learning especially in unsupervised situations: in order to earn student's interest, we might have to put our activities in the cyber-space perspective in which they live and which is so engaging for them. Adding social-networking and timing might turn a dull set of marks and assessments into a friendly competition; the 21st century didactic engineer should identify, alongside the didactical variables, the playful appealing ones, which can turn a mathematical task into a game where devolution of the task means not trying to please the teacher but to have fun, where fellow students cooperate online, turn upside down their assignments and boast their achievements on social networks. Recent works (Pelay, 2011) and political stands (Vallaud-Belkacem, 2014) tend to point in the right direction!

Mathematicians' views on undergraduate students' creativity

Gulden Karakok[1], Milos Savic[2], Gail Tang[3] and Houssein El Turkey[4]

4 University of New Haven, New Haven, USA

There are studies investigating mathematical creativity in the primary and secondary levels, but there is still a need to explore creativity in the tertiary level. Our effort of expanding research to this level started with investigating mathematicians' views on creativity and its role in teaching and student learning of mathematics. One 60-minute interview was conducted with six mathematicians who teach courses at the tertiary level and are active in research. Two themes, Originality and Aesthetics, were observed capturing participants' views of creativity in their work, aligning with existing process and product views. In addition, all participants believed creativity could be encouraged in undergraduate courses and provided suggestions on how to cultivate and value creativity in courses focusing on proving and problem solving.

Keywords: Creativity rubric, proof process, undergraduate mathematics education.

INTRODUCTION

Creativity is one of the important aspects of professional mathematicians' work. It has been documented that many mathematicians describe creativity in their work as an enlightenment that is somewhat unexpected (Hadamard, 1945; Poincare, 1958). Furthermore, creativity helps in the development of mathematics as a whole (Sriraman, 2009). However, creativity is an intricate research construct to explore, made apparent by the myriad of definitions (over 100 as reported by Mann, 2005). In fact, Borwein, Liljedahl, and Zhai (2014) demonstrated that many brilliant mathematicians had differing views about mathematical creativity.

Some conceptualizations of creativity focus on emphasizing whether the *end-product* is original and useful (Runco & Jaeger, 2012), while others describe it as a *process* that involves different modes of thinking, some of an unusual nature (Balka, 1974). Liljedahl and Sriraman (2006) suggested a definition in which creativity was viewed as a personal trait of a mathematician; "the ability to produce original work that significantly extends the body of knowledge (which could include significant syntheses and extensions of known ideas)" (p. 18). In addition, Sriraman (2005) argued that creativity in K-12 classrooms is different than the kind employed by mathematicians and that students' creativity needs to be evaluated according to their prior experiences. This particular point highlights the difference between *absolute* and *relative* creativity; the former one refers to historical inventions or discoveries at a global level and the latter one is defined as, "the discoveries by a specific person within a specific reference group, to human imagination that creates something new" (Vygotsky, 1982, 1984; as cited by Leikin, 2009, p. 131). Using a relativistic perspective, Sriraman and Liljedahl (2006) define mathematical creativity at the school level as a process of offering new solutions or insights that are unexpected for the student, with respect to his/her mathematics background or the problems s/he has seen before. This particular definition acknowledges that students "have moments of creativity that may, or may not, result in the creation of a product that may, or may not, be either useful or novel" (Liljedahl, 2013, p. 256).

Despite the acknowledgment of differences in creativity between professional mathematicians and K-12 students and studies in K-12 level, the mathematical creativity research in undergraduate mathematics education has been sparse. The purpose of our research project is to explore creativity in undergraduate level teaching and learning by first focusing on mathematicians' views on creativity. Researchers have investigated mathematicians' views on creativity (e.g., Hadamard, 1945; Sriraman, 2005), but we contribute to the existing literature by focusing on mathematicians' views on the role of creativity in teaching and students' learning, especially in the case of proving and problem solving. More precisely, our research addresses the following research questions: (1) How do mathematicians define creativity? (2) How do mathematicians view creativity in undergraduate mathematics courses, especially the ones that focus on proving and/or problem solving? (3) Can we (or should we) value and/or assess undergraduate students' creativity in proving (and/or problem solving)?

Prior to sharing findings of our analysis, we briefly summarize some studies that explored creativity from mathematicians' views and in K-12 levels.

LITERATURE REVIEW

Exploring mathematical creativity is an ongoing quest of researchers, with the earliest known attempt by two psychologists Claparède and Flournoy in 1902 (as cited in Borwein et al., 2014, and Sriraman, 2009). Following this survey-focused attempt, which elicited voluntary responses from mathematicians of that time, Hadamard (1945) resumed the exploration of mathematical creativity with surveys of his own sent to prominent mathematicians across the world. Using a psychological framework created by Wallas (1926), Hadamard theorized four stages in the process of creativity: preparation (thoroughly understanding the problem), incubation (when the mind goes about solving a problem subconsciously and automatically), illumination (internally generating an idea after the incubation process), and verification (determining whether that idea is correct). Sriraman (2005) found that Hadamard's four stages are still applicable to modern day mathematicians by interviewing five research mathematicians. Furthermore, his study provided more detail of the stages by considering the roles of personal and social attributes such as imagery, intuition, and interaction with others. Guilford (1950), however, found Hadamard's stages "superficial from the psychological point of view" (p. 451). His concerns were that these stages were not informing us on the mental processes that occur and the stages were not testable. He suggested some testable factors such as fluency, flexibility, production of novel ideas, synthesizing and analysing ability, and evaluation ability. His list was refined to *fluency*, *flexibility*, *originality*, and *elaboration*, which were expanded and used in forthcoming creativity research by others (e.g., Balka, 1974; Leikin, 2009; Torrance, 1966; Silver, 1997).

Fluency in general refers to the quantity of outputs. Silver (1997) defined it in the problem-solving setting as the "number of ideas generated in response to a prompt" (p. 76). *Flexibility* is "shifts of approaches taken when generating responses to a prompt" (Silver, 1997, p. 76). This could mean that a student approached a certain task, was not successful with finding a solution or did not feel the approach was going to be fruitful, and changes to a new approach. *Originality* (or novelty) is described as a unique production or an unusual thinking (Torrance, 1966). *Elaboration* refers to the ability of producing detailed plan and generalizing ideas (Torrance, ibid). These factors of creativity have been used in K-12 levels to determine students' creativity. For example, Leikin (2009) focused on fluency, flexibility and originality to create a creativity rubric (using a point system) that evaluated how creative a student was when s/he produced solutions of certain tasks. Similarly, Yuan and Sriraman (2011) integrated the same three aspects to measure participants' creativity in mathematical problem posing. Recently, Chamberlin and Mann (2014) proposed a fifth aspect of creativity, *iconoclasm,* which "entails the penchant of mathematically creative individuals to dissent from commonly accepted principles and solutions" (p. 35). They suggest the possibility of observing iconoclastic behaviour in individuals who are considered to have a high degree of creativity.

Even though exploring students' creativity in K-12 level is a common practice, such efforts are sparsely expanded to undergraduate mathematics level. There have been on-going efforts of implementing new pedagogical strategies (such as inquiry-based learning or problem-based learning) to improve undergraduate students' skills that are related to creativity (such as investigating ideas, providing multiple solutions, analysing others' strategies). However, we know little about how to explicitly value or assess undergraduate students' creativity in courses involving proving, or in more traditional teaching settings. To expand our understanding of how creativity can be cultivated while learning mathematics, we conducted a qualitative research study investigating mathematicians' views of creativity and their perspectives on its role in teaching and learning of mathematics.

METHODOLOGY

Participants

Participants of this study were six mathematicians who are active researchers in their mathematical areas and teach undergraduate and graduate level mathematics courses. Two of the participants are from a mid-size Ph.D. granting, but predominantly teaching mid-western university, and four participants are from a large Ph.D. granting and research dominant mid-western university. Two are tenured associate professors and four are tenured full professors, and one of whom is female. Participants had 8 to 30 years of teaching and research experience. Research fields vary from algebraic geometry, nonstandard analysis, geometry and topology, representation theory, signal analysis, and number theory.

Data collection

We conducted one 1-hour interview with each participant in his/her office. Interviews were audio- and video-taped and transcribed. The semi-structured interview had three parts. Participants were asked to talk about their views of creativity in their mathematics work in part one. In the second part, participants were asked to comment on a given a set of creativity definitions from different theoretical perspectives. The third part of the interview focused on participants' views on teaching and learning. To elicit their initial thoughts, participants were first asked to talk about their perspectives of teaching creativity and its potential role in students' learning. After, we gave three proofs constructed by three students (Birky, Campbell, Raman, Sandefur, & Somers, 2011), one at a time, and asked them to comment on creativeness of these proofs (See Appendix). All participants were then given a Creative Thinking Value Rubric (Rhodes, 2010) to evaluate the same proofs. This rubric was chosen by the authors because it claims to assess undergraduate students' creative thinking across disciplines.

Analysis

We employed grounded-theory methodology (Strauss & Corbin, 1998). Researchers independently read the transcripts several times to select passages "that express a distinct idea related to [our] research ideas" (Auerbach & Sliverstein, 2003, p. 46). After identifying these relevant texts, we searched for repeating ideas that could be combined into themes. The emergent themes describing mathematicians' views of creativity were *Originality* and *Aesthetics*. These two themes match with the *process* view and the *end-product* view in the creativity literature, respectively. Quotes that highlight the characteristic of each theme are shared with brief discussions in the next section. We also present our analyses of the mathematicians' views on teaching and student learning in relation to creativity. More precisely, we describe our participants' views on how to cultivate students' creativity in proof and problem solving courses, and how to identify, evaluate and value student creativity in such courses.

RESULTS

Views on creativity

Though participants were asked for their definitions during the first part of the interview, they stated different aspects of creativity as they responded to questions in other parts. For example, some participants would refer back to their definitions of creativity as they explored given students' proofs or as they discussed given definitions. We also noticed that some participants would contradict their definitions when discussing the students' proofs, so we asked, "How does this particular idea you mentioned align with your previously mentioned view of creativity?" For these reasons, we analysed each participant's entire interview to uncover his/her views of creativity, thereby generating a more holistic view of his/her perspective.

Overall, we observed two main themes in our participants' views of creativity: *Originality* and *Aesthetics*. Since the first theme shared some similar aspect with the originality (novelty) described in the previous literature, we used the same word. All of our participants mentioned creating a "new way", "new approach/strategy" or "new trick" when they described creativity in mathematics, generally or in their own work.

Dr. B — So for me the creative aspect is you introduce a new way to look at the problem.

Dr. C — [While talking about his creative moment] So, it wasn't that creative in the sense that there was already stuff out there that I didn't have to think about it myself, but in the process of applying it I think I created something new.

Dr. E I think the definition of creativity is approaching a problem from a different perspective or with different tools.

Within the theme of *Originality,* we noticed some sub-themes that the participants referred to as they described the process of creativity: (i) *Making Connections,* (ii) *Attempts,* and (iii) *Insight.*

All of our participants highlighted the importance of making some sort of connection. For example, Dr. A mentioned seeing connections between the task at hand and other theorems, whereas Dr. D mentioned making connections between various topics of mathematics to approach a task from a new way. Similarly, Dr. F stated,

Dr. F For example, notic[ing] that some equations result in geometry, with some geometry connects to some algebra, doing something unusual.

Participants also emphasized that in the process of creating something original, having several attempts, even incorrect ones played an important role.

Dr. A If it did happen [an incorrect attempt], then it is creative in some sense because exploring a wrong answer helps.

Dr. D Well, let's see the most recent example I can think of is when my creativity took us in a wrong or took us in a negative direction.

Further in the interview when Dr. D was asked about the role of creativity it was observed that s/he again mentioned the importance of making attempts by saying, "You have to be willing to try something."

We observed that some of our participants mentioned the role of intuition or insight in the process of creativity. This particular sub-theme, *Insight*, was not shared by all of our participants. The quotes below demonstrate ideas from these participants.

Dr. A But having the idea [of a proof in his research] was the spark...It's that initial moment that is the creative part, not the actual carrying out the thing.

Dr. D I think [...] there are people that have more and less or different types of creativity. There are mathematicians who are very intuitive, [...] who can see a broad result.

We also noticed that some of our participants stated the importance in making conjectures. For example,

Dr. A So, I was writing a paper with a colleague just last week. So I was working on that and there was an implication that the colleague had proved, A⇒B. And it occurred to me...is the converse true? Does B also imply A?

Even though this idea was not repeated by other participants, this quote from Dr. A provides a valuable insight for encouraging students' to make conjectures in courses.

The first theme of *Originality* and its sub-themes thus far speak to the *process* of proving rather than the *end-product* proof. The latter view is encompassed in the second theme: *Aesthetics*. Almost all of our participants mentioned some aspect of creativity that relates to the look of the final proof. In the following quotes, we underlined some code words that helped us create this particular theme.

Dr. B [when talking about a "creative proof"] But there is a notion...there is a <u>notion of economy</u>, of something surprising that you would not expect in that proof, and something <u>lovely</u>.

Dr. C There's kind of an element of <u>aesthetics</u> involved, or <u>beauty</u>, and so when I think of creativity in mathematics I think of people that are able to pull that out of themselves and come up with nice problems to solve that are <u>attractive</u>, somehow. Or follow a line of thought that is <u>attractive</u>.

Dr. E [when evaluating a student proof] Wow! Yeah, that does seem more creative, that is <u>cute</u>. That is really <u>cute</u>!

Dr. F [when discussing creativity in teaching] When I'm teaching classes for example, sometimes I find a <u>cute</u> way of doing the proof, or I find an <u>elegant</u> way of doing computation.

Role of creativity in teaching and learning

To understand our participants' perspectives on the role of creativity in teaching and learning undergraduate mathematics, we focused on the responses that were given during the third part of the interview. In this part, participants were first asked to talk about their ideas on how to cultivate students' creativity when teaching and then were given three student-constructed proofs to assess the creativity. The analysis of summaries from each participant yielded similar ideas.

All of our participants believed that creativity could be encouraged in undergraduate courses. They provided similar teaching ideas, which could foster creativity. For example, providing problems and letting students "play" with them and discuss different solution techniques would be one way to cultivate creativity. Another example was to show students different proofs of the same theorem and discussing the ones that are more creative and why they would be considered more creative.

Participants also discussed possible ways of evaluating creativity in proofs. They were given three student-constructed proofs (See Appendix) to the theorem "If n is an integer such that $n \geq 3$, then $n^3 \geq (n+1)^2$." All of our participants determined that the first student's proof was not creative due to the fact that the induction proof technique was an expected method to implement in this particular question. They thought the second and third proofs were more creative, and some participants discussed the importance of using prior knowledge and making connections between the tasks and the student's existing knowledge as they talked about these two proofs.

Dr. E [referring to the second proof] It is possible that they had a course where this kind of trick was really looked at.

Furthermore, participants acknowledged the mistake in the third proof, which started a conversation about the role of correctness in creativity. All participants thought incorrect attempts could play an important role during the process of creativity. However, some of our participants thought that such incorrect ideas should be fixed in the final product.

Dr. F I will risk it and say that [a proof] doesn't have to be correct to be creative. But at least it should be fixable. It can happen that you have an original idea and you mess up details, which is not surprising because if it is an original idea then it means that you haven't practiced that, you would make mistakes.

Some participants stated that they do give "higher" points to students' proofs or solutions to problems if they thought that the approach was original or unexpected. Other participants were hesitant to give extra points to "creative" proofs or solutions but said they would provide written encouraging comments to students' work.

When participants viewed and tried to implement the Creative Thinking Value Rubric (Rhodes, 2010) to evaluate three proofs, they designated applicable and inapplicable categories to mathematics. For example, all participants agreed that *Taking Risks, Innovative Thinking,* and *Connecting, Synthesizing, Transforming* categories would be applicable. They believed that the *Solving Problems* category by itself was what they expect their students to do in mathematics so it would not be applicable. Some participants thought that there were too many levels provided in this rubric (*Capstone, Milestones,* and *Benchmarks*).

DISCUSSION AND CONCLUSION

The purpose of this particular study was to explore participating mathematicians' views of creativity and its role in teaching and student learning at tertiary level. The first question relating to participating mathematicians' definitions of creativity is described by two observed themes: *Originality* and *Aesthetics*. All six mathematicians' views of creativity highlighted the notion of *Originality*. That is, we noticed that our participants discussed the process of creating ideas and mentioned the importance of making connections, trying or attempting different solutions, and having an insight or "spark," which Wallas (1926) called the "illumination" stage of creativity. In the process of creating ideas, connections between different mathematical knowledge require the individual to understand and absorb many previous definitions and theorems, which Wallas (1926) called the "preparation" stage of creativity.

With our second research question, we investigated the actions and thoughts of mathematicians with regard to the teaching and learning of mathematical creativity. We found an emphasis on the process of proving when participants were asked to evaluate students' proofs based on creativity. They thought in order to evaluate a final product or final proof, they either judged them against one another, or, similar to Sriraman and Liljedahl (2006), they needed to know the student's prior knowledge and thought process. Some mathematicians thought that the proving process might reveal mathematical creativity aspects of a student or a mathematician not revealed in the final proof. For example, the student that created proof 1 may have tried proofs that resemble proofs 2 or 3 and realized that they may not be as fruitful as the technique for proof 1. Also, having courage to take a risk and create an attempt or multiple attempts was determined to be an aspect of mathematical creativity. Therefore, valuing multiple attempts might encourage students to be creative in their proving process (Leikin, in press). But, as Dr. E stated, there is some caution in how to value those attempts; a student might make multiple attempts that have "zero chance of working."

Finally, we attempted to answer the third research question by utilizing the interviews and previous creativity rubrics (Leikin, 2009; Rhodes, 2010) to create the Creativity-in-Progress Rubric (CPR) on proving (see Savic et al., 2015, and Tang et al., 2015, for more details.) This rubric is a formative assessment to explicitly value undergraduate students' creativity during the proving process in proof-based courses at the tertiary level. Given the heavy emphasis the mathematicians placed on the process of construction, the CPR focuses on assessing the process of proving (*Originality)* rather than the final product of the proof itself (*Aesthetics*). As a formative assessment tool, the rubric has three major categories *Making Connections, Taking Risks* and *Creating Ideas*. These categories align with our participants' views of creativity and its role in undergraduate mathematics. In addition, the use of the rubric as a formative tool has merged from participants' suggestions to encourage creativity in the classroom. The greatest use of the CPR on proving, we believe, is that it can start the discussion of creativity and the proving process in the classroom. Mann (2005) states that avoiding the acknowledgment of creativity could "drive the creatively talented underground or, worse yet, cause them to give up the study of mathematics altogether" (p. 239). Since there is an increased need for students to have research-like experiences (e.g., Research Experiences for Undergraduates [REUs] (Garcia & Wyels, 2014)), valuing mathematical creativity may bridge the gap between undergraduate mathematics and research mathematics. In particular, using formative assessment tools, such as the *CPR* on proving would help in such efforts.

APPENDIX - THREE STUDENTS' PROOFS FROM (BIRKY ET AL., 2011)

Proof 1: If $n=3$, then $n^3=27$ and $(n+1)^2=16$, so $n^3>(n+1)^2=16$. Now assume that $k^3>(k+1)^2$, for some integer $k\geq 3$. On the left-hand side, we add $(3k^2+3k+1)$ and get $k^3+3k^2+3k+1=(k+1)^3$. On the right-hand side, we add the same thing to get $(k+1)^2+(3k^22+3k+1)=(4k^2+5k+2)$. We see that $(4k^2+5k+2)>(k^2+4k+4)$ because $4k^2>k^2$ and, since $k>2$, $5k+2>4k+2+2=4k+4$. Thus we see that $(4k^2+5k+2)>(k+2)^2$ and so we have $(k+1)^3>(4k^2+5k+2)>(k+2)^2$. Therefore, by the principle of mathematical induction, $n^3>(n+1)^2$ for all integers $n\geq 3$. QED

Proof 2: Assume $n\geq 3$. Then $n>2$, so $1>2/n$, and $n^2>1$, so $1>1/n^2$ also. This means that $n\geq 3=1+1+1>1+2/n+1/n^2$. So $n>1+2/n+1/n^2$. If we multiply each side of this last inequality by n^2, we get $n^3>n^2+2n+1$. Thus $n^3>(n+1)^2$. QED.

Proof 3: Assume $n\geq 3$. Then, since $n-2$ is a positive integer, $(n+1)^2<(n+1)^2(n-2)$. Thus, $(n+1)^2<n^3-3n-2=n^3-(3n+2)<n^3$. Therefore, $n^3>(n+1)^2$. QED.

Teachers of the mathematically gifted: Two case studies

Alexander Karp[1] and Vasily Busev[2]

1 Columbia University, Teachers College, New York, USA, apk16@columbia.edu

2 Ushinsky State Pedagogical Library, Moscow, Russia

This article is devoted to people who taught highly gifted schoolchildren and developed educational materials for them. Teaching the highly gifted involves changing the contents of education and, possibly more importantly, changing its form and style. Consequently, mathematics educators who are involved in such teaching face new problems, and in fact such teaching often means the appearance of a special new type of teacher at a school. In this paper, we will discuss two prominent Russian figures in the advanced course of study in mathematics. An analysis of their biographies will facilitate a better understanding of both the methodological and the pedagogical history of the advanced course of study in mathematics, as well as the social-political circumstances under which such study took place in the Soviet Union.

Keywords: Advanced course of study in mathematics, schools with an advanced course of study in mathematics, teachers of the mathematically gifted.

INTRODUCTION

Highly gifted children need highly gifted teachers. This fact was recognized quite long ago and quite widely (Stanley, 1987; Thornton and Peel, 1997), yet the study of the biographies and preparation of teachers of the highly gifted is only just beginning (see Even, Karsenty, & Friedlander, 2009; Evered & Karp, 2000; Karp, 2010; Leikin, 2011). Below, we will discuss two Russian figures in mathematics education, Vladimir Ashkinuze and Semyon Shvartsburd, who played important roles in the formation of the advanced course of study in mathematics and, first and foremost, in the formation of Russian schools with an advanced course of study in mathematics. Each of them is the author of dozens of important works. However, far less is known about their own biographies (see the obituary of S. I. Shvartsburd in the journal *Matematika v shkole*), and these will be the main focus of what follows, since the analysis of their biographies, we would argue, is useful for understanding where teachers for the advanced course of study in mathematics come from—an understanding that this study severely needs. The present article is based first and foremost on archival materials related to these two figures, which have been discovered by Vasily Busev.

ON SCHOOLS WITH AN ADVANCED COURSE OF STUDY IN MATHEMATICS

Russian schools with an advanced course of study in mathematics began attracting international attention practically from the moment of their inception (Vogeli, 1968); nonetheless, it will be useful to review certain key moments in their development.

The first Russian classes with an advanced course of study in mathematics appeared in 1959 under the supervision of Semyon Shvartsburd in Moscow under the banner of the "polytechnization" campaign that was taking place at that time, which sought to combine school-based education with production-based education (Karp, 2011). Subsequently, a number of leading Soviet mathematicians became involved in the creation and development of a system of schools with an advanced course of study in mathematics, including A. N. Kolmogorov, I. M. Gelfand, M. A. Lavrentyev, V. I. Smirnov, D. K. Faddeev, and many others. As a result, fundamentally new educational institutions were formed, in which gifted schoolchildren were offered the opportunity not only to learn mathematics more and better than usual, but also to become involved in genuine mathematical creativity. The unfolding methodological formation of the new system was evidenced by publications in the series *Problems of Mathematics Schools*, the first of which, *Teaching in*

Mathematics Schools, was edited by S.I. Shvartsburd, V.M. Monakhov and V.G. Ashkinuze (1965).

The first mathematics schools were established during the period of the so-called thaw, after the death of Stalin, when there were hopes that the Soviet regime would become more liberal. When after the resignation of Khrushchev and especially after the invasion of Czechoslovakia by Soviet troops in 1968, these hopes had to be abandoned, the position of these schools began to change. The authorities did not dare to shut them down completely, since they saw in them a most valuable source of trained workers for the military-technological struggle with the West. However, every effort was made to restrain the spirit of freedom that inevitably sprung up in schools which awakened and nurtured the striving for independent research. Naturally, the position of teachers in these schools changed as well (Karp, 2011).

At the same time, a certain development of the mathematics schools continued, despite the rigidification of the political regime. In particular, textbooks for such schools became popular during this period, for example, *Algebra* by N. Ya. Vilenkin, R. S. Guter, S. I. Shvartsburd, B. L. Ovchinsky, & V. G. Ashkinuze (1968), and *Mathematical Analysis* by N. Ya. Vilenkin & S. I. Shvartsburd (1969).

Gorbachev's *Perestroika* made mathematics schools popular and brought them government support. Their numbers grew rapidly (which was probably not especially good for their quality—Karp, 2011). One of the textbooks that enjoyed greatest popularity at this time was written by M. L. Galitsky, M. M. Moshkovich, & S. I. Shvartsburd (1986). S. I. Shvartsburd died in 1996 in Haifa, and V. G. Ashkinuze yet in 1970s, so we will not address mathematics schools during later periods in any detail. We will merely state that, despite the difficulties that they have encountered, they continue to exist and successfully to prepare future mathematicians, physicists, and engineers.

ON THE ARCHIVAL FILES OF V. G. ASHKINUZE AND S. I. SHVARTSBURD

All three files—two relating to V. G. Ashkinuze (Ashkinuze, 1963, 1967) and one relating to S. I. Shvartsburd (Shvartsburd, 1974) —were discovered in the archives of the Russian Academy of Education (RAO). The RAO is a continuation of the Academy of the Pedagogical Sciences (APN), which was established in 1943 in order to oversee and coordinate the work of scientific organizations of a psychological-pedagogical profile. Such organizations (scientific institutes and laboratories) were many, and they employed many famous scientists, for example, most of the Russian scholarly works on psychology that are known in the West were written by employees of the institutes of the Academy of the Pedagogical Sciences.

One can only speculate about the nature of the circumstances under which the files analyzed below began to be kept. Vladimir Ashkinuze worked for a certain time at the Academic Institute of General and Polytechnic Education (which until 1960 was called the Institute of Methods of Instruction), and therefore the existence of a file on him during this period was to be expected. And indeed this file mainly contains materials documenting his hiring and discharge from the institute, including his personal history statement, official forms (the so-called personal form for personnel records), character references, and his reports (this file was ended in 1963). When at a later date V. G. Ashkinuze, now employed elsewhere, returned to the APN system as a part-time employee, a new file on him was begun (and ended in 1967).

S. I. Shvartsburd likewise worked in the APN system from 1962 on, initially at the Institute of General and Polytechnic Education, and then at the Institute of the Contents and Methods of Instruction. By all appearances, however, the file on Shvartsburd began to be kept for a special reason, namely, because he was nominated as a candidate for full membership in the APN (he had been elected as a corresponding member in 1968). The cover of the file bears the following heading: "application for full member status in the APN." The file contains biographical details, including Shvartsburd's personal history statement, reviews of his work, lists of his publications, and so on (this file was ended in 1974).

TOWARD A BIOGRAPHY OF V. G. ASHKINUZE

V. G. Ashkinuze was born in Moscow in 1927, as he writes in his 1958 personal history statement, into a "family of Communist public servants." He goes on to state that "at the present time my parents are special pensioners" (Ashkinuze, 1963, sheet 5). A "special pension" was a pension assigned by special warrant, rather than in accordance with general rules; in a later personal history statement from 1966, he writes more clearly that his parents had been Communist Party functionaries (Ashkinuze, 1967, sheet 5), who had, however, already lost their positions by 1958, when he wrote his first personal history statement. In 1944 Ashkinuze enrolled in the Mathematics-Mechanics Department and in 1949 he graduated from it. As can be seen from the list of published works in his file (Ashkinuze, 1963, sheet 8), in 1951 he published an article in the *Ukrainian Mathematics Journal*: "Theorem on the Splitability of J-Algebras." Taking into account the fact that publication in a journal does not happen overnight, one can assume that the article contained Ashkinuze's scientific findings from his last years of study at the university (possibly his thesis). The promising young mathematician, however, began his professional career as a mere teacher, and the institutions at which he taught included the so-called School for Working Youth, by no means the most prestigious educational establishment. It should be borne in mind that the end of the 1940s and beginning of the 1950s were the years of the anti-Semitic, anti-cosmopolitan campaign, so it was probably difficult for Ashkinuze to find any better employment. In January 1954 (in other words, less than a year after Stalin's death), Ashkinuze was accepted to the graduate school of the Institute of Methods of Instruction, and moreover he enrolled at once in the second year of the program. In August 1955, Ashkinuze finished his graduate education and began to work at the Shakhty Pedagogical Institute (in the city of Shakhty) as teacher and department chairman. After working there for the required three years, Ashkinuze returned to Moscow, becoming in June 1958 a junior research employee of the Institute of Methods of Instruction (later called the Institute of General and Polytechnic Education). The papers that he published after his 1951 article were devoted to methodological issues, with the exception of an article published in the anthology *Matematicheskoye prosvescheniye* in 1957: "On the Number of Semiregular Polyhedra." Ashkinuze himself, listing his achievements for 1958–1959 (Ashkinuze, 1963, sheet 16), noted his participation in developing programs in mathematics for eight-year and three-year courses (in other words, for the upper grades); articles discussing these programs; testing out lessons on "The Derivative and Its Application in the Investigation of Functions" in classroom conditions, a topic that had not been studied in schools previously; delivering lectures on the methodology of teaching elementary mathematical analysis in secondary schools for teachers; working to develop a textbook for a course in algebra; and others.

Subsequently, these studies were continued, and new ones were added. A character reference from 1963 indicates that Ashkinuze was supervising two planned projects—the writing of a textbook in algebra and the writing of a study on the methodology of teaching algebra—in addition to heading a laboratory devoted to schools specializing in mathematics, which had been formed on his suggestion, and in connection with which he spent four months studying mathematical machines at another institute (Ashkinuze, 1963, sheets 48–49).

This character reference was written in connection with Ashkinuze's transfer to a different place of employment (the Moscow State Pedagogical Institute—MGPI). It is noteworthy that the purpose of the character reference was to smear Ashkinuze, to the extent possible, by describing him as an individual who was leaving a job and thus interrupting his planned projects, which "have already cost the Soviet state over 10 thousand rubles" (Ashkinuze, 1963, sheet 49). The director of the institute felt so strongly about the need to besmirch Ashkinuze's reputation that did not hesitate to add a personal attack, pointing out that Ashkinuze did not exhibit sufficient moral purity, taking work-related trips with his female laboratory assistant.

Nonetheless, in 1966 Ashkinuze returned to the APN system, while continuing to conduct his main work as a docent (associate professor) of the MGPI. He was accepted as a part-time employee at the newly founded Institute of School Equipment and Technological Means of Instructions (Levitas, 2010). However, he did not work there for long—only until 1967 (Ashkinuze, 1967, sheet 7). At this point, his files end.

TOWARD A BIOGRAPHY OF S. I. SHVARTSBURD

S. I. Shvartsburd was born in 1918 in a small town in Moldavia. His father, as he states in his personal history statement from 1974 (Shvartsburd, 1974, sheet 4), worked as a grain receiver before the Revolution and was killed in 1941. After graduating from a ten-year school in 1935, Shvartsburd enrolled in the Physics-Mathematics Department of Odessa University, from which he graduated in 1940, staying on at the same university as an assistant at the Department of Theoretical Mechanics. Having contracted polio in his childhood, he remained handicapped, and therefore was not drafted into the army. After the war began, in July 1941, together with the university, he relocated to the city of Jalalabad, where from 1941 until 1944 he worked as a mathematics teacher. In 1942, he joined the Communist Party (having become a candidate for membership already in 1939) and in 1943–44 he was bureau head and deputy head of the department of agitation and propaganda of the Jalalabad Municipal Committee of the CPSU. In August 1944, Shvartsburd returned to Moscow, where he worked as a teacher of mathematics until 1962, when he became a senior research fellow at the Institute of General and Polytechnic Education. He defended his candidate's dissertation in 1961 and his doctoral dissertation in 1973 (Russia has two advanced degrees: the degree of a candidate of sciences corresponds to a Ph.D., while the so-called doctoral degree is higher—roughly speaking, one can say that this degree corresponds to the rank of full professor). In 1968, he was elected as a corresponding member of the APN. Shvartsburd received various awards and honorary titles; he served as head of a number of influential organization: as chairman of the mathematics section of Academic Council of the State Committee on Professional Education of the USSR, as deputy head of the Academic Council on the Problem of the Advanced Study of Individual Subjects; as head of a seminar for the mathematics teachers of Moscow, etc. Shvartsburd developed numerous curricula, including—in collaboration of V. G. Ashkinuze, in 1963—curricula for secondary schools with on-the-job education for the "computer operator" track, which were important for the subsequent development of mathematics schools.

From the late 1950s on, Shvartsburd began closely collaborating with Professor Naum Vilenkin, a well-known mathematician and mathematics educator (their first joint publication, "On Certain Applications of Exponential and Logarithmic Functions," appeared in the journal *Matematika v shkole* in 1959). This collaboration continued in the field of the advanced study of mathematics, and in the development of curricula for grades 4–5 (the general supervisor of this work was A. I. Markushevich).

Shvartsburd's file contains reviews of his work by a number of leading figures in mathematics and mathematics education. Thus, Andrey Kolmogorov wrote:

> In the person of S. I. Shvartsburd, we have an outstanding representative of our mathematics education. In his field of organizing student preparation in applied mathematics in secondary schools and secondary educational institutions, he is a central figure. (Shvartsburd, 1974, sheet 24)

Elsewhere, A. N. Kolmogorov emphasizes Shvartsburd's contribution to the construction of "a system of advanced mathematical preparation with a focus on numerical analysis in the upper grades of secondary schools" (sheet 23), which he distinguishes from working with schools with an advanced course of study in mathematics (which he also credits Shvartsburd with doing, listing the textbooks that Shvartsburd wrote for such schools).

A. A. Lyapunov, a corresponding member of the USSR Academy of Sciences, mentions the fact that S. I. Shvartsburd has done a great deal

> for various types of intensive, specialized secondary mathematics education. These include different forms of elective work (such as mathematics circles, Olympiads, etc.), specialized physics-mathematics schools, classes in computer programming, and also mathematical technical colleges preparing mid-ranking professional mathematicians. (Shvartsburd, 1974, sheet 25)

The file also contains a long letter signed by a number of figures in mathematics, pedagogy, and technology, supporting S. I. Shvartsburd's promotion to the rank of doctor. The signatories of this letter include such well-known mathematicians as V. A. Uspensky.

I. Shvartsburd was not elected to full membership in the APN. His file, however, contains no information about this.

DISCUSSION AND CONCLUSION

The files examined above are interesting for several reasons. First, they offer examples of Soviet clerical practices in the scientific and scientific-methodological sphere. Today, millions of people are still alive who took part in that life, but even so, although a great deal has remained unchanged since Soviet times, many details have disappeared and are becoming forgotten, for which reason it is important to record them (for example, the fact that in order for Ashkinuze to be hired as a part-time worker, permission had to be obtained from the Deputy Minister of Higher and Secondary Education of the USSR).

Second, the files pertain to individuals whose roles in the creation of mathematics schools and of intensive, specialized education in general—to use A. A. Lyapunov's terminology—was extraordinarily important. A. N. Kolmogorov does not name Shvartsburd as the founder of the advanced study of mathematics in Russia, drawing a subtle distinction between applied advanced study, in which he clearly acknowledges Shvartsburd's preeminence, and advanced study in general, in which Shvartsburd is allotted an important, but not a leading role. In reality, the advanced study of mathematics as a whole, as has already been noted, grew out of applied advanced study, although, of course, in this process the role of, say, Kolmogorov himself was undoubtedly unparalleled. The names of the creators of a new system that exerted an influence over the entire world should not be forgotten, and consequently, the collection of details about their biographies is valuable in itself.

But perhaps even more important is the question posed at the beginning of this article: where do leaders in the education of the mathematically gifted come from? In an earlier work (Karp, 2010), we discussed teachers, famous ones, but nonetheless specifically teachers, who continued working in schools. Both Ashkinuze and Shvartsburd left schools and became involved in secondary mathematics education at a different level. Nonetheless, in this case, too, it may be said that the biographies of future leaders in the advanced study of mathematics can be very varied. It would be inaccurate, for example, based on the fact that mathematics schools were often perceived as hotbeds of liberalism (which they indeed were), to draw the conclusion that the individuals involved in organizing the advanced study of mathematics were inevitably opposed to the Soviet regime. Such individuals could well wish to serve the regime in good faith, occupying high-ranking positions if this was possible. To be sure, the regime did not always agree to offer them such positions, and could even refuse their service altogether (in the still-liberal year of 1968, S. I. Shvartsburd got elected to the APN as a corresponding member, while in 1974, as a Jew who moreover did not occupy any high administrative position, he was not elected to the same organization as a full member). Both Ashkinuze and Shvartsburd evidently had excellent preparation in mathematics, and this is probably the only characteristic shared by all prominent figures in the advanced study of mathematics. Another characteristic that is typical of the biographies of many of them, although naturally far from all, is a relative lack of access to the usual career paths, at least at the early stages of their careers. There is little use in speculating what might have happened if V. G. Ashkinuze had been admitted to graduate school in mathematics immediately upon graduating from university. We have no information concerning the circumstances that caused S. I. Shvartsburd to break off his party-member career and to remain a school teacher for almost twenty years (even while maintaining ties with academic circles, see Sector of mathematics, 1948).

Analyzing the life of her father, Aron Maizelis, who was an outstanding teacher in mathematics schools, Yelena Platonova (2007) objects to the explanation that Maizelis went to work in schools because he had been unable to find employment elsewhere, showing that even as a student Maizelis had been passionately interested in questions of teaching and instruction (which, however, does not seem to us to rule out the possibility that, if he had been given the opportunity to teach at a higher educational institution, he would not have done so). In any case, given the absence of precise biographical information, one can only speculate. It may be argued, however, that both Ashkinuze and Shvartsburd were in situations in which, in order to achieve success, they had to turn their lives around somehow, to find something new, which had not been envisioned previously. Thornton and Peel (1999) wrote about the importance of the teacher's creativity for cultivating creativity in the students. In certain cases, life itself impelled the teachers to be creative.

In conclusion, we should say that the aforementioned shortage of information poses new problems for researchers. It would be extremely interesting to continue gathering information both about those figures in mathematics education who are the focus of this article, and about others. One would like to hope that personal and state archives still exist in which documents have survived that are capable of shedding a light on the history of mathematics schools and their creators. Such research must be continued.

Mathematical creativity or general creativity?

Maria Kattou, Constantinos Christou and Demetra Pitta-Pantazi

University of Cyprus, Department of Education, Nicosia, Cyprus, kattou.maria@ucy.ac.cy

The present study aims to investigate whether creativity is domain general or domain specific, by relating students' performance on two tests: the Creative Thinking Test and the Mathematical Creativity Test. Four hundred and seventy six students (Grades 4–6) participated in the study. Through confirmatory factor analysis we purported to compare the fitness of two a-priori theoretical models, representing creativity either as domain general or domain specific. Correlation and crosstabs analysis were also conducted in order to examine whether the data obtained from the two creativity instruments were related and/or were in agreement, respectively. Data analysis converged that creativity is domain specific.

Keywords: Domain general, domain specific creativity.

INTRODUCTION

The generality-specificity issue of creativity "goes to the heart of the question of what it means to be creative" (Baer & Kaufman, 2005, p. 158). Indeed, theoretical and practical issues are related to the way that creativity is approached. For instance, some of the proposed definitions embrace context, assuming that the creative ability is specialized in one or more cognitive fields, whereas others do not make any reference to specific areas (Baer & Kaufman, 2005). Moreover, the adopted identification procedures are either based on a general creativity test, in order to predict individual's creative potential in every field, or use domain specific instruments. Similarly, the educational practices and material for the enhancement of students' creative ability either focus on the development of general abilities that are applicable across domains or they are differentiated amongst various domains.

Taking into consideration the previous discussion, the necessity for conducting research that will shed light on this controversial issue of generality-specificity seems warranted (Silvia, Kaufman, & Pretz, 2009). Indeed, such research is prerequisite of any other research in the domain due to its fundamental position to direct the appropriate adopted theoretical definition as well as the methodology employed and data analysis conducted. Hence, the present study purports to contribute in this direction by examining whether creativity is domain general or domain specific.

What is following is a review on the existing literature about defining and approaching creativity as domain general or as domain specific. Afterwards the methodology used in the study will be presented. Finally we will present the results obtained from the data analysis and discuss them.

THEORETICAL CONSIDERATIONS

Creativity as domain general

Domain general perspective views creativity as a universal ability which contributes to all creative achievements (Plucker, 1999), assuming that this ability is transferable and applicable in any cognitive area (Plucker & Zabelina, 2009). According to Beghetto and Kaufman (2009), the creative expression is similar in all cognitive areas and therefore, a person who has demonstrated a high level of creativity in a field is anticipated to show correspondingly high level of creativity in various fields.

Domain general view of creativity has been supported by empirical findings which either verified the predictive power of domain general instruments on creative achievements in several fields or concluded with similarities by comparing the creative ability in different fields (Beghetto & Kaufman, 2009). In particular, Charyton and Merill's study (2009) found high consistency between a general creativity instrument and a domain specific instrument, concluding that the creative behavior is independent of the field under investigation. Kaufman and Baer (2005) described the creative process and the creative product in various disciplines (e.g., poetry, psychology, mathematics), concluding that creative individuals exhibit similar characteristics and skills in a wide range of disciplines. Similarly, Root-Bernstein and Root-Bernstein (2004) examined the background of creative scientists and artists and found that many scientists were artistic and vice versa. Thus, they proposed that the distinction between different types of creativity might be artificial.

Creativity as domain specific

Domain-specific creativity emerged as a major theoretical position in the 1980s, assuming that creativity cannot be understood if there is no reference in the domain in which it takes place (Plucker & Zabelina, 2009). In this context, the skills, the traits and knowledge that underlie creative ability are differentiated between cognitive areas (Beghetto & Kaufman, 2009). Several studies presented evidence to support domain specificity of creativity (e.g., Baer & Kaufman, 2005; Plucker, 1999).

In these studies researchers concluded with low correlations between creative results in different fields of knowledge indicating that there is not a general creative ability that contributes to creative performance in different disciplines (e.g., Plucker & Zabelina, 2009). In particular, Hocevar (1976, in Baer, 1998) found that the correlations among various self-report indices of creativity in different domains were low to moderate. In the same line, Baer (1991) found low or non-statistically significant correlations between verbal and mathematical creative tasks. In a systematic work conducted by Baer (1993) with students from childhood to adulthood, he concluded that independently of age groups and content the correlations were consistently low.

Furthermore, using more advanced statistical analysis researchers reached multiple-factors models to describe the structure of creativity, verifying that there are distinct domains that differentiate creative ability (Silvia, Kaufman, & Pretz, 2009). For instance, Kaufman and colleagues (e.g., Kaufman, Cole, & Baer, 2009) suggested a multi-factors model to describe creativity.

PURPOSE OF THE STUDY

By considering the abovementioned discussion, it is obvious that both the domain general and domain specific perspectives of creativity are supported by strong arguments leading to a polarization of the debate (Silvia, Kaufman, & Pretz, 2009). The field is still blurred and the question whether creativity is domain general or specific remains unanswered. Hence, this study aims to examine this issue.

Moreover, Silvia, Kaufman and Pretz (2009) claimed that the methodology and statistical analyses followed by researchers may affect their conclusion regarding generality and specificity. For instance, the majority of research studies which used correlation analyses concluded to creative generality while research studies which used advanced statistical methods found evidences for the domain specificity of creativity. In order to eliminate these limitations, in the present study we will use a combination of statistical analyses, in order to investigate whether different statistical approaches offer affirmative evidences for one direction.

This study has two purposes: (a) to investigate whether creativity is domain general or domain specific; (b) to examine whether the exploitation of different statistical approaches leads to similar conclusions concerning the generality-specificity issue.

METHODOLOGY

Four hundred and seventy six students attending Grades 4 (N=202), 5 (N=165) and 6 (N=109) in public schools in Cyprus participated in the present study. Aiming to investigate whether creativity is domain general or domain specific, two tests were administered: the Mathematical Creativity Test (MCT) and the Creative Thinking Test (CTT). The tests were administered in paper and pencil form and one hour was allocated to students for completing them (MCT: 40 minutes, CTT: 20 minutes).

Mathematical Creativity Test (MCT)

The MCT consisted of four multiple-solutions tasks with problem solving and problem posing situations (see Fig1), taking into consideration relevant research studies on mathematical creativity (e.g., Kattou, Kontoyianni, Pitta-Pantazi, & Christou, 2013). The selection of the four tasks included in the MCT was based on the results of a task analysis that took place at a previous phase of the study. For each task students were asked to provide multiple solutions, solutions that were distinct from each other and solutions that none of their peers could provide. This was done in an effort to capture students' fluency, flexibility and originality. These three abilities constituted the assessment criteria. In particular, the assessment was based on the number of correct mathematical solutions students' proposed (fluency), the number of different mathematical ideas included in students' answers (flexibility) and the scarcity of answers (originality) (Kattou, et al., 2013).

Specifically, we employed the assessment method proposed by Kattou and colleagues (2013): (a) Fluency score: we calculated the ratio between the number of correct mathematical solutions that the student provided, to the maximum number of correct mathematical solutions provided by a student in the population under investigation. (b) Flexibility score: we calculated the ratio between the number of different types of correct solutions that the student provided, to the maximum number of different types of solutions provided by a student in the population under investigation. (c) Originality score: it was calculated according to the frequency of a student's solutions in relation to the solutions provided by all the students (score 1 was given to students whom one or more of their solutions appeared in less than 2% of the sample's solutions, score 0.8 was given to students whom one or more of their solutions appeared between 2% and 5%, score 0.6 was given to students whom one or more of their solutions appeared between 6% and 10%, score 0.4 was given to students whom one or more of their solutions appeared between 11% and 20%, score 0.2 was given to students whom one or more of their solutions appeared in more than 20% of the sample's answers). Therefore, three different scores yielded for each student in each task. The final score of the test was obtained by adding the respective scores of fluency, flexibility and originality in the four tasks and then by converging them to a scale ranging from 0 to 1.

Creative Thinking Test (CTT)

The CTT included two tasks, one verbal and one figural, taken from the respective subtests of the Torrance Tests of Creative Thinking (Torrance, 1974). Concretely, the first task required students to provide unusual uses of a common everyday object, while the second one asked students to complete simple repeated figures to make a picture. Students were asked to provide as many answers as they could in a specific time interval. Their answers were assessed according to their fluency, flexibility and originality as described above.

Data analysis

The data were quantitatively analysed with the modeling program Mplus (Muthén & Muthén, 1998) in combination with the statistical package SPSS. Specifically, correlation analyses took place aiming to examine the correlation between participants' performances in the two tests. Moreover, crosstabs analysis allowed us to examine whether the two tests provided similar or different results regarding the identification of creative individuals. Confirmatory Factor Analysis (CFA) was employed, to test the validity of alternative theoretical models that present creativity as domain specific and domain general. The alternative models that were compared are discussed below.

Model 1 regards creativity as domain general. In this model creativity is defined across fluency, flexibility and originality, independently of the instruments used. Model 2 regards creativity as domain specific, implying that distinct creative abilities exist. Thus domain specific creativity in mathematics is differentiated from the creative ability that was measured with a test not targeted in mathematics. Each of the domain specific creativities is comprised by the abilities of fluency, flexibility and originality.

RESULTS

Correlation analysis

Aiming to investigate the existence of correlations between the creative abilities (fluency, flexibility, originality) of the same test or/and between the same crea-

Make as many groups of numbers as you can, using the numbers given below. Label each group with its characteristic.

2, 3, 7, 9, 13, 15, 17, 25, 36, 39, 49, 51, 60, 64, 91, 119, 121, 125, 136, 143, 150

Warnings: You can use each number in more than one group.
Each group should contain more than two numbers.

Figure 1: Example of tasks from the Mathematical Creativity Test

tive ability between the two tests, correlation analysis was conducted, as presented in Table 1. From the correlation analysis it can be deduced that all variables were significantly correlated with each other (p<.01). However, the correlations exist between the abilities of the same test were higher (ranging between r=.579 and r=.812), as they are compared to the correlations of the same ability across the two tests (ranging between r=.208 and r=.421).

To examine whether the two tests used in the present study identify the same participants as creative, crosstabs analysis was conducted. It is important to mention that the participants were primarily split in categories according to their performance in each test. Specifically, four groups emerged based on students' performance on the MCT and four other groups emerged based on their performance on the CTT as follow: Group 1 included students whose performance belonged to the lowest 15% of performances on the corresponding test, whereas Groups 2 and 3 included students whose performance belonged between 15%-50% and 50%-85% of performances, respectively. Group 4 included students whose performance belonged to the highest 15% of the performances (max score was 3 – the score was obtained by adding fluency, flexibility and originality scores). The descriptive statistics of each group of students are presented in Table 2.

Crosstabs analysis was also conducted aiming to investigate whether students who were classified as creative using the MCT were also creative according to the CTT and vice versa. The results of the analysis are presented in Table 3.

Data analysis showed that 4.20% of the participants were identified as creative with both instruments. However, among the students who were regarded as high mathematical creative (Group 4) only the 28.99% (20 out of 69) were also regarded as creative according to the CTT. Similarly, only 27.78% (20 out of 72) of the students who were highly creative using the CTT for their assessment (Group 4) were mathematically creative as well. Based on the abovementioned percentages, a student who is creative using as indicator his/her performance in one of the instruments is not necessarily identified as creative by the other instrument.

	CTT			MCT		
	Fluency	Flexibility	Originality	Fluency	Flexibility	Originality
Fluency CTT	1	.615	.579	.421	.237	.166
Flexibility CTT	.615	1	.595	.301	.208	.198
Originality CTT	.579	.595	1	.314	.225	.214
Fluency MCT	.421	.301	.314	1	.719	.621
Flexibility MCT	.237	.208	.225	.719	1	.812
Originality MCT	.166	.198	.214	.621	.812	1

Table 1: Correlations between fluency, flexibility, originality in MCT and CTT

	Groups according to CTT		Groups according to MCT	
	N (%)	Mean (SD)	N (%)	Mean (SD)
Group 1	72 (15.13)	.99 (.23)	71 (14.92)	.56 (.12)

Confirmatory factor analysis

Confirmatory factor analysis allowed us to compare the validity of the structure of two alternative models for creativity. For the evaluation of model fitness, three indices were taken into consideration: The chi-square to its degree of freedom ratio (χ^2/df), the comparative fit index (CFI), and the root mean-square error of approximation (RMSEA) (Marcoulides & Schumacker, 1996). An acceptable model should have the value of CFI higher than .90, the value of χ^2/df lower than 2 and the value of RMSEA lower than .08 (Marcoulides & Schumacker, 1996). During the comparison of alternative models, apart from the appropriate values of indices, we choose the model with the highest CFI index and the lowest AIC and BIC indices (Marcoulides & Schumacker, 1996). What follows is a description of the structure of the two alternative models, however, only the model with the best “fitness” on the data of the present study will be presented diagrammatically, due to space limitation.

In Model 1 creativity is a second order factor which consists of the general abilities of fluency, flexibility and originality. Each of these three abilities constitute first order factors that are constructed by students corresponding performance in the two tests. This model implies that independently of the measure or the domain, fluency, flexibility and originality form a general factor, that of domain general creativity. Data analysis indicated that the Model 1 does not have good indicators of adjustment to the research data (CFI=.961, χ^2=276.614, df=115, χ^2/df=2.405, RMSEA=.063, AIC=-7515.508, BIC=-7282.245), due to the fact that the χ^2/df is higher than 2.

Model 2 (see Figure 2 in Appendix) suggests that different types of creativity exist which form different factors: creativity measured using the MCT and creativity measured with the CTT. Each domain specific type of creativity is comprised of fluency, flexibility and originality. Confirmatory factor analysis showed that Model 2 has very good “fitness” on the data of the present study (CFI=.990, χ^2=152.926, df=111, χ^2/df=1.378, RMSEA=.039, AIC=-7631.196, BIC=-7381.703). In particular, the analysis suggested that two independent second order factors exist. Each of these context-dependent creative abilities is formed by fluency (MCT: r=.96, p<.05, CTT: r=.87, p<.05), flexibility (MCT: r=.99, p<.05, CTT: r=.98, p<.05), and originality (MCT: r=.95, p<.05, CTT: r=.86, p<.05), implying that fluency, flexibility and originality in the two instruments do not constitute a common factor but they are distinguished according to the stimuli. Indeed, each of the three components of content-dependent creativity is comprised by the corresponding performances on the specific measurement. For instance, the second order factor “Fluency” in the MCT is comprised by “Fluency 1”- “Fluency 4”, that is the measured fluency ability in the four tasks of the MCT.

Comparing the two models, the second model has a better fit to the data; firstly the CFI index has higher value in Model 2 as compared to Model 1 (CFI_{Model1}=.961, CFI_{Model2}=.990,); secondly Model 2 has the lowest value of AIC and BIC indices (AIC_{Model1}=-7515.508, AIC_{Model2}=-7631.196, BIC_{Model1}=-7282.245, BIC_{Model2}=-7381.703,), thirdly Model 1 has an inappropriate value for one of the indices that are taking into account for the evaluation of model fitness (χ^2/df=2.405>2).

DISCUSSION

Is creativity domain specific or domain general? Although both opposing views have been examined and empirically supported by several researchers, is still one of the enduring controversies of the creativity research. According to Baer and colleagues (Baer, 1998; Baer & Kaufman, 2005) the importance in answering that question goes to the heart of the field and consequently influences the educational practices. Due to the importance of the domain generality-specificity issue both in educational and research domains (Baer, 1998; Kaufman & Baer, 2005), the present study attempted to investigate this controversial issue.

The result obtained through data analyses converged to the domain specificity of creativity. Specifically through the comparison of two alternative theoretical models which define creativity as specific or general, confirmatory factor analysis confirmed the appropriateness of the domain specific model. By employing similar statistical analysis other researchers found multiple-factors models to describe the structure of creativity, verifying that there are distinct domains of creative ability (Kaufman, Cole, & Baer, 2009). Therefore, psychologists and educators should no longer characterise individuals as creative, but instead, as creative in specific domains. Consequently, research work on creativity is anticipated to be specialized in different fields in order to develop an integrated picture of the concept, rather than considering creativity as a general aspect.

This result was also supported by the correlation analyses which aimed at investigating the relationships between creative abilities (fluency, flexibility, originality) on two different dimensions: correlations of the same creative ability between the two instruments and correlations of the three creative abilities within the same instrument. Negligible correlations were found between the same creative ability across the two measurements (e.g. MCT fluency- CTT fluency), whereas high correlations were observed between the three abilities (fluency, flexibility, originality) that were measured within the same instrument. Low correlations between creative results in different domains were identified by numerous researchers (Baer, 1991; Kaufman & Baer, 2005; Plucker & Zabelina, 2009). By interpreting this result, one may assume that there are not identical and systematic creative abilities which may arise to stimuli of different domains; hence the existence of "a universal creativity" which is transferrable from one cognitive field to another is rejected (Kaufman & Baer, 2005).

Finally, the results of the crosstabs analysis illustrated that students' performance on the two creative instruments were not in agreement. In particular, a high percentage of participants who were considered as creative using one of the instruments were not consistently found as creative using the other instrument, whereas only a low percentage of participants were identified as creative by both instruments. Based on these results we can conclude the inadequacy of general creativity instruments to identify creative thinking in specific domains. Hence, the necessity for developing domain specific instruments to measure creative ability is obvious (Hong & Milgram, 2010). Extending the above conclusion, by identifying a student who is creative in mathematics does not necessary imply that she/he is also creative in art or literature, and vice versa. Additionally, a student who has shown high creative ability in one field is not automatically excluded from being creative in the subject of mathematics.

Creativity and expertise: The chicken or the egg? Discovering properties of geometry figures in DGE

Roza Leikin and Haim Elgrabli

University of Haifa, Haifa, Israel, rozal@edu.haifa.ac.il

The relationship between mathematical creativity, knowledge and expertise is a phenomenon which can be seen as a "creativity-knowledge dilemma": Having knowledge is a necessary condition for a person to be creative; on the other hand, creativity is an important condition for knowledge construction. In this paper, we analyze mathematical activity that is directed at both the development of problem solving expertise and creativity in geometry. Creativity in this study is connected to the discovery of new properties of the given geometrical objects through investigation in DGE. We introduce a framework for the analysis of the complexity of a discovered property. Based on the analysis performed, we hypothesize that (1) discovery skills can be developed in people with different levels of problem solving expertise while the range of this development depends on the expertise; (2) the discovery process is rooted in the problem-solving expertise of a person.

Keywords: Mathematical creativity, problem-solving expertise, geometry investigations, complexity of discovery.

BACKGROUND

In his arguments about the importance of creativity for child development, Vygotsky ("Imagination and creativity in childhood," 1930, and "Imagination and creativity in Adolescents," 1931) maintains that imagination is goal-directed, culturally mediated, and emerges from the interweaving of fantasy and conceptual thinking. In his view, the development of creativity is one of the essential elements of the child's mental and social development. The educational system should pay attention to this construct.

Vygotsky (1982/1930) argues that imagination (creativity in our terms) is the central mechanism in the development of children's knowledge, since imagination allows them to construct connections between their existing knowledge and the new pieces that they study. Going a step further, we argue that creative activities in mathematics allow students to design mathematical connections and use their mathematical knowledge in an unlearned fashion. In this sense, creativity is a necessary condition for knowledge construction. To the contrary, creative processes in mathematics presume discovery of new mathematical constructs, properties and regularities to expand mathematical knowledge to new territory. This requires previous knowledge and the ability to critically evaluate that the discovered facts are new. In this sense, knowledge is a necessary condition for a creative process. Thus we consider the knowledge-creativity dilemma an intriguing phenomenon and try to explore it.

Relative and absolute creativity

The rationale for investigating creativity in school children lies in the shift from a static view on mathematical creativity to a dynamic characterization of personal development (Leikin, 2013). Rather than looking at creativity as a personal characteristic given at birth ("a gift"), we consider it a personal creative potential that can be developed if appropriate opportunities are provided for the learner. This position requires a distinction between absolute creativity as associated with discovery or invention at a universal level and relative creativity which is considered with respect to a specific person acting in a creative way within a specific reference group (cf., objective vs. subjective creativity in Lytton (1971), and that of Big C vs. Little C creativity in Csikszentmihalyi (1988)). For example, the distinction between absolute and relative creativity is obvious in Yerushalmy (2009) who provided analysis of curricular design, mainly based on mathematical investigations, which implies the development of mathematical creativity in all students.

Our study explores connections between relative creativity and expertise associated with geometry investigations. We compare their creative activity by prospective mathematics teachers (PMTs) with the creative activity of an expert in mathematical problem solving (Sharon – pseudonym).

Problem solving expertise

An expert in mathematics has been described as having a more robust mental imagery, more numerous images, the ability to switch efficiently and effectively between different images, the ability to focus attention on appropriate features of problems, and having more cognizance of their thought and of how others may think (Carlson & Bloom, 2005; Hiebert & Carpenter, 1992; Lester, 1994). Individuals with a coherent understanding of a particular mathematical topic have a complex system of internal and external representations that are joined together by numerous strong connections to form a network of knowledge. In contrast to experts, a student's system of representations of a mathematical concept may be deficient in number and deficient in connections to form an adequate network of knowledge (Hiebert & Carpenter, 1992; Lester 1994).

Whereas a novice uses a conventional means-ends analysis to solve problems, an expert categorizes problems according to solution principles and applies those principles in a forward-working manner to the givens of the problem. The expert's knowledge-based strategy is dominated by previous experience. He or she "knows into which category the problem should be placed and knows which moves are most appropriate, given that particular type of problem" (Sweller, Mawer, & Ward, 1983, p. 640).

Expert knowledge is also likely to be organised as hierarchical schemas (Chi, Feltovich, & Glaser, 1981). Problem-solving schemas are knowledge structures that consist of prototypical aspects of the problem type including declarative information about the features, facts, principles, and strategies associated with the problem. Experts have been shown to spend more time on features designated as critical to the problem (Morrow et al., 2009; Shanteau, 1992) and to rapidly encode features of problems based on goal-relevant representations. In the study on which this paper is based we were interested in examining how the investigation procedures performed by novice and expert problem solvers differ.

Mathematical investigations

We believe that mathematical investigations should become an core component of any mathematical course whether the participants in the course are teachers or students. While mathematical investigations are central to the activity of any research mathematician who is ultimately creative in the field of mathematics, mathematical discovery is always accompanied by enjoyment, it raises self-esteem and leads to curiosity and courage to make a new discovery. And as such it is necessary and should be in curricula for all learners.

Leikin (2014) analysed interplay between Mathematical Investigations (MIs) and Multiple Solution Tasks (MSTs). She argues that MSTs and MIs are effective instructional tools for balancing the level of mathematical challenge in the mathematics classroom and, thus, for realizing students' mathematical potential at different levels. Particular emphasis is placed on varying levels of mathematical challenge in school mathematical classroom by employing MSTs and MIs.

In this paper we provide an additional view on MIs with DGE used as a basic element of a teacher education course. In this context, MI is an integrative mathematical activity that includes experimenting, discov-

Given: AB – diameter in circle (O, R)
AD, BC, DC – tangent segments

Prove:

a. Prove the DOC = 90° in at least 2 different ways
b. Find at least 3 additional properties of the given object
c. Prove each discovered property in at least 2 different ways.

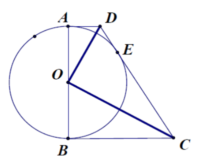

Figure 1: Problem 1

ering, conjecturing, verifying and proving. Problem 1 illustrates an investigation problem in our study.

THE PROPOSED FRAMEWORK FOR THE EVALUATION OF INVESTIGATIONS

The goal of the study presented in this paper was to design the criteria for the evaluation of MIs from the point of view of investigation processes and investigation products.

We analyse MIs using the construct of ***spaces of discovered properties*** as analogous to the notions of example spaces (Watson & Mason, 2001) and solution spaces (Leikin, 2007). We distinguish between *individual spaces of discovered properties* which are collections of properties discovered by an individual based on a particular problem and *collective spaces of discovered properties* which are a combination of the properties discovered by a group of individuals.

The analysis presented in this paper is based on two case studies (CS):

Case study-1 (CS-1) is focused on the collective space of properties discovered by Prospective Mathematics Teachers (PMTs) who are considered (in this study) as non-experts in geometry problem solving. The PMTs participated in the 56 hours courses directed at the development of their problem-solving expertise and the ability to create new geometry problems through investigations in DGE (see also Leikin, in press). The sessions with PMTs were videotaped and artefacts of their works were collected. Additionally the PMTs presented their investigations to the whole group of PMTs and these presentations were also video-recorded.

Case study-2 (CS-2) is focused on Sharon's (expert's) individual space of discovered properties. The investigation in this case was performed in the form of a thought experiment. Sharon was interviewed after the thought experiment to better understand the ways in which he arrived at the discoveries.

SPACES OF DISCOVERED PROPERTIES

In this section, Figure 2 depicts the non-expert collective space of discovered properties for Problem 1 which was achieved at the end of the 56 hours courses (CS-1). Note that the investigation activities were new for the PMTs at the beginning of the courses and the discovery skills were developed through the course. Figure 3 presents Sharon's expert space of discovered properties for Problem 1 (CS-2).

THE FRAMEWORK FOR THE ANALYSIS OF DISCOVERED PROPERTIES

The framework for the analysis of discovered properties is based on the analysis of the expert spaces of the discovered properties in CS-1. The distinctions between the *discovered properties* was defined as a complex function of

-- *the newness of the property* discovered in the courses of investigation,

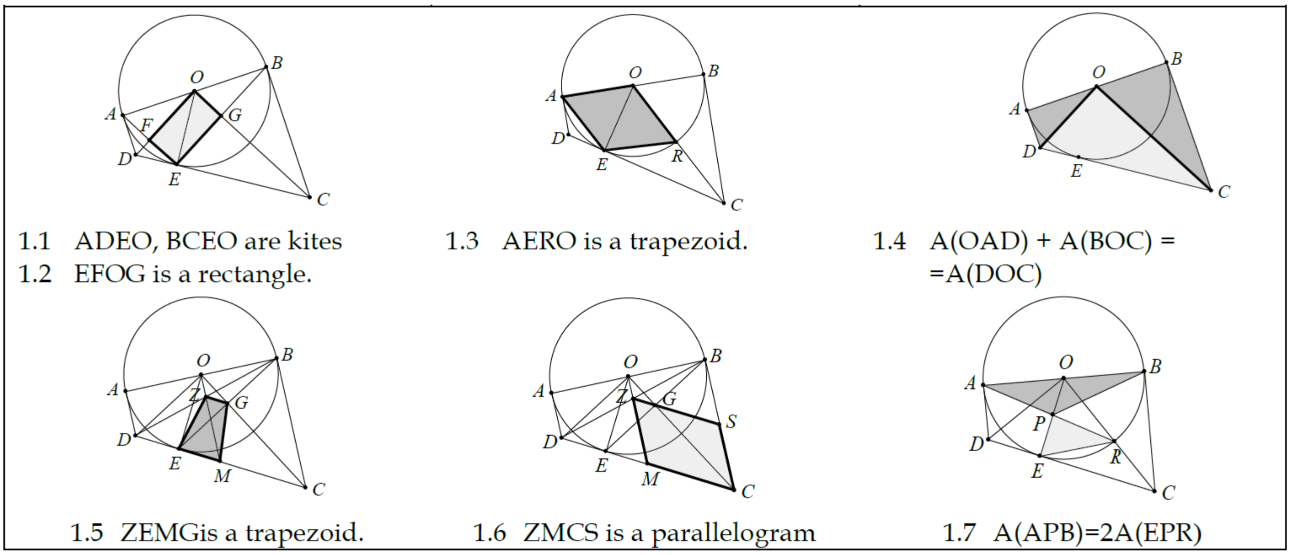

Figure 2: The PMTs non-expert collective space of discovered properties

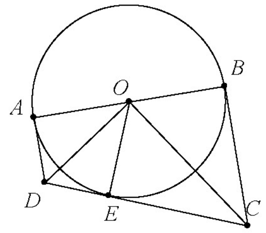
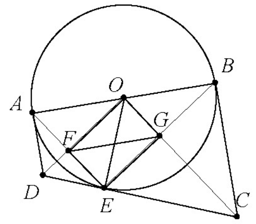
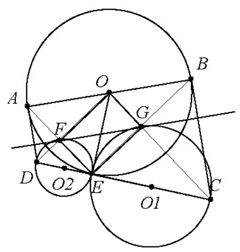


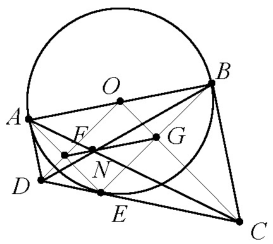
1a $OE \perp DC$
1b $BCEO$ – kite; $ADEO$ – kite
1c $ABCD$ trapezoid
1d $\sphericalangle COD = 90°$



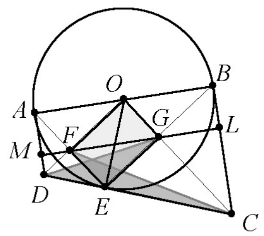
1e $EFOG$ rectangle
1f $AB \parallel FG$; $FG = \frac{1}{2}AB$
1g $BCEO$, $ADEO$ – cyclic quadrilaterals



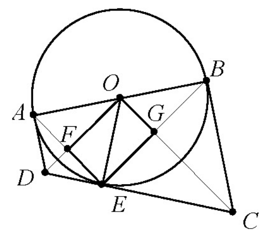
1h Circles $O1$ – diameter CE, $O2$ – diameter ED pass through F and G respectively
1i FG is tangent to circles $O1$ and $O2$
$GO1||BC$; $FO2||AD$; $FG||AB$



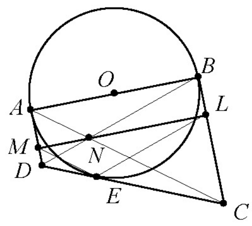
1* If $N = AC \cap BD$ then FG passes through N



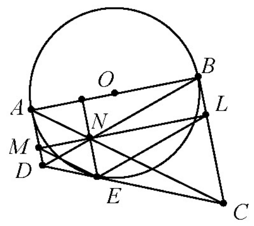
1j $A(CEF) = A(DEG) = \frac{1}{2}A(EFOG)$
1k $ABLM$ - rectangle
$A(ABE) = A(ABLM)$
$= 2 \cdot A(EFOG)$



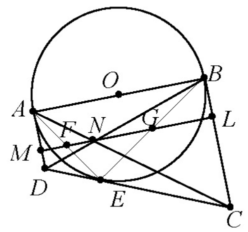
1l $\Delta ADE \sim \Delta BOE$, $\Delta AOE \sim \Delta BCE$
1m $\frac{A(BOE)}{A(ADE)} = \frac{A(BCE)}{A(AOE)}$
1n $\frac{A(ABCD)}{A(CDO)} = 2$



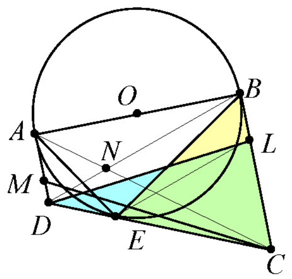
1o $N = AC \cap DB$;
$ML \perp BC \Rightarrow ABLM$ rectangle
1p $EL||BD$
1q $ME||AC$



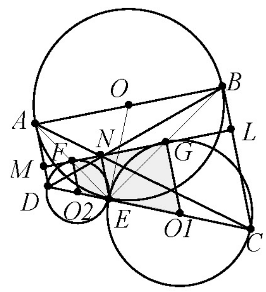
1r $NE||BC$
1s $BLEN$, $AMEN$ parallelograms
1t $JN = NE$



1u $F, G \in ML$
$NG = GL$
$MF = FN$



1v $A(CDL) = A(BCE)$
1w $A(CDM) = A(ADE)$



1x OE is tangent to circles O1 and O2
1y $FGO_1O_2 \sim ABCD$; $\frac{A(ABCD)}{A(FGO_1O_2)} = 4$
1z $FGO_1O_2 \sim ABCD \sim MNED \sim NLCE$

Figure 3: The expert individual space of discovered properties

-- *the complexity of the auxiliary construction* performed for the investigation and

-- *the complexity of the proof* of the new property.

Newness of the discovered property

The newness of the discovered property is relative to the educational history of the participant. This criterion reflects participants' critical reasoning and the ability to evaluate the property as either discovered in the process of investigation or one that was known previously. As such, we distinguish between three levels of newness of the discovered property: 0-trivial, 1-less trivial, 2-nontrivial.

For example, in Figure 3, properties 1a, b, c, d, g, are categorised as trivial, properties 1e, 1f, 1l, 1m are less trivial, whereas properties 1h, 1i, 1j, 1k, 1o. 1p, 1q, 1r, 1s, 1t, 1*, 1u, 1v, 1w, 1y, 1z are categorised as not trivial since they require complex proofs. Property 1* is a special one since through search for the proof of the property, Sharon discovered additionally several new properties

Complexity of the auxiliary construction

We distinguish between three levels of complexity of the auxiliary constructions (Table 1) according to two criteria:

Criterion 1: *The location of the auxiliary construction*. The property is discovered based on the auxiliary construction "within the given figure" vs. auxiliary construction "outside the given figure" (e.g., properties 1x, 1y, 1z Figure 3). Constructions "within/in the given figure" include (but are not restricted to) marking points on the border or in the interior part of the figure, construction of segments within the figure by connecting existing points or the new ones, construction of special lines (medians, bisectors, altitudes, inscribed circles) and more. Constructions "outside" the figure are more complex than those "within" the figure.

Criterion 2: *The number of the auxiliary constructions*. The property can be discovered without any auxiliary construction while the conjecture is raised on the basis of the measurement of segments, angles, areas and perimeters of the existing elements in the given figure and the comparison of these measurements. The number of the auxiliary constructions required for the discovery of a property determines the level of complexity of the property.

Through a combination of Criteria 1 and 2, we determine the complexity of the auxiliary construction as presented in Table 1.

For example, in Figure 3, the levels of complexity of the auxiliary constructions are 1 for properties 1l and 1m; 2 for properties 1e and 1f, 3 for properties 1o, 1r.

Complexity of the proof of a discovered property

Complexity of a proof of the discovered property is determined by the length of the logical chain of the proof and its conceptual density (Silver & Zawodjewsky 1997). Table 2 presents the levels of proof difficulty as determined in this study.

The complexity of a discovery is determined according to the combination of the complexity of auxiliary construction and the complexity of proof (see Table 3).

The number of constructions / Location	0	1	2	3 and more
Within	N/A	Easy (1)	Medium (2)	Difficult (3)
Outside	N/A	Medium (2)	Difficult (3)	Difficult (3)

Table 1: The complexity of the auxiliary construction

Proof length / Conceptual density (number of concepts and properties used during the proof)	1–3 steps easy	4–6 steps medium	7 and more difficult
1–2 concepts/properties – easy	Easy (1)	Medium (2)	Difficult (3)
3–4 concepts/properties – medium	Medium (2)	Medium (2)	Difficult (3)
5 and more concepts/properties – difficult	Difficult (3)	Difficult (3)	Difficult (3)

Table 2: The complexity of a proof

DISCOVERY STRATEGIES

Within the space constrains of this paper we present shortly the discovery strategies identified in this study (CS-2). We identified eight *types of discovery* as associated with the *process of discovery*:

1) Immediate discovery
2) Discovery by chance (through wondering dragging in DGE)
3) Discovery through association with another problem
4) Discovery in the search for a proof
5) Discovery based on the previous knowledge of related properties
6) Discovery in the course of proof
7) Discovery by symmetry considerations
8) Intuitive discovery

COMPARING EXPERT AND NON-EXPERT SPACES OF DISCOVERED PROPERTIES FOR

Table 3 shows the investigation process performed by the non-experts (properties 1.1.-1.7) and the expert (properties 1.a-1z) in problem solving. It also includes the analysis of the complexity of the discovered properties and describes the type of discovery.

	Property (in Tables 1 and 2)	Complexity of the discovery (A, B, C) A-newness of discovery B-complexity of auxiliary construction C-complexity of proof	*Type of discovery*
CS-1: Non-Expert space of discovered properties	1.1	(0, 0, 1)	*By chance (in DGE)*
	1.2	(1, 2, 1)	*By chance (in DGE)*
	1.3	(1, 2, 2)	*By chance (in DGE)*
	1.4	(0, 0, 2)	*By chance (in DGE)*
	1.5, 1.6, 1.7	(2, 3, 3)	*By chance (in DGE)*
CS-2: Expert space of discovered properties	1a, 1b, 1c, 1d	(0, 0, 1)	Immediate
	1n	(0, 0, 2)	Immediate
	1g	(0, 0, 1)	By knowledge of properties
	1e	(1, 2, 1)	*Through association with other problem*
	1f	(1, 2, 2)	*By knowledge of properties*
	1l	(1, 1, 2)	*By knowledge of properties*
	1m	(1, 1, 3)	By knowledge of properties
	1o	(2, 3, 1)	Through search of proof
	1r	(2, 3, 2)	By knowledge of properties
	1h, 1t	(2, 3, 2)	Through association with other problem
	1i, 1j, 1k	(2, 3, 3)	Through search of proof
	1*, 1p, 1v, 1y	(2, 3, 3)	*By chance (in DGE)*
	1s, 1u	(2, 3, 3)	Immediate
	1z	(2, 3, 3)	*Intuitively*
	1q, 1w	(2, 3, 3)	Symmetry considerations

Table 3: Complexity and the type of discovery

DISCUSSION

Based on the framework for the analysis of geometry investigations and the findings presented in this paper, we argue that creativity can be developed in people with different levels of problem solving expertise, but the range of the development depends on the expertise. The differences in such a range are reflected in the amount and the complexity of discoveries depicted in Figure 2 and Figure 3 and Table 3.

While surprisingly both expert and non-expert spaces of discovered properties include trivial and non-trivial discoveries, obviously, the expert space of the discovered properties is richer. Interestingly, non-experts discovered properties that were not discovered by the expert (properties1.5, 1.6, 1.7) and thus we do not consider any expert space of discovered properties as a complete one.

The major difference between expert and non-expert investigations is in the investigation strategies applied. Most of the discoveries by non-experts in problem solving are discovered "by chance" by observation of regularities which are immune to dragging. On the contrary, the discoveries by the expert were based on his mathematical knowledge and problem-solving expertise. Moreover, many of the discoveries "by chance" were based on the experts' attempt to search for a proof with the help of DGE.

Based on the findings presented in this short paper, we argue that problem solving expertise is a core element in the development of investigation skill in geometry that is a development of creativity. This development in PMTs is a rather "painful" process which requires them to overcome multiple difficulties related to geometry construction, grasping the meaning of dragging, proving and refuting multiple conjectures. Through the development of investigation skills, we also develop problem-solving expertise in PMTs and thus hope that creativity will be further developed. The process of this development is an objective of our current new study.

Students with hearing impairment: Challenges facing the identification of mathematical giftedness

Swetlana Nordheimer[1] and Matthias Brandl[2]

1 Ellen-Key-Oberschule and Humboldt-University, Berlin, Germany, swetlana.nordheimer@gmail.com

2 University of Passau, Faculty of Computer Science and Mathematics, Passau, Germany, Matthias.Brandl@Uni-Passau.de

Usually a mixture of student's interest, qualitative teacher's observation and quantitative tests is used in order to identify mathematical giftedness. However, for children with hearing impairment, traditional ways of identification and diagnosis need to be adjusted, especially when it comes to quantitative aspects. The challenges of this process are illustrated by a case study and conclusions (like less time limits in tests, more visual helps) are drawn.

Keywords: Mathematical giftedness, hearing impairment, identification, inclusion.

INTRODUCTION

In 2008, the UN *Convention on the Rights of Persons with Disabilities* was ratified in consequence of *The Salamanca Statement and Framework for Action on Special Needs Education* in the context of the UNESCO *World Conference of Special Needs Education: Access and Quality* in 1994. The Convention aims at ensuring „an inclusive education system at all levels" (UNO, 2008, Article 24) which satisfies the needs of „*all children* regardless of their physical, intellectual, social, emotional, linguistic or other conditions. This should include disabled and gifted children" (UNESCO, 1994, 6). And therefore, the question of how to recognize and foster children that bring together two different specifics, i.e., *hearing impairment* and *mathematical giftedness*, is massively challenging and important.

The purpose of the study is to present a first exploration of the field and start the development of appropriate research questions with regard to the identification of mathematically gifted students with hearing disabilities. Further, we outline several complexities in the identification of gifted children with special needs that require future systematic research.

THEORETICAL BACKGROUND

The following paragraphs shortly summarise some facts from literature on the identification of mathematical giftedness, children with hearing impairment (hi) and the mathematical development of hi-children.

Identification of mathematical giftedness

According to Renzulli (1978), giftedness is characterised by *above average ability*, *high levels of task commitment*, and *high levels of creativity*. These aspects are acknowledged to be important for giftedness in mathematics education as well (Leikin, 2011). As already discussed in Brandl (2014), there are different ways of identifying and selecting promising students for reasons of fostering (in mathematics). One option is to rely on the students' own *interest* in mathematics as the main motivational force and most important factor for mathematical giftedness (see amongst many others Kruteskii, 1976). A second way is to trust in teachers' choices, adding a *qualitative* external selection component to the students' interest (see Linke & Steinhöfel, 1986, for example). A third option would focus on *quantitative* methods and result in testing the students (see Nolte, 2012; Kontoyianni et al., 2011, amongst many others). In general, identification processes often are designed as a combination of these three ways (see Wagner & Zimmermann, 1986, for example).

Children with hearing impairment (hi-children)

The term 'hearing impairment' comprises several cases: dysfunctions of the auditory system, hardness of hearing, deafness. It may be caused by genetic reasons, trauma or disease. However, the terms "deaf" (d) or "hard of hearing" (hh) which are accepted in their community of people, not only imply the degree, type or configuration of hearing impairment, but also the way of communication the person uses. Most of hh-people rely on residual hearing and communicate through speaking and lip-reading. In noisy environments, however, it can be very hard for them to communicate verbally. Thus, they are likely to face various difficulties at school and differ in their educational and psycho-social development from their hearing (h) classmates. An hh-person may use a hearing aid to perceive what is spoken around him or her. In case of severe impairment, the person may not be able to distinguish any sounds or spoken language, even with a hearing aid. The majority of d-people use sign language to communicate. The majority of the h-people neither use sign language, nor do they have an understanding of the special needs of hi-children. This is why hi-children often find themselves facing great challenges with regard to their language skills, potentially carrying away gaps in vocabulary and difficulties in articulation, for example. This is likely to have an impact on their cognitive and social-emotional development (Leonhard 2002, pp. 71ff.).

Mathematical development and giftedness of hi-children

Pagliaro and Kritzer (2012, p. 139) summarise the results of current studies and conclude: "Consistently, over decades and across grade levels, deaf/hard-of-hearing (d/hh) students in various countries have scored poorly on mathematics assessments." The authors try to explain this "math gap" of d- and hh-children by the limited experiences and lack of ability to learn mathematical concepts, e. g. numbers by incidence, because of the language barriers separating them from their natural environment. Gregory (1998, p. 122) names two other possible reasons for the difficulties especially of d-children to cope with mathematical tests and assessments: the nature of specialized mathematical language and the suppression of sign language in mathematical education. Because of this reduction, mathematical signs cannot be developed in an appropriate way.

Further reasons for the differences in the development of mathematical thinking can be found in the specifics and obstacles within communication processes between hi- and h-people. Solving mathematical word (and modelling) problems usually starts with reading and understanding written texts. These texts often contain short words (e.g., prepositions), which are underemphasized in spoken language and can easily be overheard (or overseen by hi-students, when relying on lip-reading or sign-language). Moreover, there are specific mathematical terms like "product" or "root" which have different meanings in the common spoken language. This proves to be difficult to express in sign-language or figure out by lip-reading.

Engel (2000, p. 17) reports that many hi-children develop strategies in order to solve word problems without entirely understanding the text. These children try to simplify and restructure the text. This process can be compared with the reading of fill-in-the-blank texts. In some cases, these strategies are successful, in many others they are not. Cohors-Fresenborg (1988, pp. 102ff.) claims that hi-children excelled in solving problems, which had been represented visually or haptically without using written or spoken language. These children achieved particularly high scores, when it came to problems which demanded high modelling competences (reconstruction and reorganization). Biographies of famous deaf mathematicians and scientists also show that hi-people can be brilliant problem solvers or gifted mathematicians (confer Lang & Meath-Lang, 1995, p. 407). Obviously, not every hi-person is a mathematical genius, and the same applies to h-people. There are, however, hi-students who are very interested and gifted in mathematics, and eager to solve mathematical problems. As for the discussed language difficulties of hi-students, it is not easy to recognise their mathematical giftedness, because most diagnostic instruments use spoken or written language to represent mathematical problems.

Giftedness of children with special needs can be masked by their disability. Gifted children with disabilities also often use their intelligence to compensate for their impairment. That is why it could be very difficult to recognise special needs of gifted children (Krochak, 2007; Nielson, 2002). Children whose hearing is impaired cannot respond to oral directions in the same way hearing children do, and they may also lack the vocabulary expressing the complexity of their ideas. They sometimes cannot respond to tests requiring verbal responses (Whitmore & Maker, 1985). Since the population of gifted students with special needs is difficult to locate, they are seldom represented in standardised test norming groups. This makes every comparison highly problematic. Pedagogical literature related to gifted hi-students lists criteria which should help to recognise giftedness, i.e., *Excellent memory, Rapid grasp of ideas, High reasoning ability, Superior performance in school, Wide range of interests, Nontraditional ways of getting information, Use of problem-solving skills in everyday situations, Delays in concept attainment, Self-motivation, Ingenuity in solving problems, Symbolic language abilities like different symbol system* (Cline & Schwarz, 1999; Whitmore & Maker, 1985).

METHOD

In order to illustrate aspects of the diagnostic challenge, a single case study was done.

Description of the student

The study deals with Leon[1], who is now visiting a 5th grade at the special school for hi-children in Berlin, where pupils are grouped in small classes of ten. The classrooms are equipped with technical aids and visual materials in order to support spatial thinking, and, compared to conventional schools for h-children, students get more time to work on their assessments. At the beginning of the study in August 2012, Leon was still a 3rd grader. According to the pupil's record, Leon suffers from bilateral[2] sensorineural[3] severe hearing loss of 60 to 70 dB. Leon is hard of hearing since he was born. Since his first year he has been using hearing aids, but it is still difficult for Leon to perceive spoken language without being able to watch the lips of his communication partners. Leon's parents and all his siblings are hearing and use oral language to communicate. It was not until he started school, that Leon was confronted with sign language. After one year, his parents decided to invest in one-to-one-language therapy. Because of Leon's special needs with regard to language, his parents finally sent him to the special school for hi-children.

At the beginning of 3rd grade, Leon had difficulties to express himself and to articulate his thoughts. Misunderstandings and conflicts with his classmates or even teachers were frequent and usually ended up in tears. Probably in order to avoid these situations, Leon very often waived explanations of his needs and feelings. Still, even more remarkable than Leon's communicational obstacles was and is his tremendous motivation to do mathematics. According to an interview done with his former mathematics teacher, he attracted her attention during the mathematics lessons through his eagerness to solve mathematical problems and his endurance when working on difficult and new tasks. According to his educational file, Leon discovered multiplication on his own by working with Montessori materials for preschoolers in kindergarten, when he was four years old.

At school, he works in mathematics classes with concentration, listens to the teacher and his classmates very carefully and examines what they said mathematically. He always manages to complete more mathematical tasks and problems than his classmates and sometimes poses his own questions and problems to the teacher as well. The tasks Leon tried to avoid in 3rd grade were word problems. Usually, his mood changed as soon as he was presented with a word problem. He often did not even start working on it, unless his teacher encouraged him strongly. Then he asked for the meaning of some words and tried to solve the problem, but he was not always successful, mainly because of textual misunderstandings and mismatches between the world of mathematics and the world of written German language.

Despite his difficulties, the mathematics teacher who taught him in 1st and 2nd grade recommended Leon for "Mathe-Treff" at Humboldt University in Berlin. This is a program for gifted students from primary schools from all over the city. The "little mathematicians" meet once a week for one and a half hour to solve mathematical puzzles and problems. They are assisted and observed by students of the educational department and the leader of the project, Prof. Marianne Grassmann. The biggest part of mathematical puzzles and problems is verbalized in written German language, so this represented a real big challenge for Leon. For this reason, two students from the department for special education were supporting Leon. They adapted mathematical word problems to his communication level and offered their help. Not all children managed to participate till the very end of the course, because it was not easy to stay motivated to do mathematics after a long school day. However, Leon was among those who completed the whole one-semester course successfully.

Identification method for mathematical giftedness

In Leon's case the decisive factor for the identification of mathematical giftedness was the teacher's recommendation. As mentioned earlier, the careful observation of the child during class can be a successful qualitative method. A very important part of this observation method was the study of the child's written products. We examined number tasks and word problems, both done within regular mathematics lessons. These observations were accompanied by a quantitative extracurricular assessment, intelligence and development test: In order to compare Leon with his hearing peers and to see his mathematical giftedness within the context of his general development, the IDS (Intelligence and Development Scales) for five- to ten-year-old children was used as a further diagnostic instrument (Grob et al., 2009). IDS was invented to provide differentiated insight into intelligence and general development in areas like Cognition, Psycho-Motorics, Social-emotional Competence, Mathematics, Language and Achievement Motivation at the beginning of the school career. It focuses on the dynamics of so-called individual "strengths" and "weaknesses" and puts them in relation to the child's development profile and to his corresponding peer-group. The test consists of different modules[4] and can be used as a whole or in parts. Except for the modules Phonological Memory and Auditive Long-Term Memory, it is possible to pose and solve the test tasks without spoken language. More language instruction is necessary when it comes to the modules describing General Development.

IDS was chosen as a diagnostic instrument, because it allows for comparison of Leon's intellectual abilities with the average population. It provides for precise and distinctive insights into different areas of the intellectual and social development and shows the interaction of talents and special needs. It could help to avoid that intellectual abilities and language needs collide. In this sense it could provide insights into the ability to compensate for hearing and language problems. Besides, the part *Achievement Motivation* of the IDS allows for conclusions about task commitment, which according to Renzulli (1978) can serve as an important characteristic of mathematical giftedness. It is difficult to make conclusions about mathematical creativity using IDS as a quantitative instrument, since the answers are standardised. That is why Leon was asked to talk about IDS-items and to explain his solutions, which were written down and then used as questions for qualitative interviews.

Since time was very limited, Leon was not exposed to the whole test. Instead, a selection of *Intelligence*, *Social-emotional Competence*, *Mathematical Competence*, *Expressive Language Competence* and *Achievement Motivation* was chosen. When taking the test Leon was 9 years and 7 months old. The test was completed in a one-on-one situation.

RESULTS

We illustrate how written products can indicate mathematical giftedness by describing and analysing some chosen cuttings from Leon's booklet and items of the IDS test.

Number tasks (regular lessons)

Leon's answer to the question: "Draw your favourite number." was the number 201031 which has six digits. Leon also knows that 200000 + 1000 + 31 = 201031. At this moment most children in the classroom were expected to deal with numbers under 1000. Some of them painted numbers above 2000 but not above 3000.

When it came to the figurative representation of numbers with three digits, Leon invented his own notation. The task for "Zahlenbild" was to find a symbolizing picture for numbers. (Example: the number is 300. Intended and trained solution: □□□). In contrast to other children he did not draw three squares in order to represent for example three hundred as a sum, but he used a multiplication sign to shorten the notation (□x3). So, Leon's solution does not confine itself to non-mathematical (purely additive) pictograms but extends it by bringing in abbreviating mathematical symbols.

Some months later the students learned how to add numbers under 1000 via an algorithm. Leon did not only use this algorithm to solve several given problems without a single mistake, but invented his own problems with bigger numbers and looked for new regularities.

Word problems (regular lessons)

Compared to a regular school, at the special school for hi-children mathematical word-problems are usually verbalized clearer and the numbers in it are kept small in order to make it easier for the students to solve them. Further, text problems have been translated into visual representations or supported by other special tools like small blocks and Montessori-materials. Students could use stamps to solve the problems or to control their results. The problems were offered at three difficulty levels. Leon chose the easiest problem first and controlled his result with stamps. In a second step he applied his solution to a more difficult problem dealing with spiders. Since he had understood the structure of the first problem, he was now able to transfer it onto the text structure of the spider-problem without using stamps as visual aids. Remarkably, Leon found it important to notice the commutativity of the multiplication.

Assessment, Intelligence and Development test IDS 5–10 (extracurricular)

Leon's intellectual performance with IQ = 109 lies according to the IDS in the upper average area in relation to his hearing peers. In the sub-test Selective Attention Leon achieved the highest possible score [Value Points (VP) = 19]. The scores in the sub-tests Auditive Long-Term Memory and Conceptual Thinking are above the average [VP = 14]. The other scores lay within the standard norm of his peers [VP = 9, 11, 12, 12]. It is remarkable, that Leon could manage all tasks of the sub-tests in Figural Thinking almost within the standardized time limits.[5] Leon's answers in the sub-test Social-emotional Development show that he can perceive and recognize other people's emotions within average norm [VP = 9]. Likewise, Leon is able to regulate his emotions [VP = 14] and understand social situations [VP = 13] better than most of his peers. However, he showed heavy deficits with regard to the aspect Social Acting [VP = 6]. In the sub-test Achievement Motivation Leon again reached the highest possible score. Leon's score in the sub-test Expressive Language lay way below the average norm [VP = 2]. He was able to express his thoughts, but he could hardly do it in the grammatically correct way as it was expected in the standard test. Some of his sentences are difficult to understand. However, if the sentences containing semantic and grammatical errors counted as correct, Leon would have reached VP = 12, which corresponds to the average. Within limited time he attained VP = 14 in the sub-test Mathematics, which is above the average. Without time-limitation Leon managed to solve all mathematical problems except one word problem and reached VP = 19, which is far above the average compared to children of his age. In order to gain deeper insight into Leon's mathematical thinking we will discuss some items of the test closer.

There were two very similar word problems which were read out loud to the children. The respective tested child was given toys (small doll, cat, dog and cups) to illustrate the solution and was expected to explain it. Leon managed to solve one problem and was not successful with the other. The reason was that the chosen vocabulary and the text structure of the unsolved problem were more complicated than in the problem Leon could solve. Other problems were verbalized as well, but they could be solved almost without understanding the text. The information needed was also represented by visuals or symbols. Leon soon ignored the text and solved them only by using mathematical symbols. In the second task he had to deal with numbers which, by that time, were no subject matter of the mathematics curriculum: „A counter is counting people, who are coming into the stadium. The counter shows this number. What would the counter show, if 201 more people would come to the stadium? Write the numbers into the nearby blanks" (Figure 1 left). Leon solved the problem and even put a point into the number. This demonstrates, that he understood the meaning of the written symbols. The next two problems referred to Geometry: "How many cubes are in this figure? Fill in" (Figure 1 bottom). In these tasks Leon showed his good abilities in figural and spatial thinking.

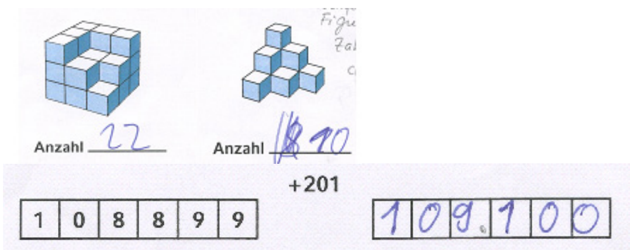

Figure 1: IDS/Items 14 to 16

The final problems checked his orientation in the range of numbers 0 to 100000. Since Leon had until then only learned numbers under 10000, he found himself working with new numbers and still managed to find the correct solutions in the given time. He could not solve the very last problem in the given time, but he found out the right numbers after the time was over. This appears even more remarkable, since he transferred his knowledge about numbers under 10000 to numbers over 10000 (Figure 2 bottom).

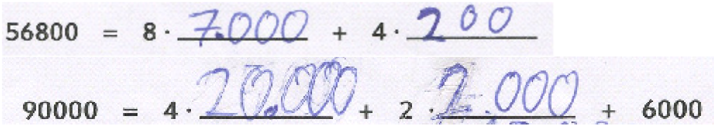

Figure 2: IDS/Item 17 & 18

CONCLUSION

Language barriers essentially complicate the identification of mathematically gifted hi-children. However, the documents presented in the results section clearly show that a hi-child like Leon can also develop the ability to analyse the structure of numbers, to play with them, to invent an own notation, to work with different modes of representation and to compensate for his language difficulties by visual help (for example stamps) or mathematical signs (multiplication sign). Although these results were achieved in the setting of a special school, the case study of Leon can inspire appropriate combinations of qualitative and quantitative methods that can work out successfully in regular (inclusive) schools, too: documents and products from student observations combined with standardised tests (perhaps including less time limits and more visual helps) may overcome language barriers and lead to differentiated insights into the child's possibilities. In the end, this could be of great help not only in order to predict a hi-student's success in programs for gifted children, but also in order to provide him with the individual support needed.

The results of the study correspond with criteria for mathematically gifted hi-children and the study leads to the following future research questions: What kind of information about mathematical giftedness of children with hearing difficulties allows for a quantitative comparison with children without hearing difficulties? Does it mean that hi-students with the same score as hearing students have greater competence, given the knowledge that they compensate for their disadvantages? In what way need criteria for mathematically giftedness to be altered in order to address students with hearing problems? How can this information help to predict hi-students' success in programmes for fostering mathematical giftedness that are usually designed for hearing students?

ENDNOTES

1. "Leon" is a pseudonym because of protection of privacy. The child's real name is known to the authors.

2. in both ears

3. caused because of dysfunction of the inner ear

4. Visual Perception, Selective Attention, Phonological Working Memory, Spatial Working Memory, Auditive Long-Term Memory, Conceptual Thinking and Figural Thinking build General Intelligence.

5. Results which were scored without time limitation were not considered by the calculation of the IQ, but they still show that Leon could achieve more if he has more time and that he is able to concentrate as long as it takes him to get the correct solution.

The effect of high versus low guidance structured tasks on mathematical creativity

Sonia Palha, Jaap Schuitema, Carla van Boxtel and Thea Peetsma

University of Amsterdam, Research Institute of Child Development and Education, Amsterdam, The Netherlands, S.AbrantesGarcezPalha@uva.nl, J.A.Schuitema@uva.nl, C.A.M.vanBoxtel@uva.nl, T.T.D.Peetsma@uva.nl

To engage in challenging tasks, students need to feel some autonomy and competence. Providing structure within the task can help to meet these needs. This study investigates the influence of structure within a modelling task on mathematical creativity among 79 eleventh-grade groups of students. Two versions of the task were developed and the groups were randomly assigned within their classroom to one of these. The analysis explored: (i) the level of mathematical creativity in groups solutions and (ii) if they were dependent on the amount of structure. The results were not statistically significant and, therefore, the question remains open. Additional results and implication of this study to mathematics education are further discussed.

Keywords: Integral calculus, creativity, modelling, collaborative learning, structure.

INTRODUCTION

Researchers express different views with regard to creativity and its connection with the learning environment. Some claim that creativity can be seen as a disposition towards mathematical activity and therefore it can be fostered through specific instruction, such as problem-solving (Silver, 1997). Others see creativity as characteristic of extraordinary individuals (Weisberg, 1988) and thus, not likely to be strongly influenced by the learning environment. Also, several researchers connect creativity to self-regulated learning (Feldhusen & Goh, 1995) and psychological characteristics such as task commitment and motivation (Renzulli, 1978). In our research we share the view that mathematical creativity can be fostered by adequate instruction and we study the relationship between aspects of the learning environment (e.g., task characteristics) and mathematical creativity.

This study is part of a longitudinal intervention research in which we investigate how aspects of the learning environment influences students' motivation, self-regulation and academic performance in mathematics. We developed a learning arrangement in which we used differentiated tasks with a deeper and broader content and method to create a more authentic and challenging learning context. The participants are 16/17 years old students in pre-university education in The Netherlands. Part of our research is to investigate which amount of structure is optimal for the students. We developed two versions of the same learning arrangement. One version consists of low-structured *(LS)* tasks and provides more open tasks, more choice and initiative for students. The other version contains more high-structured *(HS)* tasks, which still provide some choice but also hints, more sub-questions and guidance.

In this paper we discuss our findings with regard to a modelling-task: the parachute jump (Figure 1), which was used within the topic Introduction to Integral Calculus. Modelling-tasks as problem-posing tasks have been seen by several researchers as excellent opportunities for mathematical creativity (Kim & Kim, 2010; Chamberlin & Moon, 2005). The research questions that guided our study were:

- What can we say about the mathematical creativity of students' productions with regard to the parachute jump task?
- In which way does variation in the amount of structure in the parachute jump task influences students' mathematical creativity?

THEORETICAL FRAMEWORK

Mathematical reasoning and creativity

Mathematical creativity can be seen as the ability of students to create useful and original solutions in authentic problem-solving situations (Chamberlin & Moon, 2005). The core activity of the parachute task is to build a model that can be applied in the particular example and other situations. The students' products can then be evaluated in terms of mathematical creativity. In the literature, mathematical creativity is often defined in terms of three components: *flexibility*, *fluency* and *originality* (Silver, 1997; Yuan & Sriraman, 2001). Flexibility can be seen as the ability to generate multiple solutions to a given problem. Fluency can be seen as the ability to use several relevant ideas to solve the task and, in problem-situation tasks it is connected to many interpretations, methods, or answers Silver (1997). Originality concerns different solutions or innovative ways to approach a problem.

Measurement of mathematical creativity remains critical. One reason is the absence of a universal definition applicable in different academic domains (Leikin & Lev, 2013; Kattou, Christou, & Pitta-Pantazi, 2015). Another reason is that one person's creativity can only be assessed indirectly (Piffer, 2012). The ability of posing problems given one mathematical scenario have been linked by several researchers to mathematical creativity (Silver, 1997; Yuan & Sriraman, 2001). Also, over the past years, researchers (Leikin & Lev, 2013) developed an analytical framework that can be used to evaluate creativity in students' productions using the components fluency, flexibility and originality. Mathematical creativity with regard to modelling activities often includes a fourth component: *usefulness*, which concerns the degree of relevance, adaptability and generality of solutions with regard to real world situations (Chamberlin & Moon, 2005). The criterion of usefulness has been contested by some authors. Sriraman (as cited in Yuan & Sriraman, 2001) argues that mathematics creative work might not be useful in terms of its applicability in the real world. Chamberlin and Moon (2005) propose the *Quality Assurance Guide* as a reliable instrument to evaluate creativity in students' products on modelling tasks. Each solution is scored within one of five levels. *Level 1*- requires redirection- the product is on the wrong track and working harder or longer will not improve it. At *level 2*, the product requires major extensions or refinements, the product is a good start towards meeting the goal of the task. At *level 3*, the product is nearly ready to be used; it is useful for the specific data or sharable or reusable. At *level 4*, no changes are needed and at *level 5*, others can use it as tool in similar situations.

High- and Low-structured tasks (HS and LS- tasks)

According to Silver (1997) problem-oriented instruction can assist students to develop more creative approaches to mathematics by increasing their capacity with respect to the core dimensions of creativity: fluency, flexibility, and originality. For instance, ill-structured problems require problem posing and conjecturing, which can foster the generation of novel conjectures. Silver (1997) stated: "It is in this interplay of formulating, attempting to solve, reformulating, and eventually solving a problem that one sees creative activity" (p. 76). However, engaging in problem-solving activity also requires certain ability and disposition to deal with uncertainty and challenge. Aspects of the learning environment that have been found to support the development of such disposition are autonomy support and structure provision (Deci & Ryan, 2000). According to these authors, in autonomy supportive environments students are allowed to make own decisions and are encouraged to solve problems. This can be achieved by providing authentic tasks and opportunities for taking initiative and minimize the use of controlling behaviour. Also, the provisions of structure contributes for students' feeling of competence and therefore is important for motivation. Providing structure involves communicating clear expectations, set limits to students' behaviour and provide help.

Task arrangement

We investigate the relationship between structure provision and mathematical creativity in a problem-oriented arrangement that consisted of the 'parachute jump' task (Figure 1) and small group work. Working together may enhance feelings of relatedness and a sense of autonomy (Schuitema, Peetsma, & Van der Veen, 2011). And, during students' collaboration there is an unpredictable flow of ideas and actions that emerge from the elements of the group while responding to each other. Levenson (2011) states: "Together, the group tries out various strategies and possibly produces solutions based on different mathematical properties or different representations" (p. 230). This is tied to mathematical creativity in the sense that participants must be flexible, establish

(both versions A and B)

Task 25 parachute jump

Dynamical processes, like a train ride, a traveling car and other speed-time processes can be described using a *mathematical model*. A mathematical model may include tables, graphs, formulas or any combination of these representations. These mathematical models can then be used to investigate (and solve) problems through calculations and reasoning or to invent better models to attack the stated problem. In a group of three students, you will create a mathematical model in which the distance travelled against time for a parachutist is described. You also prepare a demonstration (Powerpoint, poster or video clip) of your group's work as a homework task.

But first an example of a parachute jump is presented.

Example.
Imagine the following situation: A parachutist jumps from an airplane. The first five seconds she makes a free fall. Then she opens the parachute and because of that her fall velocity decreases linearly down until after 6 seconds she achieves a fall velocity of 4 meters per second. From this moment on the velocity remains constant during 70 seconds and she lands on the ground at this velocity.

(only version A)

In the example, time is called t (in seconds), with $t = 0$ at the jump from the plane. For the free fall the velocity is given by $v(t) = 9{,}8\,t$ with v in meter per second. The total jump, until reaching the ground, was 561.5 meters. A mathematical model for this example could be a formula (or some collection of formulas), a graph or table in which the falling process is described and that may help to solve the stated problem.

The process for another parachutist will be comparable although different in the three phases of the process.

(only version B)

The process for another parachutist will be comparable, although different in the three phases of the process. That process may be described using a mathematical model. It is usual to start such a model with a concrete example and after that you try to design a more general model or representation. In this class period you will develop a mathematical model that describes the distance traveled against elapsed time for a parachutist. There are guiding questions describing an example that will help you to understand what is going on (questions a-d) and after that you are asked to design your own model (question e).

In the example, time is called t (in seconds), with $t = 0$ at the jump from the plane. For the free fall the velocity is given by $v(t) = 9{,}8\,t$ with v in meter per second.

a. What distance does the parachutist cover during the free fall?

b. What is the total distance covered from start to landing??

a. (version A) c. (version B)

Watch the Youtube video of a parachutist jump: http://www.youtube.com/watch?v=STDlEFhIPrw. Which similarities and differences do you notice, compared to the situation of the example?

d. Re-watch the video and try to collect data to design the model that describes the parachute jump (describe the data with use of tables/graphs or both).

e. Can you find a relationship between distance covered and time, based on the data you collected fom the video?

b. (version A) e. (version B)

Create a mathematical model that describes the distance covered during the total parachute jump against time.
After that, you preare a group presentation (powerpoint, poster or video for a 2-5 minutes presentation) in which:

- the mathematical model is presented;
- you give a justification of the choices made;
- show some examples of situations in which the chosen model will work;
- a critical reflection on the model.

Figure 1: Parachute jump task

mathematical relations and approach the task in distinct or novel ways.

The 'parachute jump' task was entailed to provide challenge and authentic experiences, as these are important elements of autonomy supportive tasks. It was designed according to the following four criteria.

Appealing and accessible to all students. The context of a parachute jump and the YouTube video make the task interesting to the students. And, the task becomes more accessible by providing an initial example with concrete values and asking to compare it with the one in the video. The pre-knowledge needed to start working on the task was known from previous year (functions, graphs and derivatives).

Authentic. By providing students with an authentic task, and enough freedom of choice we expect that students will be willing to spend thinking effort on it.

Foster mathematical reasoning and creativity. The accomplishment of the task requires the use of mathematical understanding and high-level reasoning. The students must produce at least one representation of the integral function (table, formula, graph, words) and describe its variation at the different instances of the jump. This involves high-level reasoning, as the students must imagine the total accumulating distance varying over time (Thompson & Silverman, 2008).

Suitable for collaborative learning. The task is complex and it can be approached at several levels of understanding. Moreover, the students were encouraged to discuss their ideas and communicate their findings within the group.

Solving the task takes about two lessons of 50 minutes each and some homework time. We agreed with the teachers that the students would work in small groups during one lesson on the task and that they should finish it in their own time (not more than one week). The final product would have the format of a Power Point or a short video-film and would be delivered to the teacher, who would send it to us.

METHOD

Participants and data collection

Seventy-nine groups of 3 students (16/17 years old) from 10 classrooms in 5 schools participated in the study. The data was collected in the spring 2014 and consists of delivered groups products and lesson observations. The groups were formed based on a cognitive ability test. The 40 groups in the LS condition and the 39 groups at the HS condition were, in each classroom, random assigned to one of the conditions.

Instrument used for the evaluation of mathematical creativity

The instrument that we used to evaluate the students' solutions to the parachute jump is based on three of the four components discussed in the theoretical section (we excluded originality because of the difficulty on assessing it in our data).

Usefulness regards the creation of a model that is useful to describe a parachute jump. For each written solution, we decided whether the model was incorrect (level 1), was in the good way but needed major improvements (level 2) or it was ready to be used but needed editing (level 3). Levels 4 and 5 were not observed in our data.

Fluency was seen as the ability to use several mathematical relevant ideas to solve the task. In the context of the parachute task it should be connected to the mathematical concept of the integral function, which is here treated as the total accumulating distance. Based on our theoretical framework, we define mathematical fluency as the ability to (i) link integration and differentiation as inverse processes; (ii) represent the total accumulated distance as a process (operational concept) and as an object (object oriented concept) within at least one functional representation (analytical, graphical, by words or numerical in a table); (iii) Indicate parameters that influence the model and to explain choices made.

Flexibility refers to the ability to set up a model and to use values that go beyond the information provided in the examples.

Analysis

To investigate the first research question we operationalized mathematical creativity in terms of the three components and explored the frequencies found in the students solutions. To investigate the second research question we gave scores to the 3 components and sub-components. Each student solution was then scored within 1–3 for usefulness, 0–2 for each subcategories of fluency, 0–2 for flexibility. We used the Mann-Whitney test, which is indicated for data at ordinal level of measurement, to explore whether the products of the two conditions differed from each other.

RESULTS

Fifty-two of the 79 groups that worked on the task in classroom handed in their final product to the teacher. In the following of this section we report on these products.

Students' creativity in terms of usefulness, fluency and flexibility

The first research question concerned the mathematical creativity of student productions. Table 1 shows that the majority of the groups solutions (36) were at level 1 and therefore, not useful to model the parachute jump. Only 16 groups produced models that could be used.

Usefulness	Groups solutions (N=52)
Level 1	36 (45,6%)
Level 2	15 (19%)
Level 3	1 (1,3%)

Table 1: Results on usefulness

The results on fluency are shown in Table 2. Almost half of the groups (22) explicitly established the link between integration and differentiation. For instance, one group draw both graphs, with the text differentiation and integration and two arrows pointing opposite directions. Most of the solutions (37) presented traces of an operational- oriented conception of total distance. This means that students can draw a total distance graph, use formulas to calculate single values but have difficulty to conceptualize the total distance as a mathematical object on which operations can be performed (Sfard, 1991). Very few groups (7) showed to have an object-oriented conception of total distance. An example of a student explanation that we consider exemplary of object-oriented conception is: "The distance increases at the beginning very fast, during the free fall. After 36 second, when the parachute opens the velocity becomes more or less constant and the distance increases linearly (...)". In contrast, students who would have no functional concept would not refer to distance in their explanations but describe the changes along the jump in terms of velocity, slope of line graphs (the line goes up or down) or in phenomenological terms. Most of the groups (34) did not consider parameters or provided choices.

The results on flexibility are summarized in Table 3. The majority of the groups (35) used only the values from the example. Few groups (14) refer to the values of the video and only 3 groups went beyond the information given in the task setting. Figure 2 contrast one of these solutions (right column) with a solution of the major group.

Influence of HS and LS task on mathematical creativity

The second research question investigates whether the amount of structure in the task has effect on

Fluency	Criteria	Groups solutions (N=52)
link between integration and differentiation	Not visible Unclear Explicit	24 (30,4%) 6 (7,6%) 22 (27,8%)
Conceptions of accumulating distance function	No functional concept Operational concept Object oriented concept	8 (10,1%) 37 (46,8%) 7 (8,9%)
Parameters and choices	No parameters nor choices Parameters or choices Both	34 (43%) 11 (13,9%) 7 (8,9%)

Table 2: Results on fluency

Flexibility	Groups solutions (N=52)
Confined to example or undefined	35 (44,3%)
Beyond example and confined to film	14 (17,7%)
Beyond video and example	3 (3,8%)

Table 3: Results on flexibility

Confined to the example

interval	afstandsgrafiek	invullen
(0-5)	s(x)=4,9x^2	s(5)=122,5
(5-11)	s(x)=-3,75x^2 + 86,5x – 338,75	s(11)=159
(11-81)	s(x)=4x-44	s(81)=280
		561,5m

Beyond the example and the film

"Imagine that you want to make a parachute jump. You want to make a free fall of 7 seconds. After opening the parachute you have a constant velocity of 3 m/s. Opening the parachute takes 4 seconds. After opening it you want to stay 3 minutes in the sky . How high must be the jump?"

Figure 2: Examples of two levels of flexibility

student's mathematical creativity. Table 4 shows the results on usefulness, fluency, and flexibility in both conditions. A Mann-Whitney test indicated that there was no statistically significant difference between the two conditions for all components and sub-components of mathematical creativity.

DISCUSSION

In this paper we explored the influence of task structure on the mathematical creativity in students' productions in the context of a modelling task. Next we discuss our results in the light of the two research questions.

What can we say about the mathematical creativity of students' productions with regard to the parachute jump task? Overall the student solutions attained low scores with regard to the three components of mathematical creativity. Only 52 out 79 groups delivered their final product, none of the groups created a general and reusable solution (levels 4 and 5) and only 16 out of 52 groups have created a model with level 2 or 3. Most students' use of mathematical functions involved thinking in operational views rather than object-oriented. Also, most groups failed in considering relevant side conditions (wind, gravity, etc.) and parameters that are necessary to present a realistic model for the parachute jump. These difficulties suggest that the task as we presented to the students was too challenging for most of them. Several researchers (Silver, 1997; Lithner, 2008) suggest that relationships between creativity and problem solving might be the product of previous instructional patterns. Therefore it is possible that students' previous experiences with mathematical tasks (note that the students are not used to problem-oriented instruction) may have limited their searching process. For instance, only few students tried to go beyond the given examples, as it can be seen by the low levels of usefulness and flexibility. Or, they have tried to explain their choices and present different parameters, as most of the students scored very low on these subcomponents of fluency. Therefore, one suggestion to improve the task is to provide additional information on side conditions that are not part of the mandatory curriculum or provide explicitly directions to look for them. Other suggestion involve the improvement of students' problem-solving activity. The teacher should encourage more the students during the solving process, e.g., to explore different paths, to look for other examples and not to give up too easily. Other aspects that we did not discuss here but also should be taken into consideration are the amount of time available to solve the task in the classroom, the specific directions to be provided by the teachers and assessment practices.

In which way does variation in the amount of structure in the parachute jump task influences students' mathematical creativity? The products created by the groups of students in the two conditions are not statistically significant different with regard to mathematical creativity. Therefore, the question whether providing more/less guidance in the mathematical

	HS-task Median	(N=27) Range	LS-task Median	(N=25) Range	Mann-Whitney U test (two tailed)
Usefulness (scores 1–3)	1	2	1	1	U=257.000, p=.066
Fluency (scores 0–2)					
integration-differentiation	1	2	1	2	U=308.500, p=.559
concept accumulating distance	1	2	1	2	U=304.000, p=.441
parameters and choices	0	2	0	2	U=333.000, p=.992
Flexibility (scores 0–2)	0	2	0	1	U=272.000, p=.144

Table 4: Results on mathematical creativity within high- and low-structured tasks

tasks have impact on students' mathematical creativity remains open. In this paper we studied the effect of task structure on the groups products without refer to the solution process. However the way students approach the tasks and reasoning processes might reveal mathematical creativity aspects of the students not revealed in the final product (Karakok, Milos, Tang, & El Turkey, 2015). This is one question that deserves further investigation. Another interesting question to be further investigated regards the collective creativity process. In our research the students work in small groups, thus the intrapersonal creativity of one student produces a creative product which is then appropriated by others. In this case it is difficult to determine to what extend the final creative ideas and solutions are the product of particular students or from the collective (Levenson, 2011). An interesting question therefore is: in what extend this collective process is mediated by the amount of structure provision in the task?

Concluding, although our study could not provide a conclusive answer to the question whether the amount of structure in the task influences students' mathematical creativity, it contributes to the field of research and teacher education in two ways. It extends previous research on mathematical creativity by accounting the relationship between the learning environment and creativity and, by providing a way to operationalize fluency and flexibility in conceptual mathematical terms. And it provides a practical example (the parachute task) with potential to engage students in problem-solving and concrete suggestions for its implementation. The use of this kind of tasks in the classroom and in teacher education can help teachers to recognize mathematical creativity in their lessons and therefore to better support it.

Visual processing and attention abilities of general gifted and excelling in mathematics students

Nurit Paz-Baruch, Mark Leikin and Roza Leikin

University of Haifa, Haifa, Israel, rozal@edu.haifa.ac.il

The present study examined the visual perception and attention abilities associated with general giftedness (G) and excellence in mathematics (EM). The research involved four groups of 16–18 years old participants varying in levels of G and EM. 190 participants were tested on a battery of visual processing tasks: visual-spatial memory (VSM), visual speed of information processing (SVIP),Visual-perception (VP) and Visual attention (VA). The results support the notion that the differences between the groups are task depended. On the VSM (Backward visual-spatial memory span) test, differences in performance were associated only with EM factor, while on the visual-perception (Pattern-recognition test) and attention (D2-CP score) tests only the G factor had a main performance effect. SVIP was associated with both G and EM factors.

Keywords: Visual processing, attention, visual speed of information processing, visual-spatial memory, giftedness, excellence in mathematics.

INTRODUCTION

The literature regarding visual processing and attention, in relation to both general G and EM, is limited. Up to now, most studies have examined G and EM factors separately, while leaving out EM students who are not gifted (Benbow & Minor, 1990) or G students who are not EM (e.g., Johnson et al., 2003; Zhang, et al., 2006). This study is part of a larger investigation aimed at defining mathematical-giftedness in mathematics. In a previous study (Leikin, Paz-Baruch, & Leikin, 2013; Paz-Baruch, Leikin, Aharon-Peretz, & Leikin, 2014) we compared relations between G and EM factors and other cognitive abilities such as: memory and speed of processing abilities. In this study, we examine these same relations with regard to visual processing and visual attention abilities.

BACKGROUND

Visual processing, giftedness and excellence in mathematics

Generally, visual processing ability is defined as the ability to generate, store, retrieve and transform visual images and sensations; visual processing is also related with the ability to recall the location of stimuli or to recall, identify or reproduce a design (McGrew, 2009).

Several studies suggest that visual speed of information processing (SVIP) abilities are related to intellectual giftedness (Dark & Benbow, 1991; Jensen, Cohn, & Cohn, 1989; Kranzler et al., 1994). Research has also demonstrated that visual-spatial ability is associated with general intelligence and academic achievement (Johnson & Bouchard, 2005). Gifted children have been found to respond more quickly than those with average IQ on a variety of SVIP (Deary, 2000; Duan, Dan, & Shi, 2013; Johnson et al., 2003) and visual-spatial tasks (Rizza, McIntosh, & McCunn, 2001).

Studies also showed a connection between SVIP and mathematical performing. Taub and colleagues (2008) demonstrated that visual processing speed is significantly related to quantitative knowledge for children. Moreover, Fuchs and colleagues (2006) found that in a group of third grade children, processing speed was a predictor of arithmetic ability when assessed by crossing-out tasks, and perceptual motor speed tasks. Geary (2011) revealed that processing speed, predicted achievement in mathematics, especially in numerical operations.

The ability to understand visual representations is considered by researchers as an important tool for mathematical learning and problem solving (Deliyianni, Monoyiou, Elia, Georgiou, & Zannettou, 2009). Excelling in mathematics students understand the problem by constructing and employing a diagram or a picture to help obtain a solution (Bishop, 1989).

Visual attention, giftedness and excellence in mathematics

The relationship between measures of attention and intelligence has been investigated repeatedly (e.g., Crawford, 1991; Rockstroh & Schweizer 2001; Schweizer, Zimmermann, & Koch, 2000; Schweizer & Moosbrugger, 2004). Few studies examined connection between sustained attention or divided attention and intelligence and showed that they are correlated with intelligence (Scheweizer et al., 2000; Schweizer & Moosbrugger, 2004). Being able to maintain attention for a long time at a high level is important whenever complex mental activities are to be performed, like problem solving and reasoning, which are closely associated with intelligence (Schweizer & Moosbrugger, 2004). Gifted individuals have swifter access to relevant knowledge due to faster automation of thought processes. As a result of which, they retain available attention capacity to tackle additional tasks (Memmert, 2008). Correlation between intelligence and divided attention depends on the tasks to be performed. Higher demanding tasks seem to yield higher correlations between measures of attention and intelligence than less demanding tasks (Scheweizer et al., 2000).

Most of the literature about mathematical ability and attention focus on children with learning disabilities and on the inhibition of irrelevant stimuli. Children who are less proficient in math have difficulties to suppress irrelevant information under high processing demand conditions (e.g., De Beni et al., 1998; Swanson, 2006). Anobile, Stievano, and Burr (2013) showed that attention and numerosity perception predict math scores. Individuals with higher math ability have less difficulty than average achievers in reducing accessibility of less relevant information that could overload and interfere during processing (Agostino, Johnson, & Pascual-Leone, 2010).

Accordingly, the goal of this study was to examine the connection between visual processing, attention and G and EM factors. We examined the hypothesis that G and EM factors are related differently to different visual processing abilities.

METHOD

Participants

We report herein our findings on 186 10th–12th grade students (16–18 years old) right-handed male and female students who were recruited for the study (see Table 1). The participants were subdivided in four experimental groups, determining the research population by a combination of EM and G factors: G-EM group: students who are identified as generally gifted and excelling in mathematics; G-NEM group: students who are identified as generally gifted but do not excel in mathematics; NG-EM group: students excelling in mathematics who are not identified as generally gifted; NG-NEM group: students who are neither identified as generally gifted nor excelling in mathematics.

Tasks and materials

Visio-Spatial Working Memory test (Corsi, 1972)

This block recall task consists of ten blocks arranged randomly on a wooden board. The test involves two parts: during the first part the researcher points at a sequence of blocks at a rate of one per second. After the researcher completes indicating the sequence, the participant is asked to replicate the sequence. If the

	Gifted (G) Raven > 27	Non-Gifted (NG) Raven < 26	Total
Excelling in mathematics (EM) SAT-M >26 or HL in mathematics with math score > 90	41	40	81
Non-excelling in mathematics (NEM) SAT-M <22 and RL in mathematics with math score > 90 or HL in mathematics with math score < 80.	53	56	109
Total	94	96	190

Table 1: Description of study groups

participant recalls the sequence of blocks correctly, another trial is administered. Successive trials are administered adding one more block each time and so forth until the participant fails two successive attempts. The maximum possible span is ten blocks.

During the second part, the researcher points at a sequence of blocks at a rate of one per second. After the researcher completes indicating the sequence, the participant is asked to replicate the sequence backwards. If the participant recalls the sequence of blocks correctly, another trial is administered. Successive trials are administered adding one more block each time and so forth until the participant fails two successive attempts. The maximum possible span is ten blocks. The measure of both test parts was a standard score according to the accepted Israeli scale (from Hebrew version of Visio-Spatial Working Memory test).

Visual- matching test (Woodcock-Johnson Tests of Cognitive Ability, 2001)

The test consists of rows that include one target symbol and 19 additional symbols. The participant has to circle all the symbols that are identical to the target symbol. The time limit for the assignment is 120 seconds.

Digit-symbol test (WISC III, 1997)

The test consists of a code table displaying pairs of digits and symbols, and rows of double boxes with a digit on the top box and nothing on the bottom box. The participant has to use the code table to determine the symbol associated with each digit (the test consists 133 digits), and to write as many symbols as possible in the empty boxes below each digit. The time limit for the assignment is 120 seconds.

Symbol-search (WISC III, 1997)

The test consists of rows marked by one target symbol and five additional symbols. The participant has to decide if the target symbols appear in the row of symbols and to mark YES or NO accordingly. The test consists of 60 items and the participant has to mark as many items as possible within 120 second.

Pattern recognition test (Thorndike, Hagen & Sattler, 1986)

The test consists of two columns of cross patterns: Pattern A is hidden in the larger pattern B. The participant has to draw a line around the crosses in B which make the same pattern as those in A. The test consists of 18 patterns and the time limit is nine minutes. The measure was accuracy (in %) of correct answers.

D2 Test of attention (Brickenkamp, 1994)

The D2 is a timed test for selective attention. The items are composed of the letters "d" and "p" with one, two, three or four dashes arranged either individually or in pairs above and below the letter. The participant is given 20 seconds to scan each line and mark all "d's" with two dashes. There are 14 lines of 47 characters each for a total of 658 items. Measures of performance include total number of items processed (TN), Total number of items correctly processed (TN-E) number of errors (E), an index of concentration performance (CP), and fluctuation rate (FR) across trials.

Data analysis

To investigate the questions addressed in this study, multivariate analysis of variance tests (MANOVA) were used to compare the scores of participants in each test. The between-subjects factors were: G and EM factors and the within-subjects factors were the scores on each visual processing and attention tests.

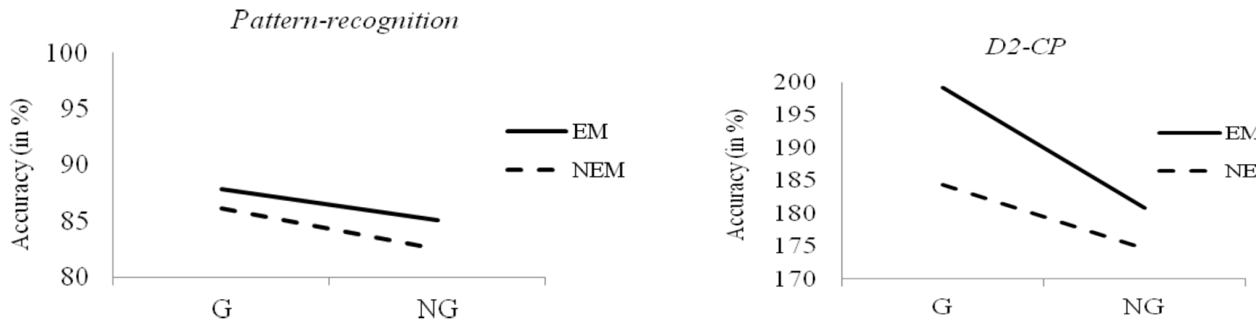

Figure 1: Significant main effect of G factor on VP and VA tests

RESULTS

Between groups differences on visual processing tests

MANOVA revealed an overall significant main effect for G factor (F(12,167)= 2.31, p< .01). Following univariate ANOVA tests showed that the sources of differences between the groups are the Pattern-recognition test (F(1,178)= 5.15, p<.05), D2-CP (F(1,178)= 9.63, p<.05). G student's accuracy on Pattern-recognition test (M= 87.04, SD= 9.33) and their D2-CP scores (M= 191.80, SD= 35.80) were significantly higher than NG students (Pattern-recognition M= 83.74, SD=11.62; D2-CP M=177.64, SD= 21.10) (Figure 1).

In addition, Univariate ANOVA tests revealed a significant main effect for EM factor in Symbol-search (F(1,178)= 4.64, p<.05) and Backward Corsi-span (F(1,178)= 3.96, p<.05) tasks. As shown in Figure 2, EM students outperformed NEM students on Symbol-search (EM: M= 73.62, SD= 10.22; NEM: M= 70.64, SD= 11.22) and Backward Corsi-span (EM: M= 6.29, SD= 1.04; NEM: M= 6.04, SD= 0.98).

CONCLUSIONS

The present study evaluated visual processing abilities linked to G (general giftedness), EM (excelling in mathematics). Between-group differences in visual processing were found to be task-dependent. On the VSM (Backward visual-span) test, differences in performance were associated only with EM factor, while on the visual-perception (Pattern-recognition test) and visual attention (D2-CP scores) tests only the G factor had a main performance effect. Visual SIP tasks were associated with both G and EM factors.

The results regarding visual-perception revealed that G students performed significantly better on this task regardless of their abilities in mathematics. These findings are in line with results of other studies which suggested that a superior visualizing ability characterizes highly gifted individuals (Silverman, 1995). The results regarding visual SIP revealed that G-EM students outperformed on two of the visual SIP tests (Symbol-search and Digit-symbol) compared to the other three groups. These findings are in line with previous studies which reported that processing speed is significantly related both to quantitative knowledge (Berg, 2008; Johnson et al., 2003; Swanson & Beebe-Frankenberger, 2004) and general giftedness (Dark & Benbow, 1991; Johnson et al., 2003; Kranzler et al., 1994), and are also partly reported in our previous study (Paz-Baruch et al., 2014).

Our study also demonstrates that the performance of G students on visual attention task, as regards concentration performance (D2-CP score) was better than

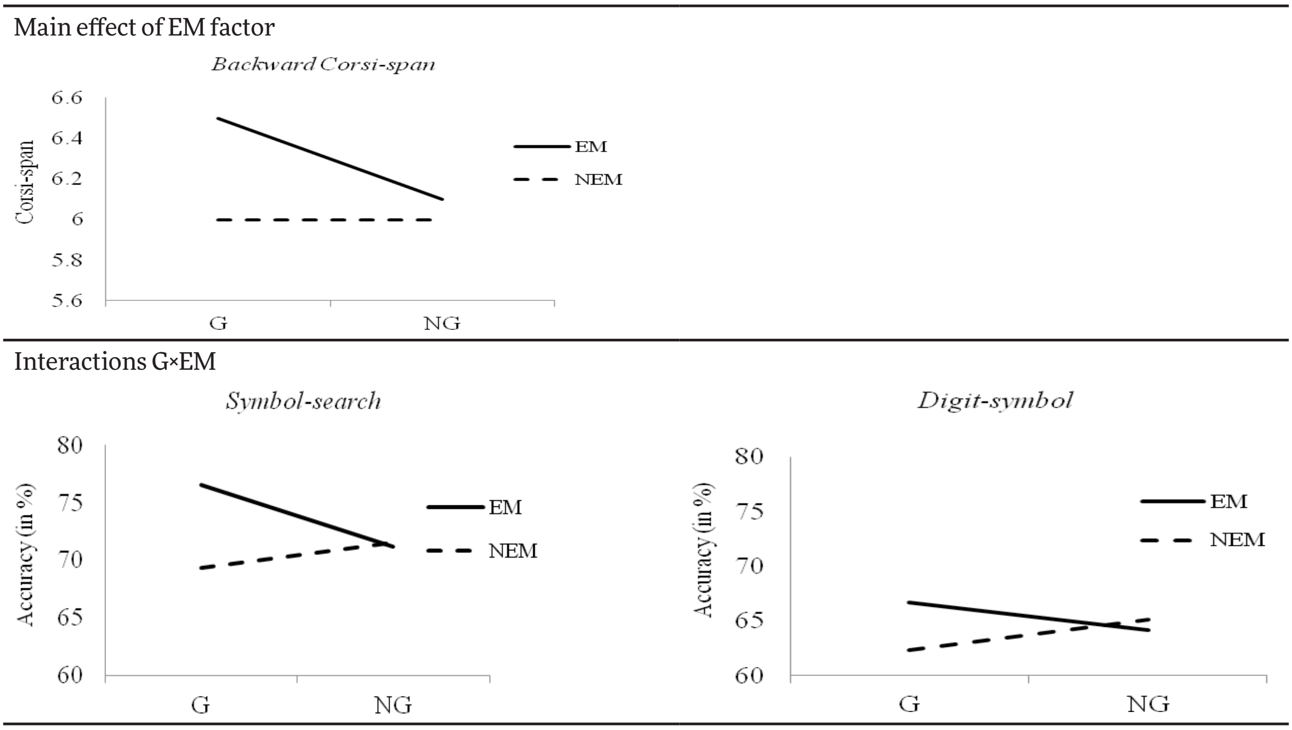

Figure 2: Significant main effects and interactions of G & EM factors on VP tests

that of NG students. It appears that gifted students are able to stay focussed on an assignment for a long time (elements of sustained attention) and are able to selectively attend to relevant stimuli while filtering out irrelevant stimuli in a rapid manner.

In summary, the present study generated data on the visual-processing abilities of adolescents, divided into four groups according to giftedness and excelling in mathematics. The study reveals that G and EM factors are different yet related mechanisms.

Assessing mathematically challenging problems

Demetra Pitta-Pantazi, Constantinos Christou, Maria Kattou, Paraskevi Sophocleous and Marios Pittalis

University of Cyprus, Department of Education, Nicosia, Cyprus, dpitta@ucy.ac.cy

The aim of this article was twofold. First, to propose a model for assessing mathematical challenging problems and second, to investigate the abilities of a group of in-service teachers to propose mathematically challenging problems based on the model suggested. The results indicated that mathematical challenging tasks may be characterised as those that are cognitively demanding and also require from students to develop other key competences: digital, social, communication in mother tongue, learning to learn and sense of initiative. About half of the participants of this study were able to provide mathematically cognitively demanding tasks which encompassed at least three of the other key competences. Participants appeared to find most difficult to incorporate in their mathematical tasks the "digital competence" and "learning to learn".

Keywords: Challenging tasks, key competences.

INTRODUCTION

Mathematical tasks are considered to be in the core of student mathematics learning because they "convey messages about what mathematics is and what doing mathematics entails" (NCTM, 1991, p. 24). Different types of tasks may potentially influence students learning, thinking and understanding of mathematics in a different way (Henningsen & Stein, 1997; Kilpatrick, Swafford, & Findell, 2001). For low cognitive demand mathematics tasks, the emphasis is on practicing and repetition of known facts and procedures. In contrast, high cognitive/ challenging mathematics tasks require understanding and extending concepts (Hsu, 2013). In recent years the emphasis of mathematics education has turned towards teaching challenging cognitive demanding tasks, given that "Challenge is not only an important component of the learning process but also a vital skill for life" (Taylor, 2006, p. 2). International organizations stressed the importance of empowering students with key competences in order to be able to confront future challenges (e.g., European Parliament and Council, 2006).

The Professional Standards for Teaching Mathematics (NCTM, 1991) claimed that students' learning depends to a great extent on the way that teachers develop and implement mathematical tasks in their instruction. Therefore, it is important for teachers to gain a coherent understanding of the importance of mathematical challenge in teaching and learning mathematics, and moreover to be able to choose, design and implement such tasks in their teaching (Applebaum & Leikin, 2014). The purpose of the present study is twofold; first, to propose a mathematically challenging problem assessment tool, and second, to examine in-service teachers' ability to design challenging mathematical problems.

THEORETICAL CONSIDERATIONS

Defining mathematical challenging tasks

The main characteristic of mathematical challenging tasks is the fact that the solver is not immediately aware of the procedures or algorithms that are critical for its solution (Applebaum & Leikin, 2014; Powell, Borge, Fioriti, Kondratieva, Koublanova, & Sukthankar, 2009). Therefore, solvers are required to attempt to find a solution based on their knowledge and understanding (Applebaum & Leikin, 2014; Powell et al., 2009). Moreover, Guberman and Leikin (2013) added other characteristics in the definition of mathematical challenge: the tasks should be neither too easy nor too difficult, and should engage students in meaningful scenarios that develop mathematical curiosity and motivate students to persevere with task completion.

The characteristics of challenging mathematical tasks make them suitable to cover a range of audiences and didactical situations (Powell et al., 2009). In particular, challenging mathematical tasks can be attempted successfully by students of various mathematical backgrounds for diagnostic purposes, for learning new concepts and procedures, for developing mathematical understanding, for formative and final assessment (Powell et al., 2009). Recent studies verified the importance of challenging mathematics tasks in teaching and learning mathematics. A number of researchers (Hiebert et al., 2005; Hsu, 2013; Powell et al., 2009; Silver, Mesa, Morris, Star, & Benken, 2009; Stein & Lane, 1996) underlined their potential to maintain curiosity, stimulate creativity, promote flexible thinking, encourage collaboration and exploration, allow communication, increase students' understanding, promote conceptual understanding of mathematics, develop problem solving and reasoning abilities.

Mathematical challenging tasks and key competences

The abovementioned characteristics are essential in a society that requires citizens to be flexible at workplace, to adapt quickly to constant changes in an increasingly interconnected world and to be innovative, productive and competitive (European Parliament and Council, 2006; Halász & Michel, 2011). Taking into consideration the declaration of the European Parliament and Council (2006) for adapting the educational systems to the demands of todays' society by empowering citizens with lifelong learning abilities, it could be supported that the design of challenging problems that develop these abilities are of great importance.

Contemporary documents made use of the term "key competences" to determine the cognitive elements, the functional aspects (involving technical skills) as well as the interpersonal attributes (social or organizational skills) and ethical values that are important for personal fulfillment, active citizenship and employability (Halász & Michel, 2011). In this framework the European Parliament and Council proposed six key competences (KC), which are of equally importance and also are interrelated, as they are defined below (European Parliament and Council, 2006; Halász & Michel, 2011). (a) *Communication in the mother tongue and communication in foreign languages*: The ability to understand, express and interpret procedures, concepts, ideas, thoughts, and feelings, in both written and oral form is fundamental to human interaction, (b) *Mathematical competences*: The ability to develop and apply mathematical thinking in an attempt to understand situations, to find explanations and to solve a range of problems in everyday situations, (c) *Digital competences:* The confident and critical use of information and communication technologies for the execution of educational, vocational and everyday work as well as for leisure and communication, (d) *Learning to learn:* The ability to pursue and organize the learning procedure of an individual or group, taking into account their needs and difficulties, the available time and information and the given opportunities and restrictions, (e) *Social, civic and cultural competences:* These competences embrace personal, interpersonal and intercultural aspects which equip individuals to engage in active and democratic participation in social and working life, (f) *Sense of initiative and entrepreneurship:* Creativity, innovation and risk-taking are among the characteristics that assist individuals to materialize their objectives.

These competences are anticipated to be acquired both by students at the end of compulsory education, as well as by adults through a process of developing and updating their skills (European Parliament and Council, 2006). Thus initial education should offer all students the opportunities to develop key competences in a sufficient level that will equip them for adult and working life (European Parliament and Council, 2006).

Designing mathematical challenging tasks

Despite the importance of mathematical challenging tasks, research has shown that it is not easy for teachers to design and implement such tasks in mathematics classrooms (Henningsen & Stein, 1997; Silver et al., 2009). The first barrier lies on teachers' pedagogical and content knowledge to design challenging tasks (Applebaum & Leikin, 2014). Teachers' content knowledge determines their understanding of the essence of mathematical challenge, their knowledge of challenging mathematics and their ability to approach challenging tasks (Applebaum & Leikin, 2014). As for the pedagogical knowledge, teachers' knowledge of the way that students cope with challenging mathematics, as well as different approaches and learning setting to teaching challenging mathematics are included (Applebaum & Leikin, 2014). Secondly, teachers find it difficult to design tasks that have a rich mathematical content, either by incorporating different mathematics topics and ideas or by demanding high cognitive effort (Silver et al., 2009; Stigler & Hiebert, 1999). In particular, in a study conducted by Silver and colleagues (2009) 84% of the activities designed by teachers focused on a single mathematics topic area rather than on multiple topics. Only 1 out of 3 activities was classified as a high-demand task, since teachers had difficulties to incorporate requirements for inquiry or explanations.

An important dimension of teachers' work is to find and/or adapt tasks. Additionally, it is extremely important to evaluate whether a task is appropriate for a particular student, from various perspectives (level of difficulty, interest, prior knowledge) (Guberman & Leikin, 2013). Moreover during employing the tasks in their instruction, teachers have to decide what they want students to achieve, what they need to emphasize, how to sequence the various activities and in what way to support students without reducing the challenge (NCTM, 1991; Vale & Pimentel, 2011). Hence, it is apparent that by providing teachers with ready-to-use challenging mathematical tasks is not sufficient for their implementation. Teachers need to be convinced about the importance of mathematical challenge and develop abilities to deal with such kind of mathematics (Applebaum & Leikin, 2014).

Another issue that appears to be surfacing is the definition of a "mathematical challenging task" in today's society. Is it simply a task that offers a certain level of mathematical, cognitive challenge to students or should it encompass other competences? Thus, the aim of the study was twofold: first, to suggest a model for assessing mathematically challenging problems, and secondly, to investigate whether in-service teachers who participated in a post-graduate problem solving course could develop mathematical challenging problems that promote key competences.

METHODOLOGY

Participants, procedure and data collection

The research was conducted at the University of Cyprus with 29 post-graduate students (PGs), who were studying for an MA in Mathematics Education, during their Problem Solving Course. In this course, ideas arising from the Research Project KeyCoMath were utilized. Twenty three of the PGs had a BA in Primary Education, and six had a BSc in Mathematics.

The postgraduate course on Problem Solving was organized in 13 three-hour seminars (a seminar per week). During the course students worked on the following topics: (a) Mathematical problems and problem solving: Definitions, stages and strategies in problem solving, different types of problems, factors that affect problem solving abilities, (b) Modeling problems: description, modeling principles, modeling perspective vs problem solving perspective, assessment of modeling, (c) Problems in international competitions (PISA and TIMSS), (d) Problem posing, (e) Teaching approaches for the development of problem solving skills, (f) Inquiry-based learning and problem-based learning, (g) Teachers role during problem solving, and (h) Key competences in mathematics education.

One of the assignments that the students had to do, for the fulfillment of the requirements of the course, was to work either individually or in groups (of 2 or 3 people) and develop four challenging mathematical problems which would also promote key competences. Moreover students had to identify how key competences can be developed through these challenging problems.

Data analysis

In the present study we propose a methodological tool to examine the extent to which a problem could be considered as a challenging one. To do so, we synthesize different theoretical approaches. For instance, Silver and his colleagues (2009) adopted frameworks that were used to distinguish levels of demands in mathematical tasks (see Kilpatrick, Swafford, & Findel, 2001) and proposed criteria for coding activities as high or low demand. In addition, a number of organizations (see European Parliament and Council, 2006) assert that students should develop key competences to meet contemporary society needs. Table 1, presents thoroughly the set of criteria that compose our proposed assessment tool. Based on the adopted frameworks, we propose that a problem could be classified as a challenging one if it required high mathematical cognitive demand and involved at least three out of the five examined key competences.

The first assessment criterion is concerned with the problem's potential to develop student's mathematical competence. Taking into consideration Silver's framework (2009), it was decided that a problem could be characterized as a "mathematical high cognitive demand", if it explicitly required students to explain, describe, justify, compare, make decisions, plan, formulate questions or be creative in some way (Silver et al., 2009). On the contrary, a "mathematical low cognitive demand" problem requires merely routine applications of known procedures, extremely guided structure or challenging on non-mathematical issues.

The second criterion of our framework relates to the extent to which a problem provides opportunities to develop student's digital competence. A problem would be classified as a high digital competence task if it explicitly required the use of a digital device to search, collect or analyze data, support critical thinking, creativity or innovation. No-use, unclear mention to the use of digital media or use of technology solely for executing computations were classified as low digital competence. The third key competence criterion involves social competence. A problem would be classified as high social competence task if required students' involvement in communicating with others, to work collaboratively, to understand, share and reinforce other's ideas. Problems that did not require group working or peer interaction were classified as low social competence tasks. Communication in mother tongue was interpreted as the ability to express and interpret concepts and present with clarity and accuracy their mathematical ideas. Thus, a problem would be classified as high in communicating in mother/mathematical tongue, if it asked students to present, justify or convince regarding their solution or explain the way in which they used mathematical language to interpret the problem. The key competence learning to learn was defined as student's awareness of his/her learning process and the ability to build on previous learning experiences to transfer knowledge in a new context. Thus, a high demand learning to learn task required the use of reflective tools, such as explicit description of the solution plan, or the extension of the proposed solution to a different context. Finally, the key competence initiative was conceptualized as student's initiative to take decisions, propose creative ideas, risk-taking in planning and managing steps in the solving procedure. In this sense, the assessment criterion for high initiative key competence included the engagement of students in taking decision, planning or evaluating situation, the existence of multiple solutions or solving plans. This would require students to turn their ideas into actions by judging the risk of each solution plan or by applying creative ideas. On the contrary, an ill-define problem or extremely guided one would be classified as low initiative.

Two researchers were independently assigned to rate each task using the abovementioned criteria. There was near unanimity in this coding, and wherever there was any disagreement this was discussed until consensus was reached.

RESULTS

Table 2, presents the classification of the problems proposed by the students based on the assessment model described above. In particular, 37 out of 57 problems were classified as high demand mathematical cognitive competence. They required students

Mathematical competence	Digital competence	Social competence	Communication in mother tongue	Learning to learn	Initiative
Low					
Routine applications, extremely guided, imposed solution	No-use, unclear mention	Absence of effective interaction, no tolerance to other ideas	No use of mathematical language, poor expression of ideas, insufficient data or without different forms of data (verbal, graphical, symbolic)	No use of reflective questions or potential of transferring knowledge	Ill-structure problems or extremely guided
High					
Explain, describe, justify, make decisions, plan, analysis, investigate, explore	Explicit and effective use of digital device to search or analyze data	Constructive communication, group working, respect to other ideas	Express and interpret concepts, thoughts and facts in oral and written form, proper use of mathematical language, flexible use of different representations	Reflective tools and questions, transfer of knowledge to new contexts	Initiative to take decisions, creativity, risk-taking, plan and manage solution

Table 1: Description of assessment criteria

to investigate real life situations, use and connect different mathematical concepts, processes and relationships. The majority of them were decision-making problems. Four problems required from students to decide which the best monthly payment plan was, based on the advertisement of four communication companies. To do so, it was required to mathematize the problem by (i) suggesting a mathematical model for evaluating the monthly cost based on the offers of the companies, (ii) proposing the cheaper package that meets specific needs or (iii) proposing the best package for a person based on the statements of his account. Another problem required from students to propose the cheaper heating option, by taking into consideration the dimensions of a flat. Another interesting problem involved finding the best wine list for a cellar shop based on real costs, promotion costs, sale costs, delivery costs and people preferences. Two groups of teachers used football scenarios. They asked students to predict the winner of World Cup 2014 in Brazil, by proposing a mathematical model that takes into consideration several parameters. A second group of high cognitive demand mathematical problems required the analysis of a situation and the design of a system for a specific goal. For instance, students were asked to design a camping place and a car park.

Twenty out of the 57 problems were classified as low cognitive demand because they simply asked students to apply known procedures. A number of low demand problems asked students to solve open problems, without providing adequate data or their questions did not involve mathematical procedures or calculation (e.g., to describe the recipe for a birthday cake).

The results of the study showed that only 11 mathematical problems gave opportunities to develop students' digital competence. In particular, eight of these problems asked students to analyse, find connections and evaluate data given in spreadsheets or in specific links. For example, a problem required students to use the data provided in a spreadsheet regarding the population of Cyprus and Japan and use the tools of the software to find which of the two countries has the greater aging population problem. Another problem asked students to search on internet about the data of runners participated in the Olympic Games in London and the World Championship Athletics 2014 and to propose the four best runners of the last years. The rest of the high digital competence problems required students to find the solution to the problem by using software. For instance, a problem asked students to use a dynamic geometry software to design the floor plan of a library, by taking into consideration the dimensions of furniture that were provided in a spreadsheet.

The majority of the proposed problems provided opportunities to develop students' social competence. In particular, 53 out of the 57 problems required students to work in groups, collaborate and communicate for the solution of the problems. Some problems required job assignment, so that all members could work constructively. Problems also included instructions regarding tolerance and respect to everybody's ideas. The four low social competence problems did not make any reference on group work or communication among group members.

Almost half of the problems (28) provided opportunities to develop communication in mother tongue. They required students to use accurate and concrete mathematical language, to express and explain their ideas both in written and oral form and to utilise different representations. For instance, a problem asked students to design a poster for presenting their solution to their peers. Other problems asked students to use graphs and convincing arguments to support their suggestion. The remaining 29 problems were classified as low social competence because they did not involve accurate use of mathematical language or utilisation of different representations.

Only 20 out of the 57 problems could promote "learning to learn". In these problems participants included reflection tools (see Figure 1) or they required to extend the solution method in a new situation (e.g., after

	Math. competence	Digital competence	Social competence	Communication in mother tongue	Learning to learn	Initiative	**Challenging Problems**
Low	20	46	4	29	37	22	30
High	37	11	53	28	20	35	27

Table 2: Classification of problems

developing a model to select the most effective lights for University lecture theatre students were asked to extend their model to adapt in any room's light). On the contrary, the rest of the problems did not include reflection tools or any extension questions.

About half of the problems (35 out of the 57) provided opportunities to develop students' sense of initiative. In particular, these problems required the construction of a mathematical model and the assignment of weights to the various criteria used in this model. For instance, a problem asked students to select the best three Universities for a prospective student based on specific criteria. To do so, it was required to assign weight to a set of criteria, such as the ranking of the university, the distance from home, the number of amenities, the distance from the airport and availability of free wi-fi. Twenty two problems were rated as low initiative, due to the fact that they were extremely structured or they were too open and ill-defined.

Work in groups to solve the following problem. It is important to listen carefully to the ideas of your peers and collaborate in a constructive manner. A family searches for available flats to rent. As Mr. Antoniou mentioned they can afford a monthly rent up to 620 euro. Mr. Antoniou works in an accountancy firm, while Mrs. Antoniou is unemployed. They want to live in Latsia (area in Nicosia, Cyprus), since the children's school is in this area. Use the data provided in the spreadsheet (dimensions, area, age, rent, etc.) and the map from Google earth to decide the best option for the family to rent. Explain your answer by using words, symbols, tables or graphs. Once you have solved the problem, answer the following questions: (1) Write the mathematical concepts and processes you used in solving the problem, (2) Draw a diagram to show the changes in group thinking during the solution process, (3) Can the proposed model be used by another family? Explain, and (4) How difficult did you find this task? Explain.

Figure 1: An example of challenging mathematical problem
