2 Dortmund, Germany

Each second year, the European Society for Research in Mathematics Education (ERME) organises a conference. The 9th Congress of ERME (CERME9) took place in Prague (Czech Republic), 4–8 February 2015. A detailed report on this conference and brief remarks on further ERME activities can be found in Krainer and Vondrová (2015) who acted as the Chair of the International Programme Committee (IPC) and the Chair of the Local Organising Committee (LOC) of this conference.

It is clear per definition that CERMEs are "European", however, we are happy to welcome colleagues from all parts of the world. CERME9 was attended by 672 people from 49 countries from all over the world. With these figures, CERME9 was the largest CERME ever. This number of participants was significantly higher than what had been anticipated. Nada Vondrová, LOC chair, and all the members of the local organising committee managed to host in very good conditions all the participants. We received a great number of testimonies from participants expressing their high satisfaction for the scientific programme and the local organisation.

The programme comprised three content-related plenary activities: (a) a plenary panel on "What do we mean by cultural contexts in European Research in Mathematics Education?", held by Barbara Jaworski, Mariolina Bartolini Bussi, Edyta Nowinska, and Susanne Prediger; (b) a plenary lecture on "Research in teacher education and innovation at schools – Cooperation, competition or two separate worlds?" by Jarmila Novotná; and (c) a plenary lecture on "Understanding randomness: Challenges for research and teaching" by Carmen Batanero. The plenary lectures contributed substantially to the success of the conference.

Of central importance for each CERME are the Thematic Working Groups (TWGs). At CERME9, due to the huge number of 436 research reports and 106 posters that were accepted, 20 TWGs needed to be implemented. All TWG leaders and their co-leaders (from 23 countries) did a great job before, during, and after the conference. Among them, five acted at CERME9 their third time as a TWG leader which means that they need to be substituted according to the ERME rules for CERME10: Jeremy Hodgen, Uffe Thomas Jankvist (who also acted as the Vice-chair of IPC), Roza Leikin, Elena Nardi, and Jana Trgalova.

In particular, the presence of societies like EMS (President Pavel Exner), its Education Committee (Chair Günter Törner) and ICMI (former President Michèle Artigue), gave the conference a special flavour, as well as interesting excursions and splendid classical music during the opening and closing ceremony produced by students of the Faculty of Education, the host of CERME9.

CERME9 shows also considerable innovations regarding the organisation of the proceedings. Following a decision of the ERME Board, there will be posted on the HAL database. This will be a very valuable evolution serving the dissemination of our works for CERME9, and for the next CERME conferences. On behalf of the ERME Board and all the ERME community we address many thanks to the editors, Konrad Krainer and Nada Vondrová, for this huge work.

Although these proceedings do not contain any document related to it, let us mention another fundamental event that took place one day before the opening of the Congress: the YERME (Young European Researchers in Mathematics Education) day. This is now a constant appointment where young researchers – doctoral students or post-doctoral researchers - meet expert scholars in thematic discussion groups. At CERME9 the organization of the YERME day was coordinated by João Pedro da Ponte (Chair of the programme committee) and Jarmila Novotná, chair of the local organising committee. The activities were led by Paolo Boero, Rita Borromeo-Ferri, Uffe Thomas Jankvist, Esther Levenson, Despina Potari, Susanne Prediger, Cristina Sabena, Mario Sánchez, Susanne Schnell.

Without the deep involvement of its members, ERME and CERME will not exist. Each CERME conference represents a challenge that was successfully achieved by all involved people, but especially by Konrad Krainer, Chair of the IPC, and Nada Vondrová chair of the LOC. We address sincere thanks to both for the incredible work they have done in preparing and supervising the organisation of the conference, and the editing of the proceedings. We extend our thanks to Uffe Thomas Jankvist and Jarmila Novotná respectively co-chair of the IPC and of the LOC, to all the IPC members and to all the local organisers for their hard work, and to the Charles University in Prague, for making us so welcome.

We encourage interested researchers to meet us at the next CERME that will take place in February 2017, in Dublin (Ireland).

The proceedings which the reader just opens is a shared product of many people, beginning with the authors of plenaries and papers from Thematic Working Groups (TWGs), the TWG leaders, and ending with the two editors.

So far, the process of editing CERME proceedings has not been openly discussed and the editors of previous proceedings approached the task differently. In order to take a step forward, we decided to describe the process here in a more detailed way, in particular highlighting innovations. This might allow the new editors for CERME10 to follow in our steps and improve the process further.

The work on the proceedings of CERME9 started immediately after the conference itself in February 2015. Already some weeks before CERME9, all TWGs presentations as well as abstracts of all plenary presentations had been available on the conference website as a kind of pre-conference proceedings. Then, the authors of TWG contributions were advised to elaborate their papers in order to meet the standard of proceedings papers of CERME, in particular, taking into account feedback they received during CERME9. In the next stage, the TWG leaders evaluated all the papers and posters and negotiated any necessary changes with the authors. This stage ended by sending the papers as complete bundles to the two editors, including letters of consent that the papers can be published in the Hall database (see below).

The proceedings consist of two main parts. The first part includes the texts of invited plenary activities, that is, the two plenary lectures and the plenary panel. There was no review process as such, but the editors commented on the papers (see below). The main part of the proceedings consists of 20 "chapters", each of them devoted to one TWG. Each chapter starts with a short introduction written by TWG leaders. In the cases of TWG09 and TWG20, the leaders responded to our call for a special kind of introduction, which is more than a short text about the papers in the TWG and a brief summary. Their introduction is rather a research paper on the advances in the topic of the TWG, however, relating it also to the developments in this field besides CERMEs.

The research reports and posters following the introduction are ordered alphabetically. All reports were reviewed twice. Prior to the conference, the papers were peer reviewed by authors from the same TWG and by at least one TWG leader. After the conference, the papers were reviewed again. TWG leaders and co-leaders acted, in fact, as chapter editors for the proceedings. They were responsible for checking the quality of the papers. Papers include accepted research papers (with a maximum of 10 pages in the original template) as well as summaries of accepted posters or short versions of not-accepted research papers (both with a maximum of 2 pages in the original template). The goal was to have all discussed papers and posters in the proceedings, if their quality allows. It was up to the TWG leaders to decide whether the final acceptance of the paper is done by them and co-leaders only, or whether people from the TWGs (e.g., former reviewers or new ones) are asked to help.[1] If the TWG leaders were unsure about the quality of the paper, they could ask the TWG liaisons in the IPC for help with the decision (before communication with the authors again), or the editors directly (this happened in two cases only).

1 For instance, when the modifications were major and the original reviewer should check them, or when the original reviewers did not agree on their decision, a different reviewer could see the modified version of the paper after the conference.

a) Editorial process for the plenary contributions

The texts for two plenaries and one panel were read and commented on by both editors. The comments were sent to the authors and they considered them. This process repeated until the editors and authors agreed that the papers were in good shape to be included in the proceedings.

b) Editorial process for the TWG introductory texts

The common CERME introductory texts were read by the two editors in order to check for any inconsistencies. The two special introductions were peer reviewed by both editors and by the leader of the second piloting TWG. The aim was to do a first systematic attempt to have all content-related texts in the proceedings (also introductions to TWGs) as research papers. This might help readers to better range the work of a TWG in the international context, might offer TWG leaders a second opportunity for a peer-reviewed paper, and, of course, contributes to raising the quality of CERME proceedings.

c) Editorial process for research papers and posters

All the files of research papers and posters were gone through by the two editors in the following way: The abstract and keywords were read in full and the rest of the text was scanned in order to see whether the language and content seemed to be on a good level. Only two papers had to be sent to their authors again to be proofread and several posters were sent to their authors so that they included an abstract and keywords. Then, the list of references were scanned in order to see whether the APA style was kept by the authors. We have to mention that there were several challenges in this area. Several papers had to be sent back to their authors to improve the literature as bibliography items missed a lot of information such as pages, editors, publisher, place of publishing. There were even problems with the name of the journal or the source document, etc. When it was possible, the editors made the changes themselves. However, the whole process was very time-consuming and finally, the editors had to give up on polishing the bibliography sections of papers and thus the APA style is not totally followed (but it is always clear what the bibliography item refers to).

After that, the approved texts were sent to the typographer (who had made a suggestion for the layout of the proceedings previously). This time we went, hopefully, for a more professional look of the proceedings, different from the mere saving of Word files into pdfs. Of course, it meant more work for the typographer, editors and also TWG leaders.

Each chapter of the proceedings related to TWGs underwent several rounds of proofreading. When the pdf files were made by the typographer, the two editors scanned the files for any typographic errors, inconsistencies (e.g., in the numbering of figures, fonts used for different parts of the text) and problems possibly caused by the transfer of the file into pdf. These changes were sent to the typographer who prepared the second version of the text which was sent to the TWG leader. His/her task was to check the files for the TWG chapter again: whether all papers were included and in the appropriate (alphabetical) order and none was omitted, whether, by mistake, some table or figure or mathematics formula disappeared and any other issue which might draw his/her attention. After their comments were taken into account by the typographer, the pre-final version was checked by the editors again.

The process was similar for the plenary texts.

The proceedings of CERME9 will be the first ones to be uploaded to Hal archive website https://hal.archives-ouvertes.fr. The ERME Board made this decision in order for proceedings to be openly available, easily searchable and downloadable and overall, more visible. It is assumed that all new proceedings will be put on the same website so that they are not in different places and elaborated in different ways. Some previous proceedings are downloadable as separate files only, some as a complete file. The Hall database enables both options. That is, the papers can be organised according to the TWGs (chapters) but can also be downloaded as separate files.

We wish the readers a pleasant journey through the ideas raised at CERME9. We thank all people mentioned above greatly contributing to these proceedings!

Plenary lectures

Cultural contexts for European research and design practices in Mathematics Education

DEDICATION

Our young friends Mustafa Alpaslan and Zişan Güner Alpaslan passed away in a terrible car accident on July 31, 2015. Both were in CERME9: Mustafa in TWG12 (History of Mathematics Education) and his wife Zişan in TWG13 (Early Years Mathematics). They both were brilliant researchers and active members of the ERME community. In CERME9, Mustafa was elected as a representative of young researchers in the ERME Board. Mustafa took part in the preparation of this panel: We enjoyed his background in history of mathematics and his deep knowledge of the history of Turkish Mathematics Education, that made him very sensitive to the issue of cultural contexts. This text is dedicated to both of them.

The authors and guest-authors of this contribution worked together to prepare a plenary panel at CERME9. Starting from acknowledging the diversity of cultural contexts in which we work, the following questions are addressed:

- *What do we mean by cultural contexts in European Research in Mathematics Education?*
- *How do cultural influences challenge the universality of research and design practices and their outcomes?*
- *Which (hidden) values in different cultural contexts influence research and design practices?*
- *How could cultural awareness among Mathematics Education researchers be raised?*

The authors give concrete examples of cultural differences and their impact on research and design practices in Mathematics Education. They address various cultural contexts, covering mathematics, classrooms, research community contexts and international comparisons. The centrality and nature of theories in addressing mathematics educational context are also discussed. Young researchers as guest-authors contribute further experiences and reflections. The joint reflection offers multiple suggestions for raising cultural awareness in Mathematics Education research and design practices and policy issues.

Keywords: differences in cultural contexts, research practices, theoretical approaches as epistemic cultures, raising cultural awareness.

1. INTRODUCTION

While approaching the complex topic of cultural contexts and their impacts on research and design practices, we addressed four main questions:

- What do we mean by cultural contexts in European Research in Mathematics Education?
- How do cultural influences challenge the universality of research and design practices and their outcomes?
- Which (hidden) values in different cultural contexts influence research and design practices?
- How could cultural awareness among Mathematics Education researchers be raised?

We have settled on three themes as a focus for our input and subsequent discussion, presented respectively by Maria G. Bartolini Bussi, Barbara Jaworski and Susanne Prediger. These are:

1) Mathematics and Mathematics Education; how we analyse mathematical concepts; how these ways of explaining and analysing mathematical concepts can be developed for the curriculum and influence the curriculum.

2) Classrooms, teachers and students – how the cultures which underpin interaction and communication, and the use of language, enable or restrict attention to classroom approaches to mathematics, ways of conducting research and the ethical and moral principles in Mathematics Education.

3) Research approaches and theoretical perspectives, and ways in which they underpin research interpretations, the ways in which research findings emerge in research communities and are presented in published works.

We also include reflections from a group of young researchers: Annica Andersson, Mustafa Alpaslan, Edyta Nowinska and Marta Pytlak; represented in the panel and in this writing by Edyta Nowinska.

Section 2 addresses the three themes. In Section 3 we have the reflections of the young researchers. Section 4 presents a synthesis of ideas, looking backwards and then forwards towards taking up cultural issues and in Section 5 we offer questions for our ongoing practices as mathematics educators.

2. MEETING CULTURAL DIFFERENCES ON DIFFERENT LEVELS – THREE THEMES

2.1 Mathematics in cultural contexts (Maria G. Bartolini Bussi)

Every thought, when coming towards the other, questions itself about its own unthought.

(Jullien, 2006, p. vi)

2.1.1 Introduction

The mathematics developed in the West by professional mathematicians is, in some sense, *near-universal* (see Barton, 2009, who introduced the acronym NUC, that is Near-Universal Conventional mathematics, p. 10). This mathematics had become dominant all over the world, mainly for its century old effective applications to the development of science and technology. Nevertheless, the process of *mathematical enculturation* (Bishop, 1988) is, at least at the beginning, strongly dependent on the local context (often, although not always, identified with a country or a region where a language is spoken). Yet, sometimes people are so embedded in their own context as to ignore that in other contexts the "same" mathematical objects (yet, are these objects really the same?) might have had a different history and might convey even different meanings. It is only when, for some reasons, one is forced to exit her safe "niche" that she may become aware of that. There is a very positive feature in such a dialogue: "every thought, when coming towards the other, questions itself about its own unthought" as strongly claims Jullien (2006, p. vi) in his beautiful discussion of Chinese and European-Greek cultures. This awareness encourages the exploration of the geography and history of mathematical thinking (Bartolini Bussi, Baccaglini, & Ramploud, 2014).

2.1.2 First example: Whole numbers

My first example focuses on some aspects of whole numbers. This choice seems provocative: are there things more universal than numbers, at least small whole numbers, when we move from one context to another, from one language to another?

There is an extended classical literature on the history of numbers (e.g., Menninger, 1969; Ifrah, 1985) and on the use of numbers in far contexts, where, for instance, the body parts are used to represent whole numbers (Saxe, 2014) or spatial arrangements substitute the lack of number words in complex arithmetical calculations (Butterworth & Reeve, 2008).

Moreover, Barton (2009) tells the story of the verbal roles of number words in Maori.

> In Maori, prior to European contact, numbers in everyday talk were like actions. [...] Our awareness of this old Maori grammar of number suddenly sharpened when we tried to negate sentences that used numbers. [...] To negate a verb in Maori the word *kaore* is used. [...] Unlike English, where negating both verbs and adjectives requires the word 'not', in Maori, to negate an adjective a different word is used, *ehara*. (Barton, 2009, p. 5)

In Maori language to negate the sentences “there is a big house” and “there are four hills” two different wording of “not” are used. When this verbal feature of Maori numbers was ignored, the mathematics vocabulary process, translated from English, acted against the original ethos of the Maori language.

One might think that these examples are relevant only for historians or anthropologists or ethnomathematicians, but the pragmatic use of numbers in everyday communication offers some surprising evidence in familiar languages too.

There are examples (in many languages) where expressions with numbers are used to denote indefinite quantities. Bazzanella, Pugliese, and Strudsholm (2011) analyse translation problems between different languages. For instance, the Italian expression “Do you want two spaghetti?”, that does not mean exactly “two” but “a few”, might produce very funny episodes, in spoken communication between an Italian host and a not Italian guest, with the latter puzzled by the idea of eating exactly “two spaghetti” for dinner. In this case, the number is used in indeterminate or vague meaning. In other cases, what is focused is the starting point of the measuring process: for instance, an Italian speaker says “8 days” or “15 days” to mean one week or two weeks (e.g., “8 days from today” means “a week from today”). Actually in Italy a week is 7 days like everywhere, but, in similar expressions, it seems that today (the “zero” day) is counted.

Philosophers studied *vagueness* since antiquity. More recently, Black (1937) transferred the philosophical attention on vagueness to human language and Quine (1960) introduced his famous *principle of indeterminacy* of translation:

> There is no need to insist that the native word can be equated outright to any one English word or phrase. Certain contexts may be specified in which the word is to be translated one way and others in which the word is to be translated in another way (Quine, 1960, p. 69).

Humans do not really need to be precise in every situation and use vagueness and indeterminacy in thinking and communication, but are not always aware of that. It is worthwhile to reflect on the vague meanings of whole numbers that depend on the cultural context, for the importance they might have in the educational setting.

From the perspective of a mathematics teacher: is the everyday use of vague numbers consistent with the use of numbers in the mathematics classroom (e.g., just half a glass, please)? What about different utterances in the mathematics classroom, when the focus shifts from communication (“Be attentive for two minutes, please!”) to an arithmetic statement (“two times ten is twenty”)? What about multicultural classrooms where translation issues are interlaced with mathematical issues? Might vagueness foster or inhibit the construction of number meanings?

From the perspective of a researcher in Mathematics Education, is vagueness to be taken into account, as a tool, by researchers in studies on arithmetic teaching and learning in the mathematics classroom? Is the presence of either precise or vague meaning of numbers related to the development of the two core systems described by neuropsychologists for representing either small numbers of individual objects in a precise way or magnitudes in an approximate way (Feigenson et al., 2004)?

Some observation may be made also about curriculum development, when a cultural lens is used. We refer to two very recent “twin” papers prepared for the panel on “Traditions in Whole Numbers Arithmetic”, to be held on the occasion of the “Primary School Study on Whole Numbers” (the 23rd ICMI Study, Macau, China, June 3–7, 2015). They are authored by Bartolini Bussi (2015) and Sun (2015) and address very popular approaches to whole numbers in the West and in China.

Sun (2015) reconstructs the ancient Chinese tradition of whole number arithmetic and its strong connection with today’s curriculum. She emphasizes both linguistic and historic-epistemological perspectives. From the linguistic perspective, Sun’s paper reads (p. 141):

> Unlike English and most Indo-European languages, written Chinese is logographic rather than alphabetic, and uses the radical (“section header”) as the basic writing unit. Most (80–90%) of characters are phono-semantic compounds, combining a semantic radical with a phonetic radical. *Thus, the large majority of words have a compound, or part-part-whole structure. This differs from the phonetically based structure of writing in most*

> *Western languages, in which order is more important than the combination of parts* (my emphasis).

Then Sun mentions "classifiers" or measure units, which, as in many East Asian languages, are required when using numerals with nouns (spoken numbers). In Chinese, each type of object that is counted has a particular classifier associated with it. As a weakening of this rule, today it is often acceptable to use the generic classifier "ones" in place of a more specific classifier. As a character, "ones" (classifier) is pronounced *gè* and written 个 which represents a bamboo shoot. This feature highlights the focus on separate units since the ancient ages in China to present days.

Mathematics in ancient China was identified with arithmetic and numbers, and, in particular, with calculation[1]. To calculate with whole numbers in China, straight rods (also named counting sticks) were used 2500 years ago and influenced the early representation of digits (see Figure 1). The rods had square cross sections to prevent them from rolling and were carried in hexagonal bundles (Figure 2) consisting of 271 pieces with 9 rods on each edge (Lam & Ang, 2004, p. 44, see Figure 3): whenever calculation was needed, they were brought out and computation was performed on a flat surface.

Figure 2 shows the structure of the bundles of rod numerals and appears in ancient pottery. The photograph in Figure 3 was taken by the author in Banpo, a neolithic settlement close to Xi'an, dating back 5600–6700 years, and shows a fragment of a potsherd. The explanation reads: "This potsherd makes the concept of point and surface, number and shape together. It proves Banpo ancestors have certain knowledge of mathematics."

This focus on numbers as discrete quantities has remained in the tradition of teaching arithmetic. Even today, Chinese spoken numerals are the following:

> Chinese spoken numerals (and English literal translation):
>
> 一个、二个、…
> One ones, two ones, ...
>
> 一十一个、一十二个、…
> one tens & one ones, one tens & two ones, ...
>
> 二十个，二十一个…
> two tens, two tens & one...

The tools for calculation in ancient China were rods or, later, *suànpán*, the Chinese abacus. Drawing on both tools, spoken numerals are transparent for place value. Actually, place value was (and still is) considered an overarching principle for whole number arithmetic. No specific chapter on place value appears in Chinese textbooks, as place value representation is the only way to approach numbers in language, in written representation and calculation practice. Finally, Sun concludes:

> By comparison, if the number concept is represented by the number line, used with calculations by counting up or down, or skip counting, the associativity of addition is developed less naturally than with the composition/decomposition model incorporated into the *suànpán* [...] The *suànpán* makes place value explicit, and the calculation procedures of combining ones with ones, tens with tens, and so forth, are built into its structure. The model for numbers provided by the *suànpán* may be contrasted with the number line, which is a continuous, non-digital model for numbers, and is not naturally connected with place value. (Sun, 2015, pp. 151–154)

One might contend that discrete quantities and figured numbers such as the ones in Figure 2 and Figure 3 were known and used in ancient Greece since the age of Euclid and earlier. But these figural representations of numbers did not show any connection with verbal and written representation of numbers in calculation at that age. Hence, place value came later (through the Arabic mediation) and had to fight against the practical ways of calculating by means of abacus as a famous picture shows (Menninger, 1969, p. 350).

As far as the number line is concerned, Bartolini Bussi (2015) reconstructs the origin of this number representation, dating back to Euclid and reconsidered in the 17th century when scholars such as Descartes

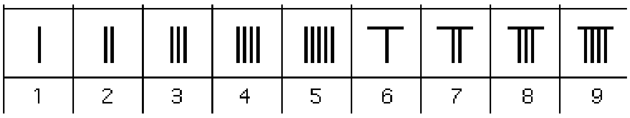

Figure 1: The first nine numerals from rods tradition

1 Actually, in Chinese 数学 (shùxué, i.e., mathematics) literally means "number study" whilst in Greek μάθημα (mathema) means "knowledge, what has to be learnt".

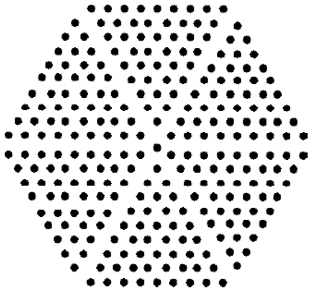

Figure 2: Cross-section of a hexagonal bundle of rods

Figure 3: A fragment in Banpo museum

and Wallis exploited the synergy between arithmetic and geometry. Euclid's use of straight line to represent numbers (in the Book 7 of the Elements, Heath, Vol. 2, p. 277 ff.) is interpreted by Netz (1999).

> Often the proof is about "any integer", a quantity floating freely through the entire space of integers, where it has no foothold, no barriers. [...] A dot representation implies a specific number, and therefore immediately gives rise to the problem of the generalisation from that particular to a general conclusion, from the finite to the infinite. Greek mathematicians need, therefore, a representation of a number which would come close to the modern variable. This variable [...] is the line itself. The line functions as a variable because nothing is known about the real size of the number it represents (Netz, 1999, p. 268).

This interpretation puts the number line into a Western cultural process, where the issue of variable, generality and proof are approached following Euclid's style.

We may conclude that rods and *suànpán* on the one hand and the number line on the other hand are cultural artefacts characterizing the Chinese and the Western curriculum. As cultural artefacts, they reveal valuable information about the society that made or used them and, when continuity between tradition and today's practices is maintained, foster the students' cultural awareness of the role mathematics played in their society. This was not always the case, in mathematics curricula, as the second example shows.

2.1.3 Second example: Fractions

The second example concerns the idea of fraction that appears in the language of everyday life, but is perceived as advanced and difficult in Mathematics Education. I have recently published with two colleagues (Bartolini Bussi et al., 2014) a short piece of speculation about the geography and the history of the idea of fraction. We observed that in most Eastern languages (Chinese, Japanese, Korean, Burmese and similar) fractions were written and are still read bottom up, i.e., reading first the denominator and then the numerator. This idea mirrors the genesis of fraction as a part of a whole: to know first in how many parts the whole has been broken and to tell later how many pieces one takes. This way of writing and reading fractions was presented also in the Liber abaci, the text, authored in Latin by Leonardo Fibonacci drawing on Arabic sources, that introduced into Europe the so-called Hindu-Arabic notation and written algorithms (Cajori, 1928, p. 269). It is still extant in some European languages developed in countries which were for centuries under the influence of Arabic and Persian culture (e.g., Turkey). Then the story of fraction names in the European languages diverged, going farther from the genesis and adopting a top-down writing and reading, with the additional puzzle of using ordinals for the denominator. A similar process happened in some Eastern countries (e.g., Myanmar) under the effects of colonialism that cut the roots with local traditions in schools.

From the perspective of a mathematics teacher: the awareness of the gap between the genesis and representation of fractions may possibly be used to support low achievers. Actually, the inversion of numerator and denominator and the use of cardinal numbers, based on the Chinese reading and writing ("three parts, take one!" "five parts, take two!") had an immediate positive effect on the performances of dyscalculic students in the task of quick positioning of a given fraction between 0 and 1 on a number line (Bartolini Bussi et al., 2014).

From the perspective of a curriculum developer: how do we consider the present trend of "imitating" Western curricula to innovate early schooling in many developing countries, when it cuts the roots with local languages and everyday experience, especially in those cases when the local language is closer to the genesis of the mathematical idea (see also Boero, 2013, pp. 25–26)?

2.1.4 Third example: Infinity and limit

The third example shortly refers to a recent study carried out by Kim, Ferrini-Mundy, and Sfard (2012) about students' colloquial and mathematical discourses on infinity and limit. The study involved large samples of USA and Korean undergraduate students. The findings of the study were interesting and the interpretation even more interesting. In a part of the study, the students were asked to create sentences with the words infinite and infinity (a separate sentence for each of these words). The two ethnic groups showed very different productions. In the USA group infinite was used in the context of real-life phenomena, whilst in the Korean group the context of the sentences was predominantly abstract and mathematical with a disconnection between colloquial and mathematical discourses on infinity. USA speakers produced processual sentences, whilst Korean speakers were more likely to produce structural sentences that are closer to formal mathematical discourse.

> In English, there is an obvious lexical continuity throughout all levels of infinity discourse. The principal link that keeps all kinds of English infinity talk together as a cohesive whole is the use of the single word infinite throughout all relevant themes and levels, and in both informal and formal versions of infinity discourse. [...] (Kim et al., 2012, p. 93).

In Korean, in contrast, there is a lexical rupture between levels. For instance, the Korean term for infinity (in everyday language) is taken from the Chinese *mu-su* (verbatim *numberlessness*) or *mu-gung* (verbatim *endlessness*), whilst the formal term (in mathematics) is taken from the Chinese *mu-han* (verbatim *boundlessness*). There is no emphasis on the shared part *mu* that means *none*. Hence, there is an evident break between everyday and mathematical terms (Kim et al., 2012).

It seems that English and, more generally, those European languages that were developed under the influence of the Greek thought, defined a path towards the mathematical idea of infinite and infinity (as it was constructed by mathematicians in the 19th century) that in some sense may model also the slow process of students from these cultures through the idea of potential and actual infinity. But this process is not likely to be the same for students coming from cultures where these ideas were developed only in schools (and not in everyday life), after and under the pressure of Western mathematics.

From the perspective of a researcher in Mathematics Education: have these findings the potential to question the faith in the "universal" validity of studies about the obstacles met by Western students in advanced mathematics?

2.1.5 Concluding remarks

In my contribution, I have considered only language to hint at the local culture and context. The examples contain arguments towards different and even opposite strategies for developing mathematics curricula: to exploit local languages and everyday experience with a slow transition from colloquial discourse to mathematical formal discourse versus to start from scratch ignoring the relationships between colloquial discourse and mathematical formal discourse. Is the difference related to the focus, i.e., elementary versus advanced mathematics? In all cases, however, it seems that considering the history and geography of mathematical thinking and the parallel development of language are essential for explaining and analysing the didactical phenomena to be considered in the design and implementation of mathematical curricula (Boero, 2013). Without this attention, it is likely that researchers from different contexts do not even understand each other and cannot exploit each other's findings (Bartolini Bussi & Martignone, 2013). This is one of the reasons why in the ongoing ICMI Study 23 (*Primary Study on Whole Numbers*, http://www.umac.mo/fed/ICMI23) a mandatory cover document about the context of each submitted paper was required in the Discussion Document. The papers which were submitted offered evidence not only of language differences (with strong effects on the arithmetic taught in primary school) but also of different societal norms, customs, institutional conditions, values and theoretical approaches, in one word, of different cultures.

In this section, I have offered mathematical examples, maybe strongly unexpected mathematical examples, as the audience's reaction showed in the panel and beyond. They question the idea of mathematics as a "universal language" or *lingua franca* of the modern world (Kim et al., 2012). In addition to general arguments about cultural relativism, mathematical examples offer a staggering evidence that cannot be ignored. They contribute to determine the contexts, the gap between them and the possibility/impossibility of easily transposing theories, findings and methodologies from one context to another, both in research and in classroom practice (Ramploud, 2015) against the naïve myth of "universality" of Mathematics Education research. In this case, it is the stunning difference that produces information.

The examples come from ethnomathematics, from the pragmatic use of numbers in everyday communication and from the comparison of mathematics curricula. In a more general way, examples may come from the curiosity about the history and geography of mathematical thinking. They concern both elementary and advanced mathematical thinking, with a potential conflict concerning continuity versus discontinuity between everyday and mathematical language. In particular, I challenge the presumed "universality" of number words and of mathematics language and, as a consequence, of theories, methodologies and findings in the studies on Mathematics Education.

2.2 Researchers, teachers, students in Mathematics Education and their values in cultural contexts (Barbara Jaworski)

The previous section (2.1) has pointed out that sometimes people are so embedded in their own context, the safe 'niche', as to ignore differences in other contexts. What seem like "the same" mathematical objects might have had a different history and might convey even different meanings. It is only when, for some reasons, someone is forced to exit her safe niche that she may become aware of that. The section focused on mathematics itself and the ways in which it is represented in writing and talking in differing cultures. Here, I take up this theme of the "safe niche" to look more broadly at context in mathematics learning, teaching and research in Mathematics Education to seek out cultural distinctions and anomalies. This will take us beyond mathematics itself into educational issues, particularly those that stem from the ways in which mathematics is regarded in education and society.

2.2.1 Introduction – who we are, and how this influences our work as Mathematics Education researchers

When we engage in research which involves human participants, we have *moral* and *ethical* responsibility towards our research participants (Pring, 2004). Pring writes:

> I shall argue that education itself is a moral practice ... Ideally the 'practice' should be in the hands of moral educators (who themselves should manifest the signs of moral development). (2004, p. 12)

As researchers in Mathematics Education, we are required to attend to ethical issues in our research. Pring (2004) goes further to suggest that we are tasked with a *moral* agenda where research in education is concerned. A question for us all is what such morality involves. For example, we need to be aware of the *values* we bring to interactions, decisions, interpretations and judgments (Bishop, 2001; Chin, Leu, & Lin, 2001), how they relate to mathematics itself, and how they fit with the cultures in which our research takes place. These cultures are manifested in our lives and work, the societies and systems of which we are a part.

As a *mathematics* educator, I have ways of seeing and arguing rooted in the mathematics which has formed a central part of my studies and professional life; this is likely to distinguish me from educators in other subjects or from scholars in the natural sciences or humanities. Mathematics itself has cultural resonances, related to moral questions and values within society, as I shall discuss further below. Indeed, Section 2.1 has drawn attention to many aspects of mathematics and how these vary across parts of the world. However, other cultures are also central to our activity. As a *researcher*, I belong to a different culture from that of a teacher I work with although we are both interested in the learning and teaching of mathematics – I have university and research values; the teacher has school and teaching values (Jaworski, 2008). Here, culture is related to where we work and the values associated with the job we do. My own values are theory-related, since an expectation of a university role is to engage with theory and research as well as the university as an institution; a teacher is concerned with school values, students' characteristics and needs, and societal and political demands such as examination results and league tables of 'effective' schools.

Being a teacher involves different expectations and values in different settings, particularly across national boundaries. Such differences are highlighted by a Finnish colleague, Kirsti Hemmi, who wrote to me as follows about her experiences as a teacher of mathematics in Finland and in Sweden:

> I was recruited to Sweden to teach Finnish speaking children in the beginning of [19]80s. Since then, over thirty years, I have worked in the cross-section of these two educational cultures and experienced and witnessed other teachers' similar experiences about the very different attitudes towards what it means to be a primary school teacher and towards what kind of skills and understanding we expect children to develop in reading, writing and mathematics during the first school years. In this work the different cultural-educational traditions really collided in various ways, not only through the Finnish and Swedish teachers' different educational backgrounds but also through the character of the teaching materials, especially in mathematics produced in these two countries. Sometimes the differences were concrete, sometimes they were hard to articulate. (Kirsti Hemmi, personal communication)

Kirsti Hemmi's words provide insight into differences between cultural settings where, more superficially, there might be expected to be common understandings and ways of interpreting educational issues. When we work as researchers across national boundaries, how we understand each other becomes central to the ways in which we undertake research. In a personal communication, Heidi Krzywacki (from Finland) wrote to me about her experiences of conducting professional development research in Peru, to provide new ideas about Mathematics Education and teacher education not common in the current educational reality in Peru. She writes:

> I have reflected on some issues related to language in international cooperation and development work that we have had with Peruvian partners for developing their education system. For example, it took a while to understand that we had no common apprehension of action research: for the Finnish partners it was used for referring to a methodological approach, but Peruvian partners interpreted it (after translation) as personal reflections.
> (Heidi Krzywacki, Personal Communication)

These words alert us to differences in perception that may be ignored, perhaps dangerously for the ensuing research, because the language of communication hides important subtleties of meaning. Since differences in practices and cultural values underpin what is possible in educational environments, researchers working in these environments must be alert to such differences and must factor them into a research study; not easy to achieve, and requiring awareness and sensitivity. In the next section, I offer further examples to highlight issues which arise from cultural norms, sensitivities and differing values.

2.2.2 Cultural contexts and their influence on how we think and behave

I start with examples from my own experience. I have worked as a teacher and as a researcher in several countries including Pakistan and Norway, where I come from a different culture (call it, rather superficially, a *British* culture) from the people in whose country I am working. In Norway, we share western ways of thinking and a Christian tradition, but there are differences, some subtle, but nevertheless important. One example, which I met very early in relationships with Norwegian colleagues, is the *Law of Jante*, created by the Dano-Norwegian author Aksel Sandemose (Sandemose, 1933/2005) – the idea that there is a pattern of group behaviour towards individuals within Scandinavian communities that negatively portrays and criticizes individual success and achievement as unworthy and inappropriate (Wikipedia; (http://en.wikipedia.org/wiki/Law_of_Jante accessed 20-4-15).

> Most Danes seem to [be] much more reserved and humble in everyday life. These rules refrain people from "judging a book by its cover," as they encourage assuming that they are no better than the person they are meeting. (Gratale, 2014).

In discussions with colleagues in Norway about research approaches and the teaching of mathematics, it became an issue for me to take a more modest, or 'humble' stance on my own perspectives. Thus, awareness of culture impacted on how I as a researcher interacted with colleagues and approached my research role.

In Pakistan, the cultural differences are more obvious, and religion plays an important role – the Muslim religion and associated social values permeate how people think and what is possible in schools and classrooms (Farah & Jaworski, 2005). For example, when working with teachers in a master's programme in Pakistan, I emphasised the *value* (in mathematics) of *asking questions* about the mathematics in which we engaged. My argument was that inquiry approaches to mathematics, involving questioning of relationships and procedures, encourage students to go beyond the procedural towards more conceptual understandings of the mathematics in focus (Jaworski, 1994). One teacher chose to write an essay about 'questioning as a pedagogic approach'. She drew attention to the fact that in Pakistani society questioning is largely discouraged because it shows a lack of respect for parents, teachers or anyone senior in the community (Jaworski, 2001, p. 312). This observation led to our addressing questioning not only as a pedagogic approach in mathematics, but also as an issue of *values* in the Pakistani society impinging on what is possible in the mathematics classroom. We see here issues related to pedagogic practice designed to improve the learning of mathematics and specific societal norms, alongside the communicative difficulties across cultural boundaries.

Anjum Halai addresses such issues from within her own and another cultural context, Mathematics Education in Pakistan and in East Africa, raising wider social issues that have a compelling need to be addressed.

> Recognition of learners who are marginalized due to socio-economic status, gender, language or other factors would mean questioning deep seated assumptions that underpin the organising structure and process of classrooms, in this case mathematics classrooms. For example, in patriarchal societies with roles defined on the basis of gender, teachers often subscribe to the dominant social and cultural views that boys are inherently better in mathematics thereby marginalizing girls in terms of participation in mathematics. (Halai, 2014, p. 69)

For researchers, not questioning those deeply held cultural views, which limit participation of both, boys and girls, is to take a moral position. Halai positively recommends *questioning*, claiming that it is through questioning that we challenge entrenched discriminatory practices. This clearly raises issues for researchers who wish to conduct research without offending their respondents/participants, but who nevertheless see a moral dimension to their questioning of values, both in teaching and learning mathematics and in the wider society. Halai writes further:

> For skills development, processes of teaching and learning in the mathematics classrooms would move away from routine memorization of procedures and algorithmic knowledge towards participatory learning involving application of mathematics knowledge to problems. Mathematics knowledge embedded in the history and culture of the learners would be a significant element of the cultural capital being re-distributed. This would socio-culturally embed mathematics learning and reduce alienation of learners with school mathematics. (Halai, 2014, p. 69)

We see here serious challenges for researchers cross-culturally: while respecting the cultures in which we work as researchers, and without alienating those with whom we work, we need to address what we know to be good didactic and pedagogic practices in mathematics for the good of the students whose lives depend on it. These words suggest that research and educational development go hand in hand to promote practices which theory and research support as more likely to promote mathematical learning.

Diverse perspectives on what constitutes good learning of mathematics and how this relates to cultural perspectives have permeated Mathematics Education's recent history, in both developed and developing worlds. Mathematics is seen in many countries as an essential ingredient of a good education, having "exchange value" for entry to diverse disciplines and work opportunities (e.g., Williams, 2011). However, for many people mathematics appears to be outside their comprehension, creating serious sociocultural antipathies, as the next section reflects.

2.2.3 Perceptions of mathematics and mathematical achievement in diverse cultures and systems

In Mathematics Education, teachers and educators have the task of promoting mathematical learning and understanding among the students with whom they work, and researchers study the processes, practices and outcomes of this work. In 1990, writing from an ICMI study focusing on the *Popularisation of Mathematics*, Howson and Kahane (1990, p. 2/3) wrote that, in most developed countries, the public image of mathematics is bad. They quote from their respondents: “All problems are already formulated”; “Mathematics is not creative”, “Mathematics is not part of human culture”, “The only purpose of mathematics is for sorting out students”. Moreover, “the image of mathematicians is still worse: arrogant, elitist, middle class, eccentric, male social misfits. They lack antennae, common sense, and a sense of humour”. We might ask *why* mathematics elicits such negative responses from a wide range of people. In more recent years, in a study of students’ views of mathematics in secondary classrooms in the UK, Nardi and Steward (2003) characterized students’ views as expressing *tedium*, *isolation*, *rote learning*, *elitism* and *depersonalization* (pp. 355–360) – students were T.I.R.E.D, of/with mathematics. These findings are an indictment on the students’ experiences of mathematics in their schooling. Such unwelcome messages challenge the educational *status quo* in the cultures to which they relate and impact on systems and practices. The challenges for researchers, and associated responsibilities, go beyond pointing out the failings towards a recognition of where persistent practices are failing learners.

For example, in the UK, long-standing practices which resist challenge involve the grouping students into ‘sets’ for mathematics based on achievement within the system. Such setting, based on achievement, is much less common in other disciplinary areas. Setting practices have discriminated against certain groups of students, leaving them to be defined as ‘low achieving’ or even ‘low ability’ (Boaler & Wiliam, 2001). In particular, setting regimes and associated forms of national assessment were found by Cooper and Dunne (2000) to discriminate again girls and students of lower social class. Why such practices are maintained, given the research evidence against them, is a cultural phenomenon, deeply embedded in the educational system and perceptions of policy-makers and teachers. In a study based on the ways in which committed teachers interpreted mathematics teaching in two schools in the UK, Boaler (1997) showed that differences in school organisation and teaching approach led to different ways in which students perceived and succeeded with mathematics, with differential effects for boys and girls. Such research findings at a national level beg questions about educational practices and learning outcomes in other countries which are addressed through international comparisons in mathematics.

In international comparisons of mathematics achievement, successive IEA studies have shown that several European countries perform relatively poorly in contrast with achievements in some eastern countries (Mullis, Martin, Gonzalez, & Chrostowski, 2004). We might ask whether ‘TIRED’ students are unlikely to achieve highly; or perhaps whether forms of ‘setting’ can be linked to national outcomes. It seems clear that the outcomes of testing students in international comparisons reflect cultural perspectives in mathematics and in education. As well as comparing learner outcomes in these countries, such studies beg many questions about the educational systems, classroom practices and education of teachers to which student learning outcomes relate. More recent studies, such as the TEDS-M study (Tatto et al., 2012), have taken up some of these questions.

For example, comparing national results in the TEDS-M study of teacher education, Kaiser and colleagues (2014) address the question: “What are the professional competencies of future mathematics teachers [in the countries to which the study relates]?” They write:

> In the secondary study, participants from Chinese Taipei outperformed all other participants, in relation to MCK [mathematical content knowledge] as well as MPCK [mathematical pedagogic content knowledge]. Participants from Russia, Singapore, Poland and Switzerland followed the Chinese Taipei prospective teachers with their achievements in MCK, German and US American prospective teachers achieved slightly above the average, … .
>
> These results point to interesting differences between prospective teachers for primary level and secondary level and confirm the superior performance of Eastern prospective teachers compared to their Western counterparts in most areas.
>
> In contrast, in Scandinavian countries, North and South America, and in countries shaped by US-American influence such as the Philippines or Singapore a so-called “progressive education” with child-centred approaches characterises

> school and teacher education. (Kaiser et al., 2014, pp. 42f)

By focusing on national achievements, these authors alert us to the differing systems and beliefs which underpin educational achievements. They suggest that links can be seen between these findings and those from surveys of student achievement in the same countries, and point towards the differing 'orientations' between countries as contributing to the findings of the study:

> The studies explore amongst others the extent to which a country's culture can be characterised by an individualistic versus a collectivistic orientation using the cultural-sociological theory of Hofstede (1986). The collectivism-individualism antagonism describes the extent to which the individuals of a society are perceived as autonomous, the role and the responsibility of the individual for knowledge acquisition plays an important role. (Kaiser et al., 2014, p. 44)

Our attention is drawn here to the differing beliefs which shape an education system, and which are rooted in the collectivist-individualist debate which underpins the values on which educational practice is based. It is far from simple to address such established positions, especially when they are supported by politics and legislation; nevertheless as moral educator-researchers we cannot ignore such challenges.

2.2.4 Values as a determinant of difference

Questions related to *values* have been addressed explicitly in research looking at the importance of values in relation to classroom mathematics. The values that a teacher holds are influential on the ways in which curriculum content is addressed in the classroom. For example, Alan Bishop has written:

> If a teacher continually chooses to present opportunities for investigation, discussion and debate in her class, we might surmise she values the ability for logical argument. (Bishop, 2001, p. 238)

Maybe further, we might surmise she believes that logical argument is important to mathematical conceptualization. Bishop argues that beliefs and values are reflexively linked for teachers deciding how to bring mathematics to the students in their classroom. For the TIRED students in the study reported by Nardi and Steward, we might wonder about the beliefs and values underpinning the teaching of these students. Although such issues are not addressed explicitly in their paper, Nardi and Steward write nevertheless: "The students seemed to resent mathematical learning as a *rote learning* activity that involves the manipulation of unquestionable rules and yields unique methods and answers to problems." (p. 362) Thus, *promoting rote learning* can be perceived by some as a legitimate way of teaching mathematics and is related to classroom values underpinning findings in this study.

In research in Taiwan, Chin, Leu, and Lin (2001) compared and contrasted the beliefs and values of two teachers and concluded that the process of making their values explicit had effects on their teaching related to the particular values they espoused. In one case, the teacher came to realize that using language that is more familiar to students, encouraging students to express mathematical ideas in their own language and only later moving to formal expressions, has positive outcomes for students' mathematical learning.

Language also formed a central issue for Lee (2006) in a study of her own teaching approaches in a UK comprehensive school. She pointed to the importance of the transition from students' own natural language to mathematical language, designing and exploring classroom approaches that promoted students' development of mathematical language. Students had to get used to using mathematical terms and expressing in their own ways the meanings of these terms. Lee, acting as teacher-researcher, stood out against the prevailing ethos in her school in relation to the wider educational system. Her research demonstrates possibilities for promoting the development of mathematical language in the classroom and stands as a beacon for other teachers within the system.

These examples point to morality issues at the classroom level, involving teachers working with their students. However, teachers have to work within the prevailing system which imposes values beyond their own activity and that of their students. The educational system, with its ways of organising schools, curriculum and examinations, is formed within the nation's societal and political forces which are culturally determined.

2.2.5 Ways of knowing and being
Cultural determination within any society might be seen in terms of 'ways of knowing and being'. Research by Belenky and colleagues (1986) pointed to "Women's Ways of Knowing", drawing attention to the ways in which women perceive their various 'worlds' differently from male perceptions. Such worlds are the focus of Holland and colleagues (1998) who have suggested that humans make sense within "figured worlds", or figurative, narrativized or dramatized worlds:

> [A figured world is] a socially and culturally constructed realm of interpretation in which particular characters and actors are recognized, significance is assigned to certain acts, and particular outcomes are valued over others. (Holland et al., 1998, p. 52)

Ways of knowing or *figured worlds* can be seen to underpin the ways in which Mathematics Education is approached and practiced in culturally different educational settings. The examples provided above are all situated with respect to such worlds which may be local national or cross-national. Researchers working in cross-national frames may be unaware of the worlds of their partners, of ways of interpreting constructs and concepts, of overpowering societal or political forces. Issues arising may present tensions and dilemmas which need to be exposed, discussed and deconstructed in reports from the research.

I have drawn attention to cultural values permeating mathematics learning and teaching in and beyond national boundaries raising moral and ethical questions for teachers, educators and researchers. Research activity and practices cannot be divorced from the educational values that permeate societies and are promoted by systems, politics and legislation. The researcher is more than a recorder of practices and issues and cannot avoid involvement. We therefore need much more cognisance of ways in which research questions cut across ways of knowing and being in the worlds in which we do our research. This in itself is a research agenda.

2.2.6 Key concepts
The following is a list of the key concepts addressed in this section:

1) The moral and ethical nature of Mathematics Education practices and associated responsibilities of practitioners and researchers;

2) The centrality of *values* to educational research and practice in mathematics;

3) Perceptions of mathematics and their relation to didactic and pedagogic practices;

4) Differences of perception of mathematics educational practice rooted in cultural contexts and issues for researchers in challenging established ways of being;

5) International studies with cross-national comparisons and the challenges they raise for culture-bound practices;

6) Figured worlds which narrativise the human collective in Mathematics Education and require recognition and acknowledgement in their power to condition beliefs and values, and hence teaching and learning.

2.3 Research approaches and research communities as and in cultural contexts (Susanne Prediger)
The previous two sections have discussed differences in cultural contexts concerning *the mathematics* itself (in Section 2.1) and the contexts of *teaching and learning mathematics* (in Section 2.2). For both cultural contexts, it was shown how the hidden assumption about the universality of our own practices and values (of writing and doing mathematics, ways of teaching, of educating teachers) must be challenged. Instead, the mathematical and educational practices and values are deeply shaped by the culture we live in. Problems of intercultural misunderstandings can appear when we are not aware of this cultural boundedness and assume that approaches or knowledge can easily be transferred between cultural contexts.

In both sections, the "culture" in "cultural contexts" mainly referred to countries or regions, where intercultural reflections can be triggered by international comparisons. However, Maria G. Bartolini Bussi has already mentioned the differences between everyday language and mathematics language about whole numbers and Barbara Jaworski has already mentioned cultural differences within a country, for example, the researchers' culture versus the teachers' culture. This widened use of the construct "culture" is in line with modern conceptualizations, not only as national culture but as *a system of shared meanings, values and practices* shared by a group of people, also within a country (Geertz, 1973; Knorr Cetina, 1999). Specifically, Knorr Cetina (1999) has coined the term epistemic cultures and showed how implicit values and practices can shape the work of research communities and their research approaches.

Within the Mathematics Education community, especially the diversity of different theoretical approaches and the underlying research practices have been discussed as different cultural contexts. This section reports briefly on the raising awareness on these more subtle cultural contexts and discusses how strategies invented for dealing with diversity of research approaches can be transferred to other cultural differences. Thus, in this section, the relation between research approaches and cultural contexts is twofold: on the one hand, the research approaches are themselves considered *as* epistemic cultures with their own values and practices, on the other hand, research approaches have emerged *in* different international contexts and different research communities, and their specific characteristics have always shaped the epistemic cultures.

On this meta-level, the mathematics is more implicit: although the theories and research approaches deal with mathematics and its epistemological specificity, the reflection on how to combine different approaches is not so specific to mathematics anymore.

2.3.1 Different research approaches – a further cultural context influencing research and design practices

Since 2005, the ERME community has gained an increasing awareness of the existence of different theoretical approaches. At CERME congresses, the methodological discourse was installed by establishing a Working Group which is ongoing now for 10 years (Artigue, Bartolini Bussi, Dreyfus, Gray, & Prediger, 2005 at CERME5; Arzarello, Bosch, Lenfant, & Prediger, 2007 at CERME6; and successors). Successively, the awareness increases that theoretical approaches are always connected to research practices, this section hence talks about research approaches at large, including the theories framing the research as well as the underlying aims and values.

No empirical finding exists independent from the way it is generated within a theoretical approach, even if this theoretical approach is not made explicit. However, the complexity of mathematics teaching and learning can be conceptualized in very different ways, depending on the chosen theory and research approach. Figure 4 sketches an example (presented and discussed in Prediger, 2010) of the empirical problem that immigrant students have difficulties with mathematical word problems. This problem can be conceptualized, described and explained by different lenses which are connected to different theoretical approaches, either in an individual cog-

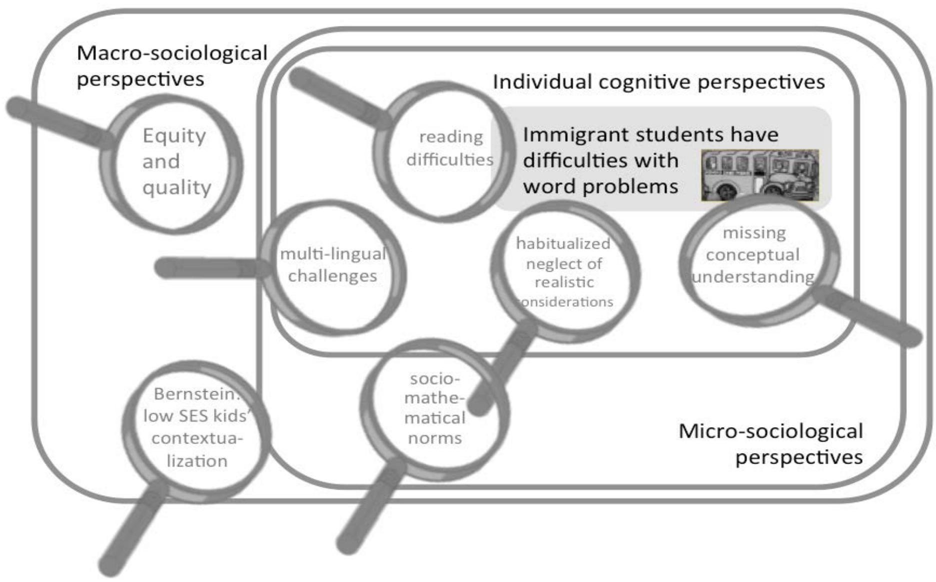

Figure 4: Different theoretical approaches to the same empirical problem (similar to Prediger, 2010, p. 183)

nitive perspective or a social perspective: Some focus (micro-sociologically) on the culture of mathematics classroom, and others also focus (macro-sociologically) on connections to students' social background and structures in society (cf., Sierpinska & Lerman, 1996, for the difference between cognitive and social perspectives at large).

In each case, the activated approach influences (but not determines) the way the problem is researched. The original problem changes its character, since the theoretical approach shapes the problem into a so-called conceptualized phenomenon (Bikner-Ahsbahs, Prediger, & the Networking Theories Group, 2014, p. 238). Additionally, the specific conceptualization of the problem influences the design consequences drawn for overcoming it. If the problem is conceptualized as students' missing conceptual understanding, the design might focus on fostering understanding. In contrast, the conceptualization as a habitualized neglect of realistic consideration due to inadequate sociomathematical norms in the classroom might lead to changing the sociomathematical norms about how to deal with word problems. If the immigrant students are mainly considered as students with underprivileged social background, a more explicit teaching might be claimed as consequences drawn from Bernstein's theoretical approach. In contrast, the conceptualization as multilingual students might result in fostering students' academic language or raising more general issues of equity (Prediger, 2010). Especially, considering challenges relating to a specific group of students (such as here immigrant students) allows for macro-sociological perspectives on issues of equity, but can also be treated as a purely cognitive problem within a specific mathematical topic.

Even this very rough outline of alternative approaches and design consequences shows how each theoretical approach influences research and design practices. This sketched example can raise the cultural awareness that *no empirical finding exists independent from its conceptualization within a (more or less explicit) theoretical approach.*

It also shows that the diversity of approaches is not only another example of cultural differences (here difference of epistemic cultures), but that it is also *necessary* in order to grasp different aspects of the complexity of mathematics teaching and learning. Having acknowledged the necessity of different epistemic cultures is however not enough to make use of the diversity, because the diversity can mainly become fruitful if the research approaches are connected (Artigue et al., 2005). As classroom reality is always complex and multi-facetted, connecting different theoretical approaches and research practices is promising in order to grasp a higher complexity at the same time.

2.3.2 Dealing with diverse research approaches and theories as an issue of methodological reflection

How can the discipline of Mathematics Education make use, more systematically, of the diversity of different epistemic cultures? As dealing with the diversity was identified as an important challenge for the international community, a subgroup of the CERME working group started to work more intensively in order to elaborate the methodological reflections, first on theories alone, later more widely on research approaches and the underlying epistemic cultures (Bikner-Ahsbahs, Prediger, & the Networking Theories Group, 2014).

Given the high complexity of mathematics teaching and learning, *one big unified theory* is not a realistic and adequate goal. Instead, the group developed the idea of aiming at connecting two or three approaches each. For this purpose, the group developed a landscape of so-called networking strategies by which these connections can be realized (Prediger, Bikner-Ahsbahs, & Arzarello, 2008).

Practical experiments with comparing and contrasting different theoretical approaches in different settings led to an increasing awareness that theoretical

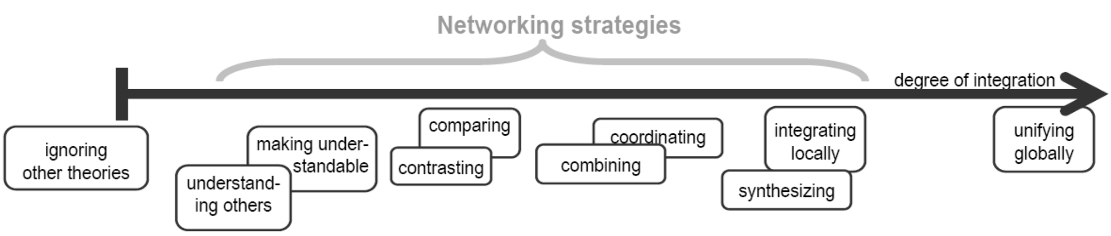

Figure 5: A landscape of strategies for connecting theoretical approaches (Prediger et al., 2008, p. 170)

approaches influence each step in a research process, not only the analysis of data as the initial example in Figure 4 might suggest:

- initial identification of a problem in classroom practice, loosely framed;
- conceptualisation of the classroom problem;
- transformation of the problem into more focused research questions;
- development of research design (including methodological choices on kinds of data, sample...);
- collecting data;
- choice and formulation of a research question;
- data analysis;
- consequences for a design of learning opportunities;
- evaluation of learning opportunities;
- ...

It was therefore an interesting experience to convert research problems from one research approach into another, because this required changes in every step of the research practice as well. These experiences showed the strong intertwinement between theories and research practices and hence the meaning of Knorr Cetina's (1999) construct "epistemic cultures".

Although there is no shared unique definition of theory or theoretical approach among Mathematics Education researchers (see Assude, Boero, Herbst, Lerman, & Radford, 2008), many authors emphasize the double role of theory being the outcome of research and, at the same time, the background theory guiding the research practice as a framework (Assude et al., 2008). Radford (2008) takes this intertwinement into account by describing theories as "way[s] of producing understandings and ways of action based on [...] basic principles, which include implicit views and explicit statements that delineate the frontier of what will be the universe of discourse and the adopted research perspective; a methodology [.... and] a set of paradigmatic research questions" (Radford, 2008, p. 320). Radford's triplet includes the so-called background theories (Mason & Waywood, 1996) with many hidden assumptions and general philosophical stances which often remain implicit.

For example, adopting a macro-sociological perspective on the example problem in Figure 4 immediately makes the researcher think about the students' background and how this is related to the mathematics learning. Relevant questions in this perspective must include societal questions. At the same time, the mathematics might be able to be treated in a more generic sense. In contrast, the cognitive perspective would focus on the specificity of the mathematical topic and its obstacles and might neglect the students' background as this question is not considered as important. Which approach is chosen might also depend on the national or regional contexts: where equity issues are prominently discussed, the macro-sociological perspective has entered Mathematics Education earlier than in other countries or regions.

Making crucial aspects of an approach explicit is therefore a major task when connecting theories and research approaches. That is why understanding another theory and making the own theory understandable was specified as the first networking strategy (cf. Figure 5), since these two strategies already require big efforts of the researchers for an "intercultural communication".

Before applying networking strategies with higher degrees of integration like combining, coordinating or synthesizing, the compatibility of the approaches in view must carefully been checked. This is necessary to avoid inconsistencies in the built network (cf. Bikner-Ahsbahs et al., 2014).

2.3.3 Theoretical approaches and research and design practices as embedded in different research communities and institutional backgrounds

Conceptualizing theories as ways of producing understandings and ways of action corresponds to culturalistic conceptualizations of research as being conducted in *communities of practice"* (Wenger, 1998). The construct *practice* is explained by Wenger as socially bound to its community:

> The concept of practice connotes doing, but not just doing in and of itself. It is doing in a historical and social context that gives structure and

> meaning to what we do. In this sense, practice is always social practice. Such a concept of practice includes both the explicit and the tacit. It includes what is said and what is left unsaid; what is represented and what is assumed. It includes language, tools, documents, images, symbols, well-defined roles, specified criteria, codified procedures, regulations and contracts that various practices make explicit for a variety of purposes. But it also includes all the implicit relations, tacit conventions, subtle cues, untold rules of thumb, recognizable intuitions, specific perceptions, well-tuned sensitivities, embodied understanding, underlying assumptions, and shared world views. Most of these may never be articulated, yet they are unmistakable signs of membership in communities of practice and are crucial to the success of their enterprises. (Wenger, 1998, p. 47)

This conceptualization of research as always being bound in epistemic cultures, or here more precisely in research communities of practice, makes it clear that the choice of a theoretical approach is not a free individual choice but always limited and fired by the specific research community and their institutional background.

The fact that Maria G. Bartolini Bussi, in Section 2.1, focuses on the mathematics itself and Barbara Jaworski in Section 2.2 on teachers, classrooms and values of the society, might also be traced back to the different research communities and institutional backgrounds in which the researchers work: Being located in the mathematics or more attached to the general education department might affect the choices about focus, perspective and theoretical approach. In this sense, every research is strongly influenced by the community of practice and its institutional background.

This point is also made by Marta Pytlak in Section 3.2: Different institutional conditions influence the research practices we can choose. For the individual young researcher, it might hence be challenging to switch between the communities.

2.3.4 Learning for cultural contexts on other levels?

After ten years of methodological reflection on the diversity of research approaches and strategies and issues for dealing with it, we can ask whether we can learn something from this cultural context on the research level for other cultural contexts (e.g., on the mathematical level or the classroom level, see Section 2.1 and 2.2 as well as 3). Are there aspects of cultural awareness that can be transferred from the level of research cultures to other levels of cultural contexts raised in other sections?

Here are some preliminary aspects which should be further discussed:

- Being aware of differences is the first step to avoid too hasty generalizations. It is worth *not to take the own assumptions for granted universally*.
- Differences do not only pose problems, but also offer *chances* since they provide a larger variety of options and increase the repertoire of research and design practices.
- Beyond openly visible differences, there are always substantial differences in more subtle, implicit layers which are more difficult to communicate. That is why *understanding* other contexts and *making* the own context *understandable* is a challenge in itself which should be taken seriously.
- *Comparing and contrasting* cultural contexts is a strategy that allows making implicit thought and aspects explicit.
- *Converting* from one cultural context to another requires very careful adaptations or even transpositions in order to adjust to the cultural context soundly.
- *Combining* different contexts requires very careful considerations of *checking compatibility* in order to avoid inconsistencies.

3. YOUNG RESEARCHERS' EXPERIENCES AND REFLECTIONS

The previous sections give concrete examples in which the *invisible culture* of mathematical thoughts (Section 2.1), classrooms, their norms and values (Section 2.2 and 2.3) had been made visible throughout a deep analysis of particular cultural contexts. These examples indicate cultural determinants of the mathematics taught and learned in mathematics classes. In the given cultural context (determined by its history, tradition, institutions, systems of values, ideologies), the invisible culture is so natural and obvious that its participants might take it for granted also for other contexts.

From the point of view of researchers it is necessary to be aware of these determinants. This awareness requires a holistic view of the learning process as a part of a certain context and its culture. The reflections worked out in Section 2.4 explain from a meta-level how researchers' awareness of the cultural dimension of learning processes might be affected by the tradition of dealing with particular theoretical perspectives being characteristic for their community. These reflections point out another level of an invisible culture – the invisible culture of scientific thought in Mathematics Education – and explain well-established strategies for raising the cultural awareness on this level.

The reflections presented by three experienced researchers motivated a group of four young researchers (Annica Andersson, Mustafa Alpaslan, Edyta Nowinska, and Marta Pytlak) to analyse and discuss their own experience in conducting and communicating research in Mathematics Education. Some results of these processes are presented in this section. They document

— the essential role of an intercultural discourse (Section 3.1 and 3.3) in raising the cultural awareness of research practices,

— the influence of the institutional context affecting the effectiveness of such a discourse (Section 3.2), and

— the need for researchers' awareness of the invisible culture underpinning ways of thinking and acting in mathematics classes in order to design effective methods for improvement of teaching and learning practices (Section 3.4).

Section 3.5 presents a discussion of the critical points raised by the young researchers and puts them in relation to the reflections presented in the previous sections. The discussion emphasizes the need for the *cultural* and *theoretical sensitivities* for better understanding of the surrounding invisible cultures in research practices in Mathematics Education.

3.1 International perspectives on local phenomena – A personal experience (guest-author Annica Andersson)

In my reflections, I focus on my experiences from Mathematics Education research and teacher education in the diverse cultural settings I have had the opportunity to work in, for example, Sweden, Denmark, Colombia, Australia, Papua New Guinea and Greenland. These cultural experiences have shown that *our own languages, contexts and cultures may become visible when we see them from the outsider's perspective, or when others confront us with questions motivating us to reflect on our own use of the languages, contexts and cultures we participate in or are familiar with.* This has been one of my richest learning experiences when communicating my cultural research with others.

For my thesis research, focusing on students' narratives about their hating/ disliking/worrying about/ Mathematics and Mathematics Education (cf. Andersson & Valero, 2015), I collected my data in Swedish upper secondary schools. The fact that I analysed my data while being outside Sweden, in an English-speaking environment (Australia), and communicated my research within an international research group in Aalborg (Denmark), facilitated me to explain and express the data to people of other languages and cultures. Consequently, I recognised some aspects influencing the ways of thinking and acting in school contexts in Sweden, and realized that languages, cultures and contexts fluctuate and are not stable. The opportunity to communicate this research within an international community raised my awareness on how one's own cultural context may be different from other contexts and how it influences the ways of acting as a teacher or researcher and, consequently, also teaching methods, research questions and theoretical approaches.

For example, Elin, a mathematics teacher I collaborated with, talked about herself as being a "Curling teacher" (Andersson, 2011). Curling is a culturally-bounded winter ice sport where competitors sweep the ice in front of a stone to get it in the best position. The metaphor of a *curling* teacher is transferred from the term "curling parent", which, in Sweden, refers to parents who "sweep the way", hence serve their children to get the right, or best, positions, solving possible problems and tensions beforehand and thus make children's lives as smooth and easy as possible. The idea of a "curling teacher" was culturally-bounded and not obvious for an international research community.

The international (or rather inter-cultural) discourse on my research contributed to make my research problems, approaches and results clear and understandable for external research communities. My experiences allow me to argue that there is value in raising discussions about understanding Mathematics Education research as culturally developed and situated. Here the question arises on how to value the "universality" of research results within an international community. It seems that this question has to be discussed from the background of the cultural contexts in which the research questions appear to be relevant.

3.2 Divergent expectations in different research communities – A personal experience (guest-author Marta Pytlak)

ERME conferences (CERMEs) are a great opportunity to get access to a research community in Mathematics Education, and get insight into new research problems, methods and theoretical approaches. Here, problems related to school mathematics, teaching and learning situations in real settings in mathematics classes are discussed from different theoretical perspectives. Theories developed in Mathematics Education are considered as important scientific achievements and research tools. CERME papers document research and development work of their authors and their quality must satisfy scientific criteria.

However, the institutional context of my work as a researcher in Mathematics Education in Poland – Faculty of Mathematics – has other criteria to evaluate my work and publications. Since Mathematics Education is not recognized here as a scientific discipline, my work is evaluated on the basis of the same criteria as the work of mathematicians. Papers published in CERME proceedings or in Mathematics Education journals are not considered as results of scientific work, regardless of the content. I am expected to focus in my work on problems relevant for a scientific work in mathematics and to deal with mathematical theories. Methods, approaches and theoretical constructs developed in Mathematics Education seem to be irrelevant in this context. This hinders the development of research communities in Mathematics Education in Poland and makes the communication within an international community very difficult.

In my PhD thesis, I focused on the development of algebraic thinking in elementary school students. In the whole process of my PhD project I used theoretical constructs, approaches and methods developed and used in international communities in Mathematics Education. While discussing my research within such communities, I received constructive responses regarding the novelty and importance of my research questions and results. Because of references to problems and literature known in Mathematics Education my work was understandable for others.

Due to my institutional context in Poland, it was nevertheless important to adapt my final version of the PhD to the institutional expectations and reduce the part related to theories in Mathematics Education. Instead, I wrote one chapter with elaboration on advanced mathematical theories relevant for my work. Addressing some historical aspects of the development of algebra allowed me to make some links between this chapter and other chapters in my thesis. The changes made to satisfy the institutional criteria for a PhD thesis brought into my work new aspects. But they also shifted the focus from theories which I had used to conceptualize particular problems in Mathematics Education to the more "universal" mathematical theories. Consequently, this changed the way that this work is embedded in the discourse of the European Mathematics Education community.

My experience indicates one of many challenges for researchers in Mathematics Education in Poland which sometimes hinder the development of research communities and the access of the small group of Polish researchers to an international community.

3.3 Cultural biases in review procedures – A personal experience (guest-author Mustafa Alpaslan)

My reflections are related to my experiences as a PhD student and graduate assistant working in teacher education for pre-service middle school (ages 11 to 14) mathematics teachers at the Middle East Technical University, in Ankara, Turkey.

My research interests focus on the integration of history of mathematics in the education of pre-service mathematics teachers. One component of my master thesis was to investigate Turkish pre-service middle school mathematics teachers' knowledge of history of mathematics and to develop a valid test for this investigation. Since the history of mathematics is a large area, the scope of the test was restricted to the historical and institutional context of mathematics taught and learned in Turkish middle schools. Mathematics curricula, textbooks and guidelines for mathematics teachers' competencies were used as a reference frame for decisions concerning this restriction.

Besides items reflecting various cultures' contributions to the historical development of mathematics, one item addressed the history of Turkish mathematical language. In it, Mustafa Kemal Atatürk's contribution to create a new mathematical language according to the new Turkish language, with Latin alphabet rather than the old Ottoman Turkish with Arabic alphabet, was captured. In Turkey, this contribution is valued as an element of our cultural identity and the awareness of it is seen as a part of mathematics teachers' professional knowledge. Atatürk's reason for preferring the new Turkish was that it was actually the spoken language in the public, thus it would provide easier and more meaningful understanding of geometrical concepts.

The context-bound nature of my research seemed to be very natural in discussions with researchers from Turkey. However, a discussion with researchers from *the International Study Group on the Relations between the History and Pedagogy of Mathematics* raised my awareness of the fact, that some items of the test designed in my research may not be understandable for this intercultural community. For example, one item in form of a multiple-choice question asking to mark Atatürk's contributions to the development of mathematics in Turkey was interpreted by the reviewers coming from other countries as an inadequate conceptualization of the investigated construct (teachers' knowledge of history of mathematics). This challenged me to provide additional information about the specific characteristic of my research context. By giving more context information, the reviewers decreased their doubts about the missing universality and significance of my research results. By my context-bound argumentation justifying my research questions, approach and results in the cultural context of mathematics teacher education in Turkey, I succeeded to publish an article from my master's thesis (see Alpaslan, Işıksal, & Haser, 2014). The cultural context was accepted by the reviewers as an essential contribution making my research understandable for them and for the potential international readers of this paper. Increased cultural awareness may help to avoid biases in review procedures.

3.4 Implementation of design research in new contexts – A personal experience (Edyta Nowinska)

In 2011, a group of researchers in Mathematics Education from Germany was assigned by the German foreign aid organization MISEREOR to support teacher education and the development of the quality of mathematics classes on the Indonesian island Sumba in order to educate the learners better for their career opportunities. For this aim, a long-term design research project had been conducted. The focus was on teaching and learning mathematics at the beginning of a secondary school, in particular on learners' cognitive habitus in learning mathematics.

Our first analysis revealed that the Sumbanese learners have difficulties with critical thinking and mathematical reasoning: On each level in the school system there, learners are used to learning by memorizing, answering collectively and waiting until the teacher tells them what is correct. They are not used to asking questions and practice monitoring (cf. Sembiring et al., 2008). Our further observations showed that there were some culture-bound variables influencing students' learning behaviour and hindering this kind of thinking and reasoning in mathematics classes. Critical thinking and rational reasoning are not essential characteristics of the Sumbanese culture, neither in the religion based on myths and legends, nor in everyday routines and system of values. This society exhibits a short-term point of view rather than a pragmatic future-oriented perspective based on critical thinking and precise planning.

It seems that the cultural context determines the ways of thinking and acting of teachers and learners. This determination results in culturally acquired epistemological obstacles, and beliefs that there are no alternative ways of acting and thinking. Thus, prior to the implementation of the teaching and learning concept developed on the basis of design principles worked out in the context of German secondary schools (cf. Cohors-Fresenborg & Kaune, 2005), a group of Indonesian pre-service mathematics teachers collaborated with the German educators to reflect on their (unconscious) ways of acting and change their own learning attitudes and teaching practice.

In this process of learning and reflecting, the pre-service teachers constructed mental models for mathematical reasoning, a system of metaphors enabling them to understand the core ideas of stepwise controlled mathematical argumentations and new beliefs about mathematics. They were astonished by the fact that the so-called mathematical "rules" can be derived and explained and that the meaning of symbols and signs can be negotiated in social interactions in class. The experience that Sumbanese learners are able to engage in such social interactions convinced the participating pre-service teachers that changes in the cognitive behaviour of the learners are possible to achieve, although the intended cognitive behaviour is not typical for the attitudes accumulated in the culture and everyday practices of the local society.

After two years of teacher professionalization courses and adapting the intervention developed in the context of German secondary schools to the Indonesian context, remarkable improvements in teaching and learning mathematics and in learners' competencies have been achieved (Nowinska, 2014). This was possible due to our holistic view of teaching and learning as a part of a certain cultural context and a culture itself. Neglecting this context and avoiding the interactive process with the participants of our project would change our intervention to a kind of indoctrination or anarchy and result in new forms of acting without understanding.

This cultural awareness and sensitivity motivated us to provide in our publications (cf. Nowinska, 2014) some explanations concerning the cultural context of our research, complementarily to the theoretical framework guiding our perception and conceptualization of "problems" in Mathematics Education. However, our experience suggests that it is a difficult task for reviewers to relate research problems and results from research and design practice in Mathematics Education to the context of this practice. It seems that in evaluating and reviewing design and research practices, the cultural aspect is often neglected and the major attention is paid to theoretical considerations and novelty of results. This may lead to trivialization of research problems and results in Mathematics Education.

3.5 Critical points raised by young researchers (Nowinska, Andersson, Pytlak, Alpaslan)

Internationalization of research in Mathematics Education (including international research conferences, publications, and collaborative and/or comparative cross-country research projects) challenges researchers to be aware of various contexts and their power to influence research and design practices in particular countries, cultures, societies, institutions and communities (cf. Atweh & Clarkson, 2001). The experiences described by four young researchers in this section indicate the essential role played by an international discourse in initiating reflections on one's own ways of thinking and acting as a researcher, educator or designer in a particular community, culture and society. Such a discourse challenges researchers to see their own practices from a broader perspective and may contribute to making them understandable for others.

The experience described by Annica Andersson indicates possible benefits that can result from participating and working in various contexts and from discourse within an international community of researchers for perception and better understanding of the unique characteristic of their own cultural context. Cultural differences and similarities become visible first as results of reflection and comparisons. Thus, an international discourse requires and facilitates cultural awareness.

Evidence of possible difficulties emerging in such a discourse is given in the reflections of Mustafa Alpaslan. His decisions while conducting his research project were affected by the historical context of the development of mathematical language in Turkey, yet this context was not made explicit when submitting a paper to an international community. Consequently, the novelty and importance of his research could not be understood by the reviewers coming from other cultural context until additional reflections on the cultural context of his research had been made explicit.

Similar challenges, yet related to the institutional context, are mentioned in the reflections provided by Marta Pytlak. The institutional criteria used to evaluate the work of many Polish researchers in Mathematics Education hinder the development of research communities and their work on problems related to teaching and learning of mathematics in schools.

Designing, justifying and evaluating indirect didactical actions is at the heart of research practices aiming at better understanding and improving teaching and learning processes (cf. Sierpinska, 1998). The experience described by Edyta Nowinska indicates that interventions and design principles resulting from design research cannot be seen as universal solutions for educational problems (cf. Plomp, 2013), even if some of these problems seem to be shared in various cultures.

From the perspective of researchers, seeing *similarities* in the nature of educational problems may contribute to a better understanding of these problems. However, complementarily, crucial *differences* between contexts where they appear should be considered. They provide some strategic guidelines for raising cultural awareness in our "daily" design and research practices: The challenge is to perceive the unique characteristic of the cultural context in which the design and research practices are conducted or have to be transferred into and to make them understandable for the participants of research as well as for readers and reviewers of research papers. Hofstede's dimensions of national culture (e.g., individualism versus collectivism, masculinity versus femininity, uncertainty avoidance, and long term orientation) (Hofstede, Hofstede, & Minkov, 2010) can be used to facilitate the *cultural sensitivity* needed to perceive such characteristics, complementarily to the *theoretical sensitivity* guiding researchers' perception and conceptualization of "problems" in Mathematics Education.

The reflections written by the four young researchers give insight into the complexity and variety of contexts that have to be taken into consideration to raise one's own cultural awareness. Some factors motivating and facilitating this kind of awareness can be identified. It seems that internalization of research and design in Mathematics Education, in particular the movement of young researchers within the international community, bring the importance of this theme again and again to light.

Critical points raised in reflections exposed by the young researchers:

— An international discourse initiates and facilitates reflections on one's own practices in a particular community of researchers, in a culture and society. It challenges researchers to raise cultural awareness and supports this awareness by providing new perspectives for contrasting one's own ways of acting and thinking with the ways of others.

— The challenge for raising cultural awareness of researchers is to make explicit the implicit decisions associated with their own design and research processes. It seems that a discursive approach within a community of researchers from different contexts may initiate, facilitate and raise cultural awareness of individuals.

— Writing about one's own research without justifying the choices of research questions and methods in the particular context of this research may not be understood by reviewers from another cultural context. Cultural awareness can help to avoid biases in review procedures.

— Internalization and globalization of design and research in Mathematics Education support transfer of knowledge and experience among researchers, in particular curricula and teaching interventions. However, teaching interventions cannot be implemented to a new context when the details of these interventions do not make sense in this context. Adaptation of design principles must take the local context into consideration.

Not only theoretical considerations but also various aspects of the particular social, historical, cultural and institutional context make design and research activities understandable.

4. LOOKING BACK AND LOOKING FORWARD

4.1 Looking back: Cultural differences in various contexts

The experiences and reflections presented in Sections 2 and 3 by experienced and young researchers all report on cultural differences which were only partly explicit and on how the differences or their implicitness affected the research or design practices.

However, these rich examples are located on different (of course overlapping) levels of cultural contexts (cf. Figure 6), covering the mathematics itself (Section 2.1), but also contexts of mathematics classrooms and the societies (Sections 2.2 and 3.1, 3.3 and 3.4), or the institutional contexts of the research communities (Section 2.3 and 3.2).

On the one hand, none of these differences are really surprising. In principle, we (should) know that these kinds of differences exist, and the international comparative studies on classroom cultures have shown such kind of differences systematically (cf. Stigler, Gonzales, Kawanka, Knoll, & Serrano, 1999; Clarke, Emanuelsson, Jablonka, & Mok, 2006). Additionally, the research on multicultural issues within one country has shown how differences in the societal context affect students in classrooms (e.g., Secada, 1992; and many others).

On the other hand, our principal awareness does often not reach our everyday research and design practices or it reaches them late, as a result of our practices instead as an input of them. The examples have shown that our daily research is often implicitly guided by the hidden assumption that contexts, problems, and outcomes are or should be universal and not shaped by the cultural relativity, briefly, the *hidden assumption of universality*. Instead, we plead for constantly questioning this hidden assumption of universality of research and design practices and outcomes and for raising cultural awareness. This seems necessary to establish the ERME community as an *epistemic community* using the multicultural diversity of its individual members and working groups to produce, widen and enrich our knowledge.

4.2 Looking forward: Raising cultural awareness

Being aware of differences and overcoming the hidden assumptions of the universality of research and development practices and outcomes, we and others can act in the directions outlined below:

— *when addressing mathematics,* we can try to be aware of cultural contingencies; we can challenge our own ways of perceiving and expressing mathematical constructs;

— *when reading other's papers,* we can avoid naïve transfers of constructs, approaches and outcomes from other cultural contexts; for example, what worked in Spain need not in Poland;

— *when reading other's papers,* we can systematically investigate the adequacy of transfers, not only for results, but also for theoretical constructs and approaches;

— *when writing papers*, we can describe explicitly our own cultural context, paying attention to the ways it affects what we write about research methodology and findings;

— *when conducting own research and development*, we can try to learn from other cultural contexts in order not to take for granted our own conditions.

Being aware of dominances and overcoming the hidden assumption of the universality of research and development practices and outcomes, we can attend to the following in our work with others:

— *when collaborating with colleagues from other cultural contexts,* we can take enough time to learn about other cultural contexts and consider differences; and we can exploit the gap between us, in order to become aware of our own unthoughts;

— *when importing research to other countries*, we can discuss and apply methodologies that allow us to be sensitive to the cultural contexts we join;

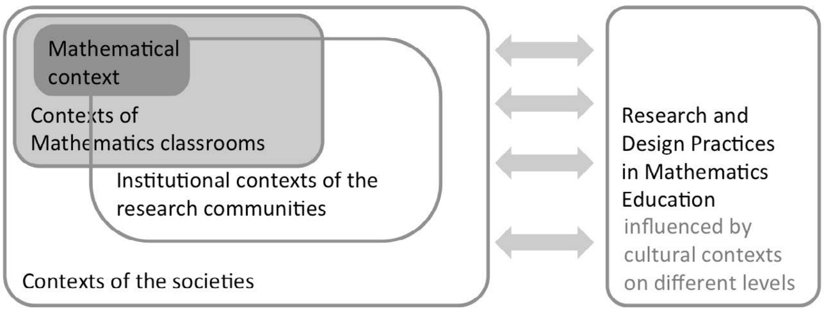

Figure 6: Nested cultural context on different levels which all influence the research and design practices in Mathematics Education

— *when acting as reviewers or editors for journals or conferences,* we can try to avoid the dominance of Western empirical research, where the sole adoption of the Western format of presentation (theoretical framework, research questions, methodology, findings) risk to hide new and fresh ideas, which have the potential to enrich our vision of the world;

— *when responsible for policy issues in international communities, we can follow good practices of* ICMI and ERME to strictly try to realize regional balances in all committees in order to alleviate cultural dominance;

— *when responsible for policy issues in international communities,* we can try to foster the standards for making explicit cultural contexts in writing and review guidelines (as, for example, in the practices seen in ERME guidelines, ICMI studies...);

— *when supervising PhD students from non-affluent countries,* we can reflect how far to impose own values on their research.

5. CONCLUSION: RAISING CULTURAL AWARENESS AS A COMMUNITY TASK

The focus here is both back onto mathematics and forward onto cultural awareness. We reflect on what we have written above and encourage questioning of our future practice. Our challenges in developing our own awarenesses place us in a position of responsibility to our academic and research communities in promoting more global values with respect to the cultural dimensions within which we work. Our intention here is to encourage discussion, and possibly debate, through which issues can be raised and addressed widely.

5.1 What makes mathematics central and different from other disciplinary areas?

In Section 2.1, we have raised issues relating to the ways in which mathematics is represented, symbolised and conceived in different parts of the world. Examples have shown how certain representational forms can foster or promote differing conceptions, some of which might be seen to limit how mathematics is understood. Perceptions of universality in mathematics can therefore be dangerous if they remain implicit and resist being challenged. Even the most experienced mathematics educators can learn from alternative cultural representations and build richer representational frames.

Section 2.2 has shown that teaching approaches and the ways in which mathematics is offered to learners carry a high responsibility with regard to learning outcomes. Narrow insistence on the internal consistency of mathematics as disseminated through representational forms and adherence to procedural rules, without corresponding attention to the underpinning concepts, have to bear a responsibility for public perceptions of mathematics and for mathematical achievement in diverse cultures. Richer cultural awarenesses can open up mathematical discourses that promote access and understanding and a broader willingness to engage and succeed with mathematics. However, these processes of innovation must themselves respect cultural differences.

5.2 How can a focus on mathematics take into account the moral and ethical issues of education for all?

The *moral* and the *ethical* are human constructs: being moral and ethical places responsibilities on mathematics educators as human beings. We have responsibilities to our disciplines of mathematics and education, and importantly to the people whose education in mathematics we promote. The intrinsic educational levels here present a complex weaving of responsibilities: educating students in mathematics; educating teachers in teaching mathematics; educating new researchers in theory and research; educating mathematics educators who educate at all of these levels. The awarenesses referred to in Section 5.1 with regard to mathematics underpin this edifice: we have to weigh the issues in deciding how best to interpret the role of educator. For example, the mathematics teacher who, with thoroughly good intentions, over-simplifies a mathematical concept to avert the struggles of the learner may not assist in the complexities in appreciating the concept; or a lecturer who emphasizes the fine details of a proof without attention to the sociohistorical origins of the proof may be true to mathematical rigor but leave a student mystified. Awareness of the choices we exercise as educators requires moral and ethical judgments in how we operate in our professional roles.

5.3 How can a focus on mathematics address the figured worlds of all who learn and teach?

The concept of *figured worlds* (Holland et al., 1998; cf. Section 2.2.5) recognizes that human beings are located within a complex synergy of cultures: societal, disciplinary, professional, familial, philosophical and personal, to name a few. In professional human relations, many of these 'worlds' are hidden; we have seen clear examples of this in the sections above. While any one or group cannot be expected to discern the extent of such complexity, we can be expected to be aware that it exists. This requires us to give overt attention to difference and meaning and their (potential) relationships to the concepts we address. It requires a willingness to be open, to encourage our learners to express their own conceptions and inform us of how things are done and seen in their contexts. As educators we have to do our best to make moral and ethical choices within our own knowledge and what we hear and learn by listening to others.

5.4 Which theories, research and design approaches can grasp the complexity and cultural differences?

As the reality of mathematics teaching and learning is very complex with all these different nuances and challenges, no single isolated theory, no single research or design approach can do justice to this complexity (cf. Section 2.3). Mathematics Education research that really contributes to relevant innovations in educational practices requires us to connect different approaches.

Raising cultural awareness also supports us to become aware of the strengths and limits of different epistemic cultures. This applies for Mathematics Education as well as for every other subject matter education and general education and requires not only the efforts of single researchers but the whole community.

5.5 What are the big issues that we should be addressing?

We wish to be true to mathematics as we know it. However, we can always learn more to enrich our own perceptions. As educators we are challenged continually to explore how best to bring mathematics and its learning and teaching to our learners. However, the biggest issue is not the question 'how can we bring mathematics and its learning and teaching to our learners?', but, 'how can we make *exploration* of such a question the basis of our professional activity'? We have to keep addressing this issue. For learners to see that their teachers, at any level of education, are also learners, questioning the very practices in which the teacher and learners are engaged, can be empowering and exhilarating, although it can also be frustrating for those who seek closure.

Closure is a philosophical position, related to seeking certainty and end points, and is something we have to address overtly. Rather than seeing closure in this concept, or this idea, or this issue, all participants can see themselves at their own stage of the educational journey, where the coming stages are open for participation. This very idea needs cultural reorientation in many contexts: for example, recognition that if we seek the 'right answer' to a mathematics problem, what is *right* may depend on a range of contextual factors; if we seek to *define* a mathematical entity, the very act of definition excludes other possibilities; if we present a Mathematics Education thesis in Poland, it will be judged differently from the same thesis in Spain. This is not to say there are no right answers, or to undermine the value of definitions, or to reject the judgments made in different communities; rather, while agreeing an answer or a definition, the limitations and exclusions of such acts need to be recognised and (insofar as we are able) addressed. Therefore, there are no end points, but many choices, challenges, and judgments. We have to embrace diversity and seek out alternative meanings and roots. Those more experienced are there to help all engage, to scaffold their growth of understanding, encourage progress and develop awareness, not to set limits or close off possibilities. This is the moral challenge for all of us!

Understanding randomness: Challenges for research and teaching

Carmen Batanero

Universidad de Granada, Granada, Spain, batanero@ugr.es

The ubiquity of randomness and the consequent need to understand random phenomena in order to make adequate decisions led many countries to include probability throughout the curricula from primary education to University level. This need was also recognized by the mathematicians who developed the probability theory. This is a relatively young field, and is not free of controversies, which are also reflected in the lack of agreement on a common definition of randomness. Psychological and didactical research, suggest widespread misconceptions and misperceptions of randomness; however, these results have not always been taken into account in teaching, where randomness is considered a transparent concept.

Keywords: Randomness, epistemology, subjective views, teaching and learning.

The most decisive conceptual event of twentieth century physics has been the discovery that the world is not deterministic. Causality, long the bastion of metaphysics was toppled, or at least tilted… A space was cleared for chance (Hacking, 1990, p. 1).

When I was kindly asked to contribute with a plenary talk to this conference, I decided to select a topic that reflected a part of European research to stochastic education. Randomness is a good example, since it may be examined from the philosophical, psychological, mathematical and didactic perspectives, each of which has been dealt with by European researchers, and which globally reflect the European perspective for didactics. Furthermore, there is an increasing tendency to teach probability to very young children. However, as we will analyse in my presentation, this concept is far from elementary and we still have to find adequate ways to introduce it to students at different ages.

With this view in mind, I will first describe some of the meanings attributed to the idea of randomness since its emergence; secondly, I will summarize the main research dealing with the personal meanings that people attribute to randomness. I will finish with some personal suggestions for teaching and future stochastic education research that may help to increase our understanding and managing of random situations.

FROM CHANCE TO RANDOMNESS

From childhood, we are surrounded by uncertainty, in our personal lives, our social activities and professional work. The omnipresence of randomness implies our need to understand random phenomena in order to make adequate decisions when confronted with uncertainty. Mathematicians developed the field of probability as a set of models that can be applied to uncertain situations; however, progress in mathematical methods did not solve the philosophical debate around randomness.

Today, mathematics curricula for compulsory teaching levels increase the study of random phenomena. Expressions such as "random experiments", "random digit", "random variable", "random variation", "random even", "random sampling", "randomly", "randomization", "random variable" appear in curricular documents (e.g., CCSSI, 2010; Franklin et al., 2007), as well as in the school textbooks.

However, in these documents, the meaning of randomness is not always clear and unequivocal, because these expressions refer to an abstract entity, not entirely defined; thus, increasing potential difficulties for students or teachers arise. Randomness is a multifaceted object, as shown in the various interpretations received throughout history (Batanero, Green, & Serrano, 1998; Batanero, Henry, & Parzysz, 2005; Bennett, 1999; Saldanha & Liu, 2014). Even today, we find no simple definition that we can use unambiguously to classify a given event or process as being random or not. In the following, the reflections about the nature of randomness by eminent statisticians, philosophers, psychologists and researchers in mathematics education are summarised.

Primitive ideas

Early notions of chance were found in many ancient cultures. However, for centuries there was no theoretical speculation about the nature of randomness or systematic study of frequencies of results of these games. Possible reasons for the tardy development of probability, such as the connection of chance and divination to predict the future, were discussed by David (1962). Borovcnik and Kapadia (2014a) suggest that in Greek mathematics, data about variability was ignored as contrary to their ideal of scientific argument. Later, many different conceptions of chance arose, in particular (Batanero, Henry, & Parzysz, 2005, p. 27):

> Believing in a destiny predetermined by God or spirits; Assuming a personal chance factor, unequal for different individuals; Accepting natural necessity, ineluctably subjected to laws which still are partially unknown and which govern the world's origin and evolution; Arguing the inextricable complexity of the infinitesimal causes generating macroscopic phenomena, which we consider fortuitous as the only possible reasonable interpretation; Assuming the existence of a fundamental, chaotic and absolute natural randomness.

Bennet (1999) analysed different historical conceptions of chance that was later formalized in the mathematical concept of randomness (Saldanha & Liu, 2014). Some of these conceptions still appear in students and teachers (Batanero, Arteaga, Serrano, & Ruiz, 2014; Engel & Sedlmeier, 2005). Below I give a brief summary of these developments.

Chance and causality

We can find a first meaning of randomness in the Spanish dictionary by Moliner (2000) where "random" is defined as "Uncertain. It is said of what depends on luck or chance" (p. 123), and "chance" is defined as "the presumed cause of events that are neither explained by natural necessity nor by a human or divine intervention" (p. 320). In this description, random is something with unknown causes and chance is the assumed cause of random phenomena.

This meaning was prevalent in a first historical phase in the development of randomness according to Bennett (1999). According to David (1962), the astralagus was used in games of chance around 3500 B.C. Cubic dice were abundant in primitive civilizations like the Egyptian or Chinese civilizations, which used games of chance in an attempt to predict or control fate in decision-making. In spite of this wide use, there was no scientific idea of randomness until the Middle Ages. Whether it was attributed to supernatural forces or not, randomness suppressed the possibility that human will, intelligence or knowledge would influence decisions or destiny (Poincaré, 1909/2011).

Throughout this period, some philosophers related chance to causality (Bennet, 1999): Democritus suggested that everything is the combined fruit of chance and need. Leucippus believed that nothing happens at random; everything happens for a reason and out of necessity. Aristotle considered that chance results from the coincidence of several independent events whose interaction results in an unexpected result. Implicit in this meaning is to believe that every phenomenon has a cause. Randomness is only the measure of our ignorance. Random phenomena are, by definition, those whose laws are unknown (Poincaré, 1909/2011).

A deterministic vision of the world was common throughout the Renaissance as is visible in Bernoulli (1713/1987, p. 14):

> All which benefits under the sun from past, present or future, being or becoming, enjoys itself an objective and total certainty… since if all what is future would not arrive with certainty, we cannot see how the supreme Creator could preserve the whole glory of his omniscience and omnipotence.

This conception of chance as opposed to cause and due to our ignorance remained until the 19th century: "Present events are connected with preceding ones by a link based upon the evident principle that a thing cannot occur without a cause which produces it" (Laplace, 1814/1995, p. vi).

Modern concept of chance

This conception changed at the beginning of the 20th century. For example, Poincaré (1912/1987) noticed that some processes with unknown laws, such as death, are considered deterministic. Moreover, other phenomena, such as Brownian motion, are described by deterministic laws at a macroscopic level, while the behaviour of particles is random. Other situations are considered to be random because “A very small cause, which escapes us, determines a considerable effect that we cannot fail to see, and then we say that this effect is due to chance” (Poincaré, 1912/1987, p. 4).

Among the phenomena with unknown laws, Poincaré distinguished random phenomena that can be studied with probability calculus from other phenomena where probability is not applicable. Furthermore, probability will not lose its validity when we find out the rules governing the random phenomena. Thus, the director of a life insurance company is ignorant of the precise date when each person taking the insurance will die. Moreover, the distribution of the entire population´s lifetime does not change when we add knowledge about the precise death for each particular individual. Today, we accept the existence of fundamental chance around us and, in addition to the theory of probability, other theories, such as those of complexity or chaos, may be used to describe randomness.

The different philosophical conceptions of chance are compatible with the axiomatic mathematical theory of probability, which provides a system of concepts and procedures that serve to analyse uncertain situations (Batanero, Henry, & Parzysz, 2005). Mathematical probability does not enter philosophical debates and uses the ideas of random experiment and randomness as primitive (with no consideration of the nature of chance in each particular application). However, even today, the interpretations of randomness and probability continue to be subject of philosophical debates and the teacher of probability needs to be aware of these interpretations, because they influence students’ reasoning when confronted with chance situations.

CONCEPTUALIZING RANDOMNESS

According to Hacking (1975), probability was conceptualized from two complementary perspectives since its emergence: as a personal degree of belief in the likelihood of random events (epistemic view), and as method to find objective mathematical rules through data and experiments (statistical view). These two views unfolded in multiple perspectives that described what random events are, and how can we assign probabilities to them.

Randomness as Equiprobability

In the earlier applications of probability, randomness was related to equiprobability, which was a reasonable assumption in games such as flipping coins or drawing balls from an urn. Consequently, it was assumed that a member of a class was random (or was selected at random), when there was exactly the same probability to obtain this object or any other member of the same class. Thus, there is exactly the same probability to get the number 1 or any other number from 1 to 6, when throwing a dice. We can find, for example, this interpretation of randomness in the Liber de Ludo Aleae by Cardano (1663/1961, p. 189).

> The most fundamental principle of all in gambling is simply equal conditions…of money, of situation…and of the dice itself. To the extent to which you depart from that equality, if it is in your opponent’s favour, you are a fool, and if in your own, you are unjust.

Accordingly, in the classical definition of probability given by de Moivre (1718/ 1967) and refined by Laplace (1814/1995), probability is simply the number of favourable cases to a particular event divided by the number of all cases possible in that experiment, provided all the possible cases are equiprobable.

Kyburg (1974) criticised this definition of randomness since it imposes unnatural restrictions to its applications. We can only consider that an object is a random member of a class if the class is finite. If the class is infinite, then the probability for selecting each member is zero, and so (apparently) identical, even when the selection method is biased. Applying this definition in order to discriminate a random from non-random member in a given class is difficult, even in games of chance. How could we know, for example, that a given coin is not slightly biased?

Randomness as stability of frequencies

By the end of the 18th century, the study of random phenomena was extended beyond the world of games of chance to natural and social sciences. In these applications, for example, to the study of the blood type of a newborn, we cannot apply equiprobability. The concept of *independence* was essential to assure randomness in successive trials (Bennet, 1999). In this new view, we consider an object as a random member of a class if we could select it through a method providing a given a priori relative frequency in the long run to each member of this class.

In his attempt to extend the scope of probability to insurance and life-table problems, Jacques Bernoulli (1713/1987) gave the first proof of the Law of Large Numbers and justified the use of relative frequencies to estimate the value of probabilities. In the frequentist approach sustained later by von Mises (1928/1952) or Renyi (1966/1992), probability is defined as the hypothetical number towards which the relative frequency tends. Such a convergence had been observed in many natural phenomena so that the frequentist approach extended the range of applications enormously. A practical drawback of this conception is that we never get the exact value of probability; its estimation varies from one repetition of the experiment (called sample) to another. Moreover, this approach is not appropriate when it is impossible to repeat the experiment under exactly the same conditions. Another theoretical problem is that the number of experiments that provides sufficient evidence to prove the random nature of the object is undefined.

Subjective view of randomness

In the classical and in the frequentist approaches, randomness is an objective property of an event or an element of a class. Kyburg (1974) criticized this view and proposed a subjective interpretation of randomness composed of the following four elements:

- The object that is supposed to be a random member of a class;
- The set of which the object is a random member (population or collective);
- The property with respect to which the object is a random number of the given class;
- The knowledge of the person giving the judgement of randomness.

In this interpretation, randomness depends on the person's knowledge. Consequently, what is random for one person might be non-random for another; randomness is no longer a physical objective property, but a subjective judgement. We recognize here the parallelism with the subjective conception of probability, in which all probabilities are conditioned by information, and this is adequate in situations where some information may affect our judgement of randomness.

This view was reinforced by the Bayes's theorem, published in 1763, that proved that the probability for a hypothetical event could be revised in light of new available data. Following this new interpretation, some mathematicians like Keynes (1921), Ramsey (1931), or de Finetti (1937/1974) considered probability as a personal degree of belief that depends on a person's knowledge or experience. Via the Bayes' theorem, an initial (prior) distribution about an unknown probability changes by relative frequencies into a posterior distribution. However, the subjective character of the prior distribution in this approach was criticized; even if the impact of the prior diminishes by objective data and de Finetti (1934/1974) proposed a system of axioms to justify this view.

Axiomatization and formal mathematical views

Despite the fierce discussion on the foundations, the application of probability in all sciences and sectors of life was enormous. Throughout the 20th century, different mathematicians tried to formalize the mathematical theory of probability. Following Borel's work on set and measure theory, Kolmogorov (1933/1950) proposed an axiomatic theory that was accepted by the different probability schools because the different view of probability (no matter the classical, frequentist or subjectivist view) may be encoded by Kolmogorov's axioms. However, the particular interpretation of probability and the method used to assign probabilities to events differ according to the school one adheres to.

The development of statistical inference and the importance of assuring random sampling to apply inferential methods led to the practical interest to find procedures to produce sequences of "pseudo-random" digits. This need induced new discussion about theoretical models of randomness (Zabell, 1992). The need to distinguish two components in randomness was clear: the generation process (*random experiment*) and the pattern of the *random sequences* produced. We can generate random sequences with two different methods: one is using physical devices, such as coins or dice. Another is using deterministic algorithms; therefore, we can separate the generating process from the result (random sequence). More correctly, these results are called pseudo-random, because the generating process is a deterministic algorithm, although the sequence can pass some statistical tests for randomness. Most computer packages and calculators incorporate these algorithms, and thus we can easily obtain pseudo-random sequences of a given length with particular characteristics.

Different approaches served to describe the properties of a random sequence (Fine, 1971). Von Mises (1928/1952) defined a *collective* (population) as a mass phenomenon, a repetitive event or a long series of observations, for which we could accept the hypothesis of stabilization or the relative frequency towards a fixed limit. Starting from this idea, he defined a sequence of events to be random if, in any infinitely long series of outcomes, the relative frequencies of the various events have limiting values, and these values do not change in an infinite subsequence arbitrarily selected. Thus, contrary to the belief held by many players, there is no algorithm (at least theoretically) that serves to predict the behaviour of random sequences. However, since no statistical test can consider all potential pattern generators—because there are infinitely many—the possibility that a given sequence, in spite of having passed all our tests must always remain, and it should have some unnoticed pattern and so not really be random. Another problem is that we only produce finite sequences, so inevitably some tests will fail. In this sense, randomness is a theoretical concept and can only be applied to a process producing infinite sequences.

Kolmogorov (1965) defined the randomness of a sequence using the idea of *computational complexity*, taken from automata and computability theory. The complexity of a sequence is the difficulty in describing the sequence with a code that we can use later to reconstruct the sequence (or to store in a computer). The minimal number of signs needed to codify a sequence provides a scale of complexity. For example, 0101010101 can easily be coded with just a few symbols: 5{01}; while 0100110001 defies finding a shorter code, and then the first sequence is more complex than the second. In this approach, a sequence would be random if any coded description of the same is as long as the sequence itself. Therefore, a sequence would be random if the simplest way in which we could describe it is by listing all its components. Chaitin (1975) suggested that this definition establishes a hierarchy in the degree of randomness for different sequences and that perfect randomness is only theoretical.

Epistemic meanings of randomness

To sum up, we can use some ideas from the onto-semiotic approach to mathematics education. In this framework, mathematical knowledge has a socio-epistemic dimension, since it is linked to the activity in which the subject is involved and depends on the institutional and social context in which it is embedded. Mathematical activity is described in terms of practices or sequences of actions, regulated by institutionally established rules, oriented towards solving a problem (Drijvers, Godino, Font, & Trouche, 2013). In this framework, the meaning of mathematical objects is linked to the mathematical practices carried out by somebody (a person or an institution) to solve specific mathematical problems. Around the mathematical practices linked to these specific problems, different rules (concepts, propositions, procedures) emerge (Godino, Batanero, & Font, 2007); these rules are supported by mathematics language (terms and expressions, symbols, graphs, etc.), which, in turn is regulated by the rules. All these objects are linked to arguments that serve to communicate the problem solution properties and procedures, and to validate and generalize them to other contexts and problems.

An epistemic configuration (either institutional or personal) is the system of objects involved in the mathematical practices carried out to solve a specific problem (Figure 1). Each different epistemic meaning of randomness is linked to a specific type of problem whose solution involves particular mathematical objects, part of which are summarised in Table 1. Consequently, there is a specific onto-semiotic configuration linked to each of these meanings, which differ from each other not only in the philosophical aspects debated in the previous sections, but in the mathematical objects that characterize them. As a result, reducing the teaching of randomness to only one or a few of these views implies a reduction of the overall meaning of the concept.

Meaning of randomness	Problem	Concepts/Properties	Procedures
Intuitive	Divination Attempt to control chance	Luck, fate Opinion, belief	Physical devices (dice, coins...)
Classical	Establishing the fair betting in a game of chance	Equiprobability Proportionality Favourable/possible cases Expectation	Enumeration Combinatorial analysis Laplace's rule A priori analysis of the experiment
Frequentist	Estimating the tendency in the long run	Repeatable experiment Frequency Convergence	Collecting data Estimation Limit in the long run
Subjective	Updating a degree of belief	Subjective character Depends on information Non repeatable Conditional probability Prior distribution Posterior distribution Likelihood, risk	Bayes' theorem Decision theory and methods
Formal	Describing mathematical properties of randomness	Random experiment Sample space Events algebra Measure Complexity Random sequence	Abstract mathematics (e.g., set theory) Randomness tests Simulation Algorithms that produce pseudo-random sequences

SUBJECTIVE CONCEPTUALIZATION OF RANDOMNESS

Research dealing with people's conceptualization of randomness has a long history, and different research paradigms are visible in this research.

Levels of acquisition of the concept of randomness

The pioneer work in probabilistic reasoning was due to Piaget and Inhelder (1951) who described levels (or stages) in children's understanding of chance and probability. These authors assumed that randomness is produced by the interference of independent causes, and then, children first have to understand deterministic cause-and-effect phenomena before they can grasp the nature of random events. Another prerequisite for understanding randomness, according to these authors is combinatorial reasoning, which is needed to describe the set of possibilities in random phenomena, and to accept that each isolated outcome is unpredictable.

Piaget and Inhelder (1951) investigated the understanding of patterns in random distributions by children.[1] They designed an experiment simulating the fall of raindrops on the tiles of a pavement. After situating a few counters (raindrops) on the pavement, they asked the children where the next raindrop would fall. In a first stage (6–9 year-old), the children assumed that the raindrops would approximately fall in equal numbers on each square of the pavement. When there was one drop in every square of the pavement, except for one empty square, the children invariably located the next drop in the empty square, so that a uniform distribution was achieved. With increasing

1 Piaget and Inhelder based their research on the classical view of probability.

age, Piaget and Inhelder assumed that the irregularity of the distribution would be accepted and that adolescents would understand randomness.

Later research, however, contradicted this assumption: Green (1989) investigated the probabilistic reasoning of 2 930 children in the United Kingdom and used some tasks related to perception of randomness at age 11–16; his findings suggest that the percentage of students recognizing random distributions does not improve with age (stagnation of children's perception of randomness during this period). Similar results were found by Green (1991) and Engel and Sedlmeier (2005) with different tasks (to students at age 10–15).

Intuitions and personal beliefs

While Inhelder and Piaget focused on the formal understanding of randomness, other authors tried to describe personal beliefs and intuitive understanding of this concept. This research suggests that the paradoxes and controversies about the meaning of randomness are reproduced in the intuitions people build when they face random situations; these intuitions often contradict the mathematical rules of probability (Borovcnik & Kapadia, 2014a).

Children use qualitative expressions (probable, unlikely, feasible, etc.) to express their degrees of belief in the occurrence of random events; however, their ideas are too imprecise and have difficulty in differentiating random and deterministic phenomena (Fischbein & Gazit, 1984). Young children may not see stable properties in random generators such as dice or marbles in urns and believe that such generators have a mind of their own or can be controlled by them (Fischbein, Nello, & Marino, 1991; Truran, 1994). Although older children may accept the need to assign numbers (probabilities) to events to compare their likelihood, a correct probabilistic reasoning rarely develops spontaneously without a specific instruction (Fischbein, 1975); for this reason, adults often have wrong intuitions about probability.

Fischbein's assumption has been confirmed by research in the field of decision making under uncertainty, where erroneous judgements in out-of-school settings are pervasive. The widely known studies by Kahneman and his collaborators (e.g., Kahneman, Slovic, & Tversky, 1982) support the idea that people violate probabilistic rules and use specific *heuristics*[2] to simplify uncertain decisions. According to these authors, heuristics such as *representativeness* or *availaibility* reduce the complexity of probability tasks and may be useful in many situations; however, under specific circumstances these heuristics cause systematic biases with serious consequences. Furthermore, some people do not understand the purpose of probabilistic methods, which allow us to predict the behaviour of a distribution, but are invalid to predict each specific outcome (Konold, 1989). A detailed survey of students' intuitions, strategies and learning at different ages may be found in Chernoff and Sriraman (2014), Jones (2005), Jones, Langrall, and Mooney (2007), and Shaughnessy (1992).

Generating and recognizing randomness

There is a wide research into adults' subjective perception of randomness (e.g., Bar-Hillel & Wagenaar, 1991; Batanero & Serrano, 1999; Chernoff, 2009; 2011; Engel & Sedlmeier, 2005; Falk, 1981; Kahneman & Tversky, 1972; Wagenaar, 1972), Two types of tasks have commonly been used: (a) In generation tasks subjects follow standard instructions to invent a series of outcomes from a typical random process, such as tossing a coin; (b) In comparative likelihood tasks (Chernoff, 2011), people are asked to select the most or least likely of several sequences of results that have been produced by a random device or to decide whether some given sequences were produced by a random mechanism. Related tasks have also been proposed using two-dimensional random distributions of points on a squared grill (e.g., Batanero & Serrano, 1999; Green, 1991; Engel & Sedlmeier, 2005; Toohey, 1995).

Generation tasks: Producing random distributions

In a longitudinal study on randomness with 7 to 11 year-old children, Green (1991) asked them to invent random sequences of heads and tails representing the results of flipping 50 times a fair coin. He first analysed whether the children produced approximately the same number of heads and tails in their sequences and found that they were very exact in reproducing equiprobability (the average number of heads was close to 25); furthermore, the children produced sequences with very consistent first and second parts (about 12 heads in each part). Green concluded that children were too consistent to reflect the random

2 The specific meaning of word heuristics in this research is a cognitive process that helps to solve a problem by reducing part of the data.

variability. Moreover, these children did not perceive the independence, as they produced sequences with too short runs (of heads or of tails), as compared to the length we expect in a random sequence. As suggested by Bryant and Nunes (2012), the independence of random events is hard to grasp and many adults believe that a head is more likely to appear on the sixth flipping of a coin after a run of five tails.

Comparative likelihood tasks: Properties attributed to randomness

Results from research asking people to distinguish random from non-random sequences of events suggest that our judgements about what random sequences are, is subjected to biases (e.g., Batanero & Serrano, 1999; Chernoff, 2009, 2011; Green, 1983, 1991; Kahneman & Tversky, 1972; Konold, Pollatsek, Well, Lohmeier, & Lipson, 1993; Shaughnessy, 1977).

An example of this research is Green's (1983) study with 11–16 year-old children. In his questionnaire, he asked the children to discriminate between a random and a non-random sequence (both sequences consisted of results of flipping a coin 150 times). Most participants in the study chose the non-random sequence, regardless of their age. Some of them provided incorrect reasons to justify their choice; for example, they argued that the pattern of the sequence was too irregular (and then they did not accept the variability of the random sequence). Other participants expected exactly 50% of heads and tails in a random sequence or rejected the possibility of long runs. Very similar results were found in another study (Green, 1991) where the author asked the children to discriminate random and non-random sequences of heads and tails, as well as random and non-random bi-dimensional distribution of points.

Toohey (1995) used part of Green's tasks in a study with 75 12–16 year olds in Melbourne. He suggested that the understanding of randomness involves accepting the ideas of equal/unequal likelihood, multiple possibilities, model, causality and unpredictability. He also identified two different possibilities (local and global) in attributions of randomness. The local perspective of randomness is based on isolated results, while global perspective is reliant on the frequency distribution of the different outcomes.

Batanero and Serrano (1999) proposed some items taken from Green (1991) to 277 students aged 14 and 18 and analysed the reasons they gave to decide that a sequence or a distribution was random. The students' arguments were related to the observed frequencies of events (close or different from the expected value), the overall pattern of the distribution (uniform distribution or variability), the length of the runs (too short or too long runs), the existence of multiple possibilities and the unpredictability of results. Even when the authors found some widespread misconceptions, they also noticed that the students were able to perceive the characteristics of the random sequences presented to them and that this recognition improved by age. They also identified some partly correct conceptions that reproduced the conceptions of randomness described in the first sections of this paper, which were considered correct in different historical periods. Consistent results were reported by Engel and Sedlmeier (2005) in a cross sectional study that examined German students' understanding of variability in empirical data and by Batanero, Gómez, Gea, and Contreras (2014) in a study with Spanish prospective primary school teachers[3].

Facing the subjects with their own misconceptions: statistical analysis of their own data

As analysed in the previous sections, the perception of randomness is deduced with either generation or recognition tasks. Batanero and colleagues (2014) combined both tasks in a study with 208 Spanish prospective primary school teachers, using a formative activity with two parts. In the first part (a classroom session), the prospective teachers carried out an experiment to decide whether the group had good intuitions on randomness or not. The experiment consisted of trying to write down apparent random results of flipping a fair coin 20 times (without really throwing the coin, just inventing the results) in such a way that other people would think the coin was flipped at random (invented sequence). Participants recorded the invented sequences on a recording sheet (this is a typical generation tasks). These sequences were analysed by the researchers and were consistent with previous research reported on generation tasks.

Batanero and colleagues also asked the prospective teachers to analyse some variables deduced from

3 Prospective primary school teachers do not follow a specific course of probability. They study elementary probability in their first year of studies and along secondary school (as a part of mathematics).

their invented sequences (number of heads, number of runs, and length of the longer run) and compare them with the same variables in real coin-flipping sequences as a result of flipping a fair coin 20 times. The prospective teachers were asked to carry out the statistical analysis of differences between the same variables in the real coin-flipping and invented sequences for the whole group. They were also asked to prepare a report with their conclusions about how good their perception of randomness based on the statistical analysis, was. Each prospective teacher analysed the results in his or her group (30–40 students per group) using elementary graphs and statistics; they had freedom to use any method they wished. This second part of the activity is a sophisticated version of a comparative likelihood task, because the participants were not only asked to discriminate the random (real flipping) from non-random (invented) sequences. They were only asked to perform (intuitively) the type of analysis that researchers use to study people's perception of randomness. This activity was highly motivating for the prospective teachers and served to simultaneously increase their statistical and didactical knowledge.

Results from this second part firstly showed that these prospective teachers were able to use their statistical knowledge to solve a real world problem (deciding if the perception of randomness in the group was good). They secondly completed a modelling cycle: they started from a real problem (studying the intuitions on randomness), simplified the problem, and decided which aspects were relevant. They thirdly built some mathematical models to study the problem, worked with the models, and finally interpreted the results to answer the real world question. As regards their perception of randomness, many of the primitive conceptions described in Batanero and Serrano (1999) appeared and part of them were identified by the prospective teachers' themselves. Participants also recognised that the classroom showed a good perception of the expected value and a poor conception of both independence and variation. Some new results emerged; for example, some prospective teachers believed that it is not possible to apply mathematical methods (statistics) to study random phenomena, because of their unpredictability. A few participants also believed they could predict or control the outcomes in a random process (illusion of control described by Langer, 1975).

Other research paradigms

A different approach to evaluate people's perception was taken by Konold, Lohmeier, Pollatsek, and Well (1991) who concentrated on the random process (instead of concentrating on the random sequence). They asked the subjects in their study to decide whether different types of situations (processes) were or were not random and justify their responses. They used processes with equiprobable and non-equiprobable outcomes. While they found no differences in the subjects' categorization of the situations as random, novices tended to feel that the non-equiprobable situations were not random. The analysis of students' arguments served to describe the following conceptions of randomness:

— *Randomness as equiprobability:* Subjects that only consider randomness where all the possible results are equally probable.

— *Randomness as opposed to causality*, or as a special type of cause.

— *Randomness as uncertainty;* existence of multiple possibilities in the same conditions.

— *Randomness as a model* to represent some phenomenon, depending on our information about it.

Randomization is an important statistical procedure that assures the proper application of statistical methods, such as statistical tests. Pratt (2000) and Pratt and Noss (2002) investigated children's understanding of randomization when playing chance games and found 10-year olds that understood the connection between randomness and fairness, and the role of randomization in ensuring fairness (see also Johnston-Wilder & Pratt, 2007; Paparistodemou, Noss, & Pratt, 2008). Pratt (2000) suggests that children reason with two different meanings for randomness (very close to the description by Toohey, 1995): a local perception is related to the impossibility to predict the process behaviour in each trial, while a global perception involves the children´s understanding of patterns in the long run and in the distributions.

As it is apparent in our survey, research into people's perception of randomness has been faced with different paradigms that provided complementary results. Yet new questions remain open; in particular, it is not clear what model of randomness is better suited for children at different ages, or how we can help students acquire progressively more complete models of randomness as they become adult. We now analyse the way the topic has been taken into account in the curricula.

TEACHING AND LEARNING

Randomness in school curricula

The different views of probability have been reflected on the teaching of probability in schools, and on the way, randomness has been conceptualized in the curricula in Spain and other European countries; the concept itself is often only introduced via examples of random and non-random situations, or with indirect reference to isolated properties (e.g., unpredictability) (Azcárate, Cardeñoso, & Serradó, 2005), but is not formally defined.

According to Henry (2010), the classical view of probability based on combinatorial calculus dominated the French school curricula until the 80s, and this was also the case in Spain and other European countries. Since combinatorial reasoning is difficult, the teaching of probability was postponed until grades 8 or 9 (14 year-olds), an age where wrong intuitions difficult to eradicate are already acquired. Throughout the "modern mathematics" era, probability was used to illustrate set theory; there was little interest in modelling random phenomena from the real world. In these two approaches, the applications were restricted to games of chance; consequently, many school teachers considered probability as a part of recreational mathematics, with not much value for the education of children and tended to reduce its teaching.

Today, due to the technology available, we use the frequentist view to introduce probability as the limit of relative frequencies in a long series of trials. This change also involves a shift from a formula-based approach to an emphasis on providing probabilistic experience. Even very young children are encouraged to perform random experiments or simulations, formulate questions or predictions about the tendency of outcomes in a series of these experiments, collect and analyse data to test their conjectures, and justify their conclusions based on these data. This view also connects to the current interest for modelling in school mathematics (Henry, 2010), since simulation can also help students distinguish between model (the theoretical probability) and reality (frequencies of experimental results) (Girard, 1997; Engel & Vogel, 2004).

Randomness receives prominence today at high school level in relation to the introduction of inference (or "informal inference"). For example, in the CCSSI (2010) for grade 7 we find "use random sampling to draw inferences about a population" and "understand and evaluate random processes underlying statistical experiments". For high school (grades 9–12), this curriculum specifies "define a random variable for a quantity of interest by assigning a numerical value", "use random number generators", and "collect data from a random sample of a population". Many other curricula in Europe, as well as in the Australia, New Zealand and the United States approach probability and inference in a frequentist way, using simulation and resampling to estimate the probabilities of interest (e.g., Frischemeier & Biehler, 2013). The subjective view, that takes into account one-off decisions, which are frequent in everyday life, and where we cannot apply the frequentist view, is hardly considered in the curriculum. Moreover, the experiments we often simulate are atypical examples of random situations, in the sense that in few real-life applications of probability can we repeat a process many times in exactly the same conditions (Borovcnik & Kapadia, 2014a).

A didactic approach to randomness

The many perspectives and properties of randomness described in the previous sections suggest that a complete understanding of randomness is only achieved gradually. Moreover, probability models do not exactly fit reality and therefore should be viewed more as scenarios to explore reality than as images of this reality (Borovcnik, 2006). Since feedback in probability is only indirect (after a long series of trials), understanding of probability is not easy.

Throughout primary school, we can encourage children to discriminate certain, possible and impossible events in different context, and use the language of chance. Starting with specific materials with symmetrical properties, such as dice or coins, the children can compare their predictions from the a-priori analysis of the structure with frequency from data collected from repeated experiments to estimate probability.

In a second stage, we can progressively move to the study of materials lacking symmetry properties – spinners with unequal areas, thumbtacks, etc. –, where we only can estimate probability from frequencies. Once this phase is successful, we can turn to real life (e.g., sports, demographic, or social phenomena), using data available from the daily press, Internet, or other sources. Subjective situations (e.g., should the teacher ask me next time?) where only personal probabilities can be applied, can complete the field of application of probability.

By the end of primary school or in early middle school (10–11 year olds) children can start simulating simple situations using devices such as the box model simulator in the National Library of Virtual Manipulatives (http://nlvm.usu.edu/). Today, there are plenty of technological resources, including software specially designed to explore probability (see also Lee & Lee, 2009). With simulation, we introduce a modelling approach where the essential features of the situation are modelled by the simulator and irrelevant properties are disregarded. As shown by Pratt (2000), simulation of familiar objects like dice, can help 10–11 year-old children express their previous beliefs and articulate a more complete meaning for randomness in the light of their experiences with the simulator.

Towards the end of secondary school (15–16 year olds) a deeper analysis of the properties of the random numbers generated through a calculator or computer may be introduced. The experiments, recording and analysis of the sequences produced in these simulation activities will help to integrate study of probability and statistics. Eichler and Vogel (2014) propose a modelling approach for each of the main views of probability (classical, frequentist and subjective) and discuss the role of simulation in supporting students' understanding in each of these perspectives. The context of decision making, such as for example, taking insurance, is useful to introduce subjective views. When facing the uncertainty of a single decision, this decision could be made more transparent if we ask the students to weigh up the different possibilities, and compute the expected values of costs or prizes (Borovcnik, 2006).

The gradual introduction of concepts and notation will serve to mathematically explain the regularities observed in the data. Exploration of microworlds (e.g, Cerulli, Chioccariello, & Lemut, 2006) may serve to confront children´s intuitions to mathematical ideas. Johnston-Wilder and Pratt (2007) suggest that these tools help children see randomness as a dynamic process, since a printout of a random sequence loses the essence of what random is to be.

Through these activities, students will progressively acquire understanding of the following essential characteristics of random phenomena:

— In a random situation there is uncertainty; more than one result is possible.

— The actual result, which will occur, is unpredictable (local variability of random processes).

— We can analyse either the process (random generator) or the sequence of random results: these two aspects can be separated.

— In a few situations (e.g., games of chance) we can analyse the process before the experiment; this analysis will inform us of the likelihood of possible results

— Commonly, there is the possibility—at least in the imagination—of repeating the experiment (or observation) many times in (almost) similar conditions.

— In this case, the sequence of results obtained through repetition lacks a pattern; we cannot control or predict each result (local variability).

— In this apparent disorder, a multitude *of global regularities* can be discovered, the most obvious being the stabilization of the relative frequencies of each possible result. This global regularity is the basis that allows us to study random phenomena using the theory of probability.

— In one-off uncertain situations we still can apply probability if our initial degrees of beliefs are consistent (have reasonable properties).

— To conclude, randomness is a model we apply to some situations, because this model is useful to predict or control the situations.

As argued by Konold and colleagues (1991), it is preferable to consider randomness as a label with which we associate many concepts, such as experiment, event, sample space, probability, etc. In this sense, the word randomness refers to a collection of mathematical concepts and procedures, which we can apply to uncertain situations. We need to think about the orientation we take towards the phenomenon that we qualify as "random" rather than think of randomness as an objective quality of the phenomenon itself. We apply a mathematical model to the situation, because it is useful to describe it and to understand it; but we do not believe that the situation is identical to the model. Deciding when a probability model is more appropriate for the situation than other mathematical models is a part of the competence we want the students to develop.

FINAL REFLECTIONS

The complexity of the idea of randomness explains the counterintuitive results that abound even in basic probabilistic concepts (Székely, 1986; Borovcnik & Peard, 1996). This complexity is also reflected at higher levels in probability theorems (e.g., the Central Limit theorem) that are expressed in terms of probability. According to Borovcnik and Kapadia (2014b), our poor intuitions in this field may be explained by our desire for deterministic explanations, but they might also be attributed to an inadequate education.

In spite of this complexity, "Probability is the only reliable means we have to predict and plan for the future; it plays a huge role in our lives, so we cannot ignore it, and we must teach it to all future citizens" (Devlin, 2014, p. ix). It is then important to reinforce probability in the school curricula and to find appropriate conceptualizations of randomness for different ages.

One goal of probability education is to take advantage of children's intuitions from elementary school as a basis for the acquisition of probability reasoning. One important insight into this line of research is the power of representation formats, such as natural frequencies (Gigerenzer & Hoffrage, 1995) or "tinker cubes" and other manipulatives (Martignon, Laskey, & Kurz-Milcke, 2007). Experimental interaction with mathematical modelling in a co-operative setting can likewise help children develop secondary intuitions (Nilson, 2003). Besides, as suggested by Andrà and Stanja (2013) it is important to pay attention to the interpretation and use of signs, which is not self-evident in probability, and may be interfered with experience with the same signs in other mathematical domains.

It is also important to confront the students with their own misconceptions and erroneous beliefs. As discussed by Borovcnik and Kapadia (2014b), progress in the development of mathematical concepts is usually accompanied by ruptures and conflicts, but there is an opportunity for learning when one tries to solve the conflict and understand paradoxical results.

Eichler and Vogel (2014) analyse the role of simulation to explore a model that already exists, develop an unknown model approximately, and represent data generation. However, though simulation is vital to improve students' probabilistic intuitions and to materialize probabilistic problems, a genuine knowledge of probability can only be achieved through the study of some formal probability theory. Of course, the acquisition of such formal knowledge by students should be gradual and supported by experience with random experiments.

We should also complement the objective and subjective views of probability. Even when many people believe that events have a unique probability rather than considering probability as a measure of our knowledge (Devlin, 2014), the idea of updating previous information in the light of new data is very intuitive as it reflects the way how people think.

It is also important to empower teachers with a specific preparation to teach probability because teachers' beliefs influence their instructional planning, their classroom practices, and have an impact on their students' learning (Eichler, 2011). Even if prospective teachers have a major in mathematics, they may be unfamiliar with different meanings of randomness and probability, or with their students' most common misconceptions. Teachers should also be conscious that teaching principles valid for other areas of mathematics, are not always appropriate in the field of probability (Batanero & Díaz, 2012). As described in a teaching experiment reported by Brousseau, Brousseau, and Warfield (2002), the teacher may fail to produce a specific random result when needed (even if he/she manages to assure a good probability of happening for the given result). Thus, even a reasonable knowledge of probability would not suffice for the teacher to be able to reproduce the didactic situation exactly as he/she prefers, and this could be a source of challenge for the teacher.

The preparation of teachers requires the design of activities where teachers are first confronted with their previous ideas and then perform and discuss experiments (e.g., Batanero, Biehler, Engel, Maxara, & Vogel, 2005; Batanero et al., 2014) in order to simultaneously increase teachers' probabilistic and didactic knowledge.

Research in teacher education and innovation at schools: Cooperation, competition or two separate worlds?

Jarmila Novotná

Charles University in Prague, Faculty of Education, Czech Republic, jarmila.novotna@pedf.cuni.cz

The plenary lecture builds on the plenary lecture from ICME10 (Survey team 3). The lecture defined areas that had attracted little attention of researchers but were crucial (not only) for teacher education. It also comes out of discussions on ICMI Study 15 and recommendations formulated in these discussions. The lecture is also significantly informed by the work of Working Groups at CERME conferences since CERME1 until CERME8, partially also taking into account information from CERME9. The field of research in mathematics teacher education has changed considerably over the years since ICME10, which asks for a new definition of issues and trends. The goal of the lecture is to point out some trends in this area of research, especially in the field of cooperation between teacher education and innovations at school.

The first part of the text focuses on trends in current research into teacher education and practice. The goal of this part is not an exhaustive overview but indication of the main trends in the research domain. The second part of the text presents a more detailed discussion of several current research areas, their theoretical backgrounds as well as applications of their findings in teacher education and everyday school practice.

Keywords: Teacher education, cooperation of teachers and researchers, changes in teachers' knowledge, beliefs and approaches, problem solving.

INTRODUCTION

Let me begin the text by my personal confession: When the Programme Committee of CERME9 offered me to give a plenary lecture on the topic "Research into teacher education and practice", I felt that this was great honour and I was excited, even thrilled by the ideas of starting work on the plenary lecture. However, my initial enthusiasm slowly lessened. The reason for this faltering were not any doubts on the relevance of the topic. However, the deeper I emerged into the issue, the more aware I grew of the immense scope of research I could get access to. I realized that my lecture would never be and could not be exhausting and that I would have to focus on selected aspects of the issue only. I decided to build the plenary lecture on three important resources to which I had personally contributed:

— The plenary lecture from ICME10 (Adler, Ball, Krainer, Lin, & Novotná, 2004) in which the areas that had attracted little attention of researchers but were crucial (not only) for teacher education were defined. However, the field of research in mathematics teacher education has changed considerably over the years since ICME10, which asks for a new definition of issues and trends.

— ICMI Study 15 "The Professional Education and Development of Teachers of Mathematics" (Ball & Even, 2009). This study confirmed the great variety of research in this area. All this research attracts a lot of attention worldwide and brings new and interesting results.

— CERME conferences, where teacher education has always been paid much attention to. The focal point has been shifting with respect to the development of research in the area. However, it has always been based on the interaction between practices in teacher education and requirements of everyday school practice.

The focus of the first part of the text is on developments in research into teacher education and practice until present. The goal of this part is to point out main trends in the research domain. It is important not only to list the topics addressed by research since CERME1 but also to show the used methodologies and posed research questions.

The aim of the second part of the text is to illustrate some of the trends in research in teacher education and innovations at schools, focusing mainly on the further development of teachers' knowledge, beliefs about and approaches to mathematics education resulting from cooperation with researchers. When selecting from the many, the attention was paid to those areas of research that the author is familiar with and in which she has been involved.

RESEARCH INTO TEACHER EDUCATION AND PRACTICE UNTIL PRESENT

Survey Team 3 at ICME10. Research on mathematics teacher education: Mirror images of an emerging field

The Survey Team 3 (ST3) consisted of the following members: Jill Adler, Deborah Ball, Konrad Krainer, Fou-Lai Lin and Jarmila Novotná.

As a member of ST3 at ICME10 in Copenhagen, I was involved in collecting information on research focusing on mathematics teacher education in the years 1999–2003 (Adler et al., 2005). This work clearly showed it was inevitable to delimit the areas and issues we would come out of. The survey included published research in international mathematics education journals, international handbooks of mathematics education and some international mathematics education conference proceedings. Some regional sources from various parts of the world were also included. The survey was restricted to 1999–2003, covering the period between ICME9 and ICME10. More than 200 papers were analysed.

The central question for the survey was: *Is research in the field contributing to the improvement of the education of teachers of mathematics?*

The work was framed by the following considerations: What is the state and status of research in mathematics teacher education, within and across contexts? Which problems have been constructed as central in this field in the recent past, and how have these been approached? What shifts – theoretical and methodological – can be discerned and how might they be explained? Who does the research? Where? What progress has been made, empirically, theoretically, methodologically? Are there evident gaps, and if so where? What kind?

We investigated "the *who* (who was writing/doing the research, and from where), the *how* (what methods were used) and the *what* (what was being studied, theoretical orientations, assumptions and outcomes)" (Adler et al., 2004). We also examined the range of findings and conclusions in these studies. These helped to identify four areas that asked for further investigation.

Where is the centre of the field? The investigated publications were divided into two groups. The first includes publications focusing on theorising and understanding teacher learning. The second concerns aspects of curriculum reform, the goals of teacher education initiatives, i.e., evaluation. We identified the shift from studies that tended to tell success stories about teacher education initiatives, and advocacy in the initial phases of curriculum reform, to deeper reflective research that is more convincing in the scholarly sense. Teacher educators' learning was paid much less attention to. It was noted that: "We do not understand well enough how mathematics and teaching, as inter-related objects, come to produce and constitute each other in teacher education practice. We lack adequate knowledge about what and how this happens inside a teacher education program, and then across ranging or contrasting programs, contexts and conditions."

What are the theories and methods in the field? We stated that the field is emerging and needs to increase rigour. The vast majority of this research is case study research, where at least one of the researchers is also a teacher educator, and often the educator(s) whose programme is under study. It certainly makes sense if we want to study teachers' learning and teaching practices. The emergence of theories of situated learning, and attempts to theorise learning of professional practice were identified. In many papers, theoretical frameworks are left implicit. Small-scale qualitative research predominates.

Contexts of mathematics teacher education research: Who, where, and with whom? Most teacher education research is conducted by teacher educators studying the teachers with whom they are working. Attention has mainly been paid to showing that particular programmes of teacher education 'work'; a large number of papers were dealing with reform processes, particularly in the USA, and with teachers in professional communities and in other institutional settings.

Dominance of English-speaking world. This dominance was remarkable (e.g., 80% of the papers published in JMTE have been written by authors from, and report research done in, English-speaking countries). Obviously, the situation is different if we focus on national or regionally focused conferences and journals. The influence of this situation on the orientation of research was not analysed but it certainly has a great impact.

ST3 also formulated domains of interest that were underrepresented in the analysed resources. It was noted that there were fewer studies on:

Teacher working outside of "reform" contexts: Many teachers make effort to develop their teaching skills in environments where reform is not the dominant issue but where they are assisting a wide range of learners in learning mathematics.

Teachers' learning from experience: We do not know enough what teachers learn from experience, whether they learn from experience at all, and what actually supports learning from experience. Teachers spend most of their time doing teaching; we do not understand enough about what helps some teachers to learn from their own teaching while others do not.

Teachers' learning to directly address inequality and diversity in their teaching of mathematics: We do not know enough about teachers' learning to directly address inequality and diversity within their teaching of mathematics (culture, gender, language, socio economic status and mathematical background).

Comparisons of different opportunities to learn: We lack comparisons in the field that compare different opportunities to learn. How does one approach to helping teachers to learn mathematics compare with another?

"*Scaling up*": We do not know enough about what happens when programmes spread to multiple sites, what it means to scale up or what it means to extend a programme that has worked in one setting to another setting – what works, what goes wrong, what designers need to know and think about.

Education of teacher educators: Despite their important role in the system of teacher education, educators' education, professional background, etc. was not studied in the analysed publications.

This was the situation in 2004 perceived through the analyses of ST3. Approximately at the same time, another important event focusing on teacher education, The Fifteenth ICMI Study, was launched. The study was designed to offer an opportunity to develop a cross-cultural conversation about mathematics teacher education in mathematics around the world. The Study Volume is described below (Even & Ball, 2009).

ICMI Study 15: The Professional Education and Development of Teachers of Mathematics

ICMI Study 15 focused on mathematics teacher education practice and policy around the world. As stated in (Even & Ball, 2009), its premise was that the education and continued development of teachers are keys to pupils' opportunities to learn mathematics. What teachers of mathematics know, care about, and do is a product of their experiences and socialization both prior to and after entering teaching, together with the impact of their professional education. It was claimed that systems of teacher education, both initial and continuing, are built on features that are embedded in culture, the organization and nature of schooling, and too rarely is there cross-cultural exchange of knowledge and information about the professional development of teachers of mathematics. Learning about practices and programmes around the world can provide important resources for research, practice, and policy in teacher education, locally and globally.

The contributions accepted to ICMI Study 15 were divided into two Themes: Theme 1 – *Initial mathematics teacher education*, and Theme 2 – *Learning in and from practice*. In several aspects, both Themes brought new ideas in the issues considered by ST3 as less studied in 2004. It is evidenced by the list of main questions discussed in the ICMI Study 15.

Theme 1 focused on the following main questions:

Structure of teacher preparation: How is the preparation of teachers organized – into what kinds of institutions, over what period of time, and with what connections with other post-secondary study? Who teaches teachers, and what qualifies them to do so? How long is teacher preparation, and how is it distributed between formal study and field or apprenticeship experience? How is the preparation of teachers for secondary schooling distinguished from that of teachers for primary and middle levels of schooling?

Curriculum of teacher preparation: What is the nature of the diversity most pressing within a particular context – for example, linguistic, cultural, socio-economic, religious, racial – and how are teachers prepared to teach the diversity of pupils whom they will face in their classes? How are teachers prepared to know mathematics for teaching? What are the special problems of content preparation in different settings, and how are they addressed?

Recruitment and retention: Who enters teaching, and what are the incentives or disincentives to choose teaching as a career in particular settings? What proportion of those who prepare to teach actually end up teaching, and for how long?

Most pressing problems of preparing teachers: Across the initial preparation and early years, what are the special problems of teaching mathematics within a particular context and how are beginning teachers prepared to deal with these problems?

The early years of teaching: What are the conditions for beginning teachers of mathematics in particular settings? What supports exist, and how effective are they, for what aspects of the early years of teaching? What are the special problems faced by beginning teachers, and how are these experienced, mediated, or solved? What is the retention rate of beginning teachers, and what factors seem to affect whether or not beginning teachers remain in teaching? What systems of evaluation of beginning teachers are used, and what are their effects?

Mathematics educators' activities and knowledge: It concerns one of the underrepresented domains mentioned by ST3. These contributions focused mainly on models of educators' development, their quality, national support, their own practice and research.

During the Theme 1 sessions at the ICMI Study 15 conference, additional important questions emerged that had not been included in the Study Volume: What is the role of didactics of mathematics (mathematics education) in teacher education? What is the place of ICT in teacher education? How is the practical part of this preparation (the teaching practicum) integrated? What do we know about the construction of professional knowledge of teachers in relation to teacher education programmes?

The collection of papers in Theme 2 provides a range of approaches to studying teachers' learning. The papers focused on four main domains:

Development of teaching in and from practice: What are the characteristics of the process of developing professional expertise in the teaching of mathematics in and from practice? What are the beliefs, experiences and structures that are significant as far as the development of mathematics teachers and teaching are concerned? What are the conceptual, institutional, cultural, etc. structures that enable and constrain research into teacher development?

Process of learning in and from practice: What are the changes and approaches to professional development? How is the new organization of professional development initiatives for teachers conceived and implemented?

Models, tools and strategies to support learning in and from practice: What are the tools, dynamics, tasks, contexts, and learning settings that can be mobilized for pre- and in-service mathematics teacher education? What are the tasks for mathematics teacher education that are offered to teachers for deepening their knowledge of what and how to teach their pupils? What can be learned from analysing instructional episodes? What is the role and advantages of forming teachers' learning communities where they can share experiences, meanings, knowledge, lessons, etc. from their school practice?

Balance of teachers' mathematical content and pedagogy knowledge: How can we overcome the difficulties in practising teacher education and professional development that are caused by the complexity of the knowledge required for teaching? What is the relationship between teachers' content knowledge and pedagogical practices, considering it from various perspectives?

The Study Volume contains one chapter summarising key issues for research in education and professional development of teachers of mathematics. It focuses on the goals of education, the role of mathematics education, understanding of practice-based professional development for mathematics teachers and the future of strengthening practice in and research on professional education and development of teachers of mathematics.

Examples of more recent work

Research in the area of teacher education and in the area of the potential and consequences of cooperation between teachers and researchers has undergone turbulent developments over the decade since ICME10 and ICMI Study 15. This can be documented by the variety of publications in the area – monographs, articles and special issues of renowned journals as well as various conferences focusing on research in this area. Let us present examples of some more recent work that do not focus narrowly on one aspect of research in the field but try to relate this area into a wider context of mathematics education. Considerable attention is paid to involvement of teachers in research, albeit in the form communities between teachers and teacher educators (see, e.g., Jaworski, 2005; Novotná et al., 2006) or in the form of independent research conducted by teachers themselves (see, e.g., Kincheloe, 2012). All these research studies stress the benefit of teachers' participation in them, despite some limitations.

Teacher education also attracts attention of the International Group for Psychology of Mathematics education. Every year the area is addressed by a significant number of research reports, short oral presentations, posters, working sessions, discussion groups and other components of the programme and is frequently addressed in plenary lectures, panels and research forums. The importance that IGPME pays to teacher education is highlighted also by publishing Handbook of Research on the Psychology of Mathematics Education (Gutiérrez & Boero, 2006) where the fifth section includes two chapters summarizing the PME research on teacher education and professional life of mathematics teachers (Llinares & Krainer, 2006; da Ponte & Chapman, 2006).

Third International Handbook of Mathematics Education (Clements, Bishop, Keitel, Kilpatrick, & Leung, 2013)

The book offers an overview of past, present and future aspects of all areas of mathematics education (social, political and cultural dimensions in mathematics education; mathematics education as a field of study; technology in the mathematics curriculum; and international perspectives on mathematics education). Four out of the eight chapters of the second section focus on mathematics teacher education; they present research methods in mathematics teacher education, teachers as researchers, teachers' learning from teachers and developing mathematics educators.

The chapter *Developing mathematics educators* discusses different types of mathematics educators including teacher educators. It addresses cooperation between teachers and researchers. The concept of teachers as researchers is discussed from different points of view. It contributes to the area described as underrepresented in research in the material prepared by Survey team on ICME10.

Note: The issue of teacher educators has been addressed increasingly in the last ten years. An important step was Volume 4 of the Handbook of Mathematics Teacher Education (Jaworski & Woods, 2008). Recently, the proceedings of the international conference on "Educating the Educators" were published (Maaß, Törner, Wernisch, Schäfer, & Reits-Koncebovski, 2015).

Encyclopedia of Mathematics Education (Lerman, 2014)

This reference work covers all topics in the area of mathematics education. The entries offer theoretical background, summary of important findings and results in the area and provide references to important publications where more detailed information can be found.

One section coordinated by Mellony Graven addresses research in teacher education. The entries cover both the areas of pre- and in-service teacher education and the area of teacher educators, i.e. an area described as underrepresented in research on ICME10. More than twenty entries address directly teacher education and teacher practice and many other are somehow connected to the areas. The consequence of this effort to describe fully and comprehensively all aspects of mathematics education is that also topics described as underrepresented in research on ICME10 were paid due attention. Very valuable are the references to other literature and publications dealing with the topics but also focusing on development of research in the area over years.

ZDM, Mathematics Education (special issue, 47(1), Rösken-Winter, Hoyles, & Blömeke, 2015)
This special issue of the journal focuses on scaling up sustainable interventions through evidence-based CPD. In the articles, four perspectives are considered: crucial aspects of teacher learning, different CPD frameworks and their influence on developments in CPD, the meaning of developing CPD in an evidence-based way and crucial aspects of spreading CPD on a large scale. As Roesken-Winter, Hoyles and Blömeke state in their introductory survey paper, they "draw on Coburn's four dimensions characterizing the process of scaling CPD interventions, depth, sustainability, spread, and shift in reform ownership to discuss how the challenge of scaling high-quality CPD might be successfully addressed". The articles help to fill in some gaps in areas identified by Adler, Ball, Krainer, Lin and Novotná (2004) as underrepresented in research.

CERME CONFERENCES

An immense amount of work on the topic of teacher education and professional development has been done during the CERME conferences, from their early beginnings in Osnabrück, Germany in 1998. Teacher education has always been paid much attention. One Thematic Working Group has always focused on the issue, both on pre-service and in-service levels. Table 1 contains a more detailed look at the development of the issue at CERME conferences. Proceedings from CERMEs are available online at http://www.mathematik.uni-dortmund.de/~erme/index.php?slab=proceedings. It shows that even if the programme components did not have the same focus and followed contemporary trends in research in the area of teacher education in the corresponding period, they always paid attention to interactions between practices in teacher education and requirements of everyday school practice.

The significance of the issue of teacher education since the beginnings of CERME conferences is confirmed by the publication of a separate third part of *CERME1* proceedings: *On Research in Mathematics Teacher Education. From a Study of Teaching Practices to Issues in Teacher education* (Krainer, Goffree, & Berger, 1999). The book builds on the work done by Working Group 3 *Theory and practice of teaching from pre-service to in-service teacher education.* It is divided into six parts with respect to the topic that is addressed: Teacher education and investigations into teacher education; Teacher education and investigations into teachers' beliefs; Teacher education and investigations into teachers' knowledge; Teacher education and investigations into teachers' practice(s); Teacher education through teachers' investigation into their own practice; Investigations into teacher education: Trends, future research, and collaboration.

CERME	WG	Other programme type

9	Mathematics teacher education and professional development	Plenary lecture *Research in teacher education and innovation at schools – Cooperation, competition or two separate worlds?*

Table 1: Development of the topic at CERME conferences

As far as the focus of this plenary lecture is concerned, the most interesting is the last of the above listed areas. The title of the plenary lecture speaks of collaboration, not competition or two separate worlds. Let us recapitulate here the main ideas presented in CERME1 proceedings. They remain topical for research in teacher education and innovation at schools despite being published in a book from 1999 (i.e., 16 years ago).

In the area of *Research in the perspective of teacher education*, the following questions, substantial for the area, are studied: To what extent do mathematics teachers' general beliefs relate to local beliefs (e.g., to specific topics as teaching algebra)? What are the conditions and constraints that influence teaching practice? How do teachers manage the connection between pupils' activities and the acquisition of mathematical knowledge? (The term "acquisition" used here is worth attention, it is broader than the term learning.) What is the interplay between mathematical knowledge and ability, self-confidence, personal history and conceptions of mathematics teachers? How do internal factors interplay with external factors concerning the professional development of teachers? How can problem solving be used as a tool to find out of mathematics teachers' beliefs in order to improve teachers' mathematical knowledge and mathematics teaching?

In the area of *Research in the context of teacher education,* authors study, for example, the following questions: Considering the professional development of teachers, what is the interplay between cognitive processes and cultural, social, affective processes? How do (student) teachers construct (what) knowledge? What is the role of discourse and collaboration? What kind of knowledge do teachers bring to in-service education and how does it grow? Is the gap between what teachers learn at the university (pre-service education) and their practice at schools evident and how could we explore it? How do student teachers develop their understanding of children's ways of thinking during school practice? Why and how do mathematics teachers from one school (want to) further develop their teaching practice using alternative learning and teaching methods?

In the contributions, serious attempts to find bridges between theories and practices of teacher education are present. In particular, the idea of viewing learning environments for (student) teachers at the same time as a meta-learning environment for teacher educators who investigate into (student) teachers' growth and at the same time reflect on their influence within the interaction process is obvious.

The following are the *major trends* sketched in the texts. A broader understanding of research in teacher education is needed; it covers investigations focusing on teachers including their beliefs, knowledge and practice, and engagement of (student) teachers in investigating their own practice. There is an increasing importance of action research as the systematic reflection of practitioners into their own practice. There is an increasing importance of "stories" (narratives, curricula vitae, cases, …). It seems more attention should be paid to cultural, situated, and organizational aspects of processes in classroom and teacher education courses. Moreover, looking for integration and interconnections is crucial.

Pupils' learning, (student) teachers' learning and researchers' and teacher educators' learning are considered as three domains of strongly interconnected learning. The attention is paid to learning from investigations (learning from research questions, from research methodologies, from elaborating the data and from presenting the research).

The Working Group continued its work also at *CERME2*. Its focus was on "teacher education between issues and practical realization". The contributions were based on teachers' knowledge, investigations into teachers' practices, their attitudes; research on the impact of the use of information technologies was also included.

The work in the WG was characterized as follows by its coordinators: "More than in other fields, the researcher in the field of teacher education subject has to balance what is suggested by the theoretical considerations and what is possible to realize in practice. The discussion reflected this position and the themes touched fluctuated between the two poles."

The WG formulated *perspectives for the future*: To investigate professional growth of pre-service teachers, qualified teachers and teacher educators, relationship between theory and practice, teacher development in the classroom, connection between pre-service and in-service education, development of teachers' subject knowledge.

At *CERME3*, two components of the programme were devoted to teacher education: The WG *Inter-relating theory and practice in mathematics teacher education* and the Plenary Panel *Theory and Practice: Facilitating teachers' investigation into their own teaching.*

The topic of the WG attracted an increasing number of authors. In order to keep the discussions efficient, the participants were divided into five subgroups: Teaching approaches in particular curricular areas; Teaching approaches and their development; Elements of reflection in teacher education; Role and nature of collaborative work in teacher education; Inter-relating theory and practice.

WG formulated *issues emerging from discussions*: Situations and problems in teaching are complex and need particular solutions that can only be developed in the specific context of their appearance. There are no general solutions that might be transferred from theory to practice; also at schools, improving and understanding one's own practice is important. More teachers who reflect critically on their teaching, exchange their experiences, and read theory-driven papers in order to broaden their understanding of educational processes are needed. More teacher educators who take their teacher education practice as an object of evaluation and research are needed. Also more collaboration between teacher educators and teachers in order to promote teacher education – as a field of practice and research is essential.

The Plenary Panel, chaired by B. Jaworski, focused on the relationship of theory and practice in mathematics education. Besides Jaworski's introductory and final thoughts, three panellists presented examples from their own country. Bartolini Bussi (2004) briefly presented one special national project for education in Science and Technology SeT Project (1999–2002). Krainer (2004) investigated the relationship theory-practice in the theoretical perspective of four dimensions of "learning systems": *Action*; *Reflection*; *Autonomy*; *Networking*. Bergsten (2004) showed the theory-practice relation in mathematics education as multifaceted.

At *CERME4 and 5*, WGs related to teacher education were focusing on the same main topic: *From a study of teaching practices to issues in teacher education.* In both cases, the work was organized in subgroups; see Table 2 where corresponding topics are in the same row.

It is also of interest to compare emerging issues from the discussion in WGs at both conferences, see Table 3.

Much attention was paid to communities of practice and collaborative work in them. Cooperation between teachers and researchers was evaluated as important. It attracted much more attention at CERME5. At CERME4, attention was also paid to the assessment in mathematics teaching and implementation of ICT. At CERME5, these topics became so common in the discussion that they needed no special emphasis. Moreover, they were also discussed in other WGs focusing on ICT in mathematics education or assessment.

At *CERME6*, teacher education and development were included in WG *Mathematical curriculum and practice* where teacher education was directly linked with school practices. Its subtitle *From study of teaching practices to issues in teacher education* evoked its close link with the corresponding WG at CERME4 and 5. The call for papers asked for theoretical, methodological, empirical or developmental papers on teachers' practices, professional knowledge and teacher education. The work of this WG was organized in the following subgroups: Mathematical curriculum and practice; Professional knowledge (similar but different terms used: knowledge base for teaching; pedagogical content knowledge; competence; subject didac-

CERME4	CERME5
Understanding practice, understanding and promoting the mathematics teacher's development	Models to analyse the practice
Process of becoming a mathematics teacher	Knowledge for teaching (or professional knowledge).
Means, resources and methodology to research on and promote the mathematics teachers' development	Tasks and resources in pre-service teacher education
	Approaching reflection in mathematics teachers' professional development

Table 2: Subgroups at CERME4 and 5

CERME4	CERME5
Demand for theories, perspectives and methods capturing or approaching the flavour and the essence of the classroom activity (various theoretical frameworks)	Discussion on theories, perspectives and methods to approach the flavour of classroom activity
Incompleteness of current models to give an account of the real teaching-learning process	Confrontations of frameworks and models by means of analysing some corpus of a classroom teacher practice observation
Relationship between researchers and teachers	The nature and conditions of collaborative work. Particularly the role of the experts, and the necessity of making it possible that teachers meet together in order to reflect on their practices
Knowledge, pedagogical content knowledge, teachers´ competence (including communities of practice and the socio-cultural theory)	Notion of community of practice and related notions
	Different notions about reflection
Assessment instruments as a tool to support learning	
The role of teacher when using ICT	

Table 3: Emerging issues formulated at CERME4 and 5

tical competence; practical knowledge – beliefs and knowledge); Professional development; Approaching reflection and collaboration in mathematics teachers' professional development (Reflection is a privileged way for professional enhancement. Collaboration is a means for professional development and for research strategy.); Models to analyse the practice (The practice of teachers includes classroom teaching, as well as education and other professional development contexts; How can we manage to make research results and instruments useful for teachers as means in their professional development, and for educators in education contexts?).

One of the *main conclusions* formulated in this WG was the following: "As for primary teachers, also for secondary teachers, mathematical content knowledge and pedagogical content knowledge must be interrelated in teacher education." (Durand-Guerrier, Soury-Lavergne, & Arzarello, 2010, p. 1690).

At *CERME7 and 8*, WGs returned back to the previous title *From a study of teaching practices to issues in teacher education*, which clearly expresses the main focus of the work. In Table 4, the subgroups at both conferences are summarized; again, the allied topics are in the same row.

At both conferences, *critical issues* instead of emerging issues were formulated. The descriptions of these issues at both conferences differ substantially in their number as well as details in their formulations.

CERME7	CERME8
Mathematical content knowledge for teaching	Resources for teaching: Teacher knowledge and teacher beliefs
Professional content knowledge for teaching	
Reflection in mathematics teachers' professional development	Teacher reflection
Professional development	Teacher education and professional development)
Collaboration in mathematics teachers' professional development	Teacher collaboration
Conceptions and practices	Studying mathematics teaching
Interaction in the classroom	

Table 4: Subgroups at CERME7 and 8

CERME7:

- Recognition of the value and complementarities of different approaches to the professional development of teachers

- Recognition that there are constraints and affordances for different approaches, which vary between cultural contexts; working across cultures on teacher development projects, which employ different strategies, was considered to be a useful way of moving forward our understanding of different approaches

- Considerable work to be done in understanding how different frameworks relate to one another and in supporting researchers in selecting elements of different frameworks that will enable them to answer specific research questions

CERME8

- Working with multiple frameworks

- Suitable model for teacher knowledge

- The purpose for developing new theoretical models or for modifying/revising the existing ones

- Analyses of the influence of different types of knowledge

- Ways for promoting teacher knowledge

- Study of the mutual relation between teachers´ knowledge and practice

- The role of context

- Role of teacher educators in helping students/teachers to develop different components of their knowledge – differences for prospective teachers and in-service teachers

Sierpińska's (2011) plenary lecture was devoted to research in teacher education and practices. In the talk, results of an ongoing research, focusing on a framework for analysing the "Teaching Mathematics" courses were presented. "Teaching Mathematics" courses were designed and implemented by the author in cooperation with her colleague. Sierpińska presented her research conducted within the frame of implementation of these courses. The framework of this research might be useful for other researchers wishing to contribute to professionalization of elementary mathematics teacher educators' work.

At *CERME9*, for the first time, teacher education was the theme of three TWGs: *Mathematics teacher education and professional development*, *Mathematics teacher and classroom practices* and *Mathematics teacher knowledge, beliefs and identity.* For the detailed information about all three TWGs discussions and results see the corresponding chapters in CERME9 proceedings.

However, research on teacher knowledge can be come across not only in the corresponding TWGs, it pervades all TWGs, whichever area of mathematics education they deal with. In every TWG, one can come across papers that focus on the topic of the working group but at the same time are related to teacher education. And this is why I decided to call my plenary lecture *Research in teacher education and innovation at schools – Cooperation, competition or two separate worlds*? Are teacher education and innovation at schools closely related areas or are they two separate worlds that have very little or nothing in common? Is teachers' attitude to innovation in mathematics education influenced predominantly by the environment of the school they work at, their own experience with pupils, or by what they have learnt in their teacher education? In other words: Is teacher education an obstacle in the introduction of innovation at schools or does it support the process? Or are they independent of each other? It is very easy to understand the questions, to formulate them. However, it is far from easy to find answer to them and it seems the answers will not allow to be generalized.

Research studies – Summary

Research studies in the field of teacher education and innovation at schools on international level can be divided into at least two main areas: I. Focus on curricula of teacher education; II. Focus on the knowledge a mathematics teacher needs to teach well.

Area I usually includes issues of pre-service teacher education (primary and secondary) and the first years of their teaching practice: for example, structure of teacher education; admission of students into teacher education and their prospective career in the field;

curricula for pre-service mathematics teachers; conditions for novice teachers; preparation of teachers for overcoming obstacles they will come across in their practice; history and development of systems of education in various countries; international comparative studies of teacher education.

The fundamental question related to life-long learning of mathematics teachers and primary teachers is how they can learn for, during and from their teaching practice.

The areas in the spotlight are: What can mathematics teachers learn from their own and other teachers' practice? How do they further develop their knowledge of mathematics and of the ways of teaching mathematics if they work with recordings from teaching practice? How do they learn important information about variety, sociocultural and economic background of their pupils? How is teachers' life-long learning organized? How difficult is it for a teacher to get access to materials such as video recordings, journals, to come to lessons and observe them, etc.?

Research in *Area II* focuses on the knowledge prerequisite to successful teaching of mathematics. International community distinguishes between several types of prerequisite knowledge related to mathematics: the most prominent ones are mathematical content knowledge, MCK, and pedagogical content knowledge, PCK (Shulman, 1986).

There is a lot of discussion on whether MCK and PCK should be regarded as independent of each other or interlinked: For example, should pre-service teachers be taught pedagogical knowledge separately from content knowledge in different courses and seminars or should this be taught simultaneously as pedagogical content knowledge? Much attention is also paid to comparison of experience of novice and experienced teachers.

The turbulent developments in ICT has brought fast development of research focusing on the impact of ICT on teaching mathematics. Knowledge of the potential, advantages and possible risks of using ICT in teaching has become an important part of a teacher's knowledge. ICT supported mathematics education is a complex activity that requires a teacher's deep insight into mathematics, knowledge of a suitable ICT tool and understanding of pupils' thinking processes. That is why the PCK model was amended by knowledge from the area of technology, the so called TPCK (technology pedagogical content knowledge) (Mishra & Koehler, 2006). Apart from the concept of TPCK, research also focuses on consequences of TPCK for teacher education programmes.

COOPERATION OF TEACHERS AND RESEARCHERS

In the second part of the text, we will focus on one aspect of the relationship between teachers' knowledge, approaches to teaching and beliefs on the one hand and innovation at schools on the other. It is connected to two areas: teachers as researchers and cooperation of teachers, teacher educators and researchers. This theme is not new, for example, a PME working group, *Teachers as Researchers*, first met in 1988, and then was meeting annually for nine years. Its work was based on the belief that classroom teachers could and should carry out research connected to the practice of teaching mathematics. The output of this work is the publication of a book (Zack, Mousley, & Breen, 1997). The attention paid at PME conferences to the topic did not end with this publication. The Plenary Panel at PME 27 focused on the issue "Teachers as researchers" (Novotná, Lebethe, Rosen, & Zack, 2003). The follow-up was organized in various forms: discussion groups, working groups and a research forum (Novotná et al., 2006).

In literature, a lot of attention is paid to the impact of teachers' contact with new educational trends in the development of their knowledge in a variety of ways: organisation of teacher education (pre- as well as in-service), opportunities to experience new approaches, access to appropriate resources, etc. Jaworski (2005) believes that one way to add to the body of knowledge is through 'co-learning partnerships':

> The action research movement has demonstrated that practitioners doing research into their own practice [...] learn *in* practice through inquiry and reflection. There is a growing body of research which provides evidence that *outsider* researchers, researching the practice of other practitioners in co-learning partnerships, contribute to knowledge *of* and *in* practice within the communities of which they are a part. (p. 2)

The important issue of teachers as researchers, either cooperating in communities with researchers or doing their own research, is frequently analysed from the perspective of what it adds to the body of knowledge on mathematics education. Less investigated is the issue of what impact this type of teachers' activities has on their beliefs, teaching approaches, their knowledge.

There is no doubt that the cooperation of teachers and researchers is influenced by their pedagogical beliefs and mainly by teachers' reactions to innovative approaches. Hofmannová, Novotná and Hadj-Moussová (2003) investigated how in-service and pre-service teachers react to them.[1] The authors are convinced that without deep changes in teachers' beliefs and attitudes, major changes in pupil learning cannot occur. This corresponds to (Rogers, 1996): "The introduction of learning changes into the area of attitudes is perhaps the most difficult task that faces the teacher educator." The results of the presented research into affective barriers showed prevailing negative attitudes of participating teachers towards new educational trends. The following scheme of categories based on Rogers (1996) was created:

Inner barriers: fear of failing, fear of not meeting the requirements, fear of uncertain success. The identified causes of inner barriers were: changes caused by aging, negative self-concept, too high self-requirements and too positive perception of the others, fatigue.

Outer barriers: lack of time, personal and family problems. The identified causes of outer barriers: inability in time management, too much stress.

These findings had a major impact on the teacher education course because it enabled inclusion of new incentives into the course curricula. These new elements focus on work with teachers' motivation and attitudes. Barriers could thus turn into resources (Moschkovich, 2002).

1 The innovative approach selected for this study was Content and Language Integrated Learning (CLIL): CLIL refers to any teaching of a non-language subject through the medium of a second or foreign language. CLIL suggests equilibrium between content and language learning.

In the following, one example of collaboration of teachers and researchers with an important input of participating teachers is described. The research project is presented from the point of view of the further development of teachers' beliefs and approaches to mathematics education resulting from the cooperation. It shows one form of research collaboration between university academics and teachers of mathematics. The question in the background is: What are the advantages and limitations of such cooperation?

Impact of teachers' participation in research (Eisenmann, Novotná, Přibyl, & Břehovský, 2015)

This study is a part of a three-year research project GAČR P407/12/1939 *Development of culture of problem solving in mathematics in Czech schools*. The goal of the research project is the development of a theory of mathematics problem solving with a focus on the role heuristic strategies play in the development of *pupils' culture of solving problems* (CSP). CSP is understood as a structure of internal factors that influence a pupil's performance and success in problem solving (Eisenmann, Novotná, & Přibyl, 2014).

In short-term (3 months) and long-term (18 month) experiments, lower and upper secondary pupils were introduced by their teachers to heuristic strategies that they rarely or never came across in usual lessons but that are very effective and useful in problem solving. The pupils were led systematically to the use of a suitable heuristic strategy when they come across a problem they cannot solve using "school solving algorithm" (Eisenmann, Novotná, & Přibyl, 2014; Novotná, Eisenmann, & Přibyl, 2015). The research focused on a number of research questions two of which are connected to the area of teacher education and teacher pedagogical beliefs: Will the experiments have impact on the teachers involved? And what will this impact be?

The research team developed sets of problems that can effectively be solved using one heuristic strategy. All these problems were carefully elaborated and commented upon and can be solved in several ways. Selected problems were also subject to a priori analysis (Nováková, 2013) and were piloted on a one-time basis in non-participating classes.

All participating teachers can be described as committed teachers who invest a lot of energy into their teaching and who had attended in-service teacher education courses. They were introducing their pupils to the use of heuristic strategies through solving problems for the period of the experiments.

During both types of experiments, the impact on the participating teachers was analysed. The following changes are reported based on interviews and observation data from the collaborative work with the teachers over the period of the whole experiment and on the basis of the analysis of the structured interviews. The teachers (Novotná, Eisenmann, & Přibyl, 2015)

— lowered their demands on accuracy and correctness in their pupils' communication and recording in favour of understanding the problem solving procedures (which does not entirely correspond with the commonly accepted characterization of mathematics as a domain where accuracy and correctness of communication is an important issue),

— showed more tolerance to variety in pupils' solutions,

— acknowledged a change in their teaching towards constructivist and inquiry-based approaches,

— grew more interested in pupils' solving processes while solving problems;

— one of them reported that she started to think how to eliminate the pervasive pupils' sense of failure (e.g., she decided to use group work more often).

One of the most important results is that most of the participating teachers started to pose their own problems with the aim of making the pupils understand the various strategies better.

How is this research study linked with the results presented in (Hofmannová, Novotná, & Hadj-Moussová, 2003)? It contributes to the discussion on the conditions of cooperation between researchers and teachers and on its benefits for the involved teachers. Deeper understanding of the conditions for successful participation of teachers in research offers

> teachers the scientific background by providing information about research results which is stimulating and which influences their work. Subsequently, the movement reversed and teams of researchers and teachers worked together, either in order to create and disseminate tools for improving education (curriculum, materials, recommendations) or to answer the ongoing needs of certain researchers. (Novotná, Brousseau, Bureš, & Nováková, 2012, p. 326)

The cooperation of teachers and researchers in mathematics education represents a broad and relevant topic. The focus is mostly on the improvement of the quality of mathematics teaching and learning (Brown & Coles, 2000). The above presented studies focus on another research area which is a change in behaviour and practices of teachers involved in research in the area of mathematics education.

CONCLUDING REMARKS

The plenary lecture only covers a small part of research on teacher education and its relationship to innovative teaching strategies. Its ambition was not to be (and considering the scope of the issue could never be) exhaustive. As it was already mentioned, there is an immense number of individual and collective monographs on the issue, a great number of national and international conferences, seminars, summer schools, there are journals specializing on mathematics teacher education, for example, the renowned Journal of Mathematics Teacher Education (JMTE).

Teacher education is the topic of a number of international projects, for example, the completed project Teacher Education and Development Study in Mathematics TEDS-M (Tatto et al., 2012; http://teds.educ.msu.edu/) focusing on pre-service teacher education or the currently running project FIRSTMATH – The First Five Years of Mathematics Teaching (firstmath.educ.msu.edu/) focusing on the first five years of teaching practice of novice teachers. One of the recent events, ICMI Study 23 Primary Mathematics Study on Whole Numbers, whose conference took place in June 2015 (Sun, Kaur, & Novotná, 2015) and the Volume is now under preparation, pays considerable attention to research in teacher education – two chapters in the volume focus on this topic.

The presented survey in various resources implies that some of the issues that seemed to be underrepresented at ICME10 in Copenhagen are now much more fully developed (e.g., the issues concerning teacher educators). However, there are still areas that deserve more attention and research work.

To conclude, let us recapitulate the main and most frequent areas of study in research into teacher education since ICME10: Much attention has been paid to the balance between mathematical content knowledge (MCK) and pedagogical content knowledge (PCK). This area also covers works on knowledge prerequisite to cross curricular teaching of mathematics (inside mathematics or between mathematics and other subjects). Another important issue is the field of professional seeing of (student) teachers of mathematics and the "ability to notice" as integral part of PCK.

Also technology pedagogical content knowledge (TCPK) is one of the subjects of research in mathematics education that have become more prominent. The use of e-learning and b-learning (blended learning) environments in teacher education and teaching practice belong to this field.

School mathematics is based on problem solving. Therefore it comes as no surprise that much attention of research is paid to a teacher's knowledge prerequisite to the efficient use of various solving strategies when solving mathematics problems (see e.g., Novotná, Brousseau, Bureš, & Nováková, 2012). This is closely related to a teacher's competence to pose problems.

Another research area that got more attention is the issue of mathematical literacy and numeracy. This research studies the relations between mathematical literacy and mathematics education and tries to define the requirements on the teacher and their knowledge. Important here is the teacher's mathematical culture and the potential for its development. Some researchers also focus on knowledge and skills prerequisite to the development of pupils' mathematical culture which has important consequences for research into assessment in mathematics and into didactic approaches to possible learners' difficulties. All this is in a narrow relationship with the cooperation between researchers and teachers and the further development of mathematics teachers' beliefs.

The paper started with the author's personal confession. Let it be concluded in a similar spirit: The three presented examples come from research studies in which the author was involved. They illustrate different views on the topic of this plenary lecture. I am convinced teacher education and innovation at schools are related to each other, they influence each other and if they are separate, the conditions for their development are much worse. Researchers in mathematics education should always bear in mind whom the research concerns and how to make the teaching community interested in the findings. Either by inviting teachers to participate in the research, its design and activities, or by communicating the findings well to practising teachers, giving them support and getting from them feedback on how the innovation works in real school conditions.

ACKNOWLEDGEMENT

The research was partly supported by Czech Science Foundation project P407/12/1939.

TWG01
Argumentation and proof

Introduction to the papers of TWG01: Argumentation and proof

Samuele Antonini[1], Orly Buchbinder[2], Kirsten Pfeiffer[3] and Gabriel J. Stylianides[4]

4 University of Oxford, Department of Education, Oxford, UK

INTRODUCTION

The role and importance assigned to argumentation and proof in the last decades has led to an enormous variety of approaches to research in this area. The 21 papers and 5 posters presented in TWG Argumentation and proof come from 15 countries, residing in 4 continents, and offering a wide spectrum of perspectives. These contributions intertwine educational issues with explicit references to mathematical, logical, historical, philosophical, epistemological, psychological, curricular, anthropological and sociological issues.

Taking into account this diversity, the contributions were presented and discussed in working sessions under seven themes: theoretical and philosophical issues; theoretical and philosophical issues including Habermas' rationality; argumentation and proof in teacher education; argumentation and proof in textbooks; argumentation and proof at the university level; proof representation; and performance, assessment and abilities.

THEORETICAL AND PHILOSOPHICAL ISSUES

The three papers presented in this session concerned various theoretical issues.

Knipping, Rott and Reid contrast three different perspectives when analyzing classroom argumentation (interactional, task analysis, and sociological). In particular, they state that multiple perspectives and levels of analysis are required in research on classroom argumentation, showing that each of these perspectives offers insights into students' argumentations but no single perspective is adequate to completely describe the nature of students' argumentations and ways to support their development.

In the framework of Husserl's transcendental phenomenology, Moutsios-Rentzos and Spyrou present a reading of the genesis of proof in ancient Greece. The philosophical and historical analysis aims to set up a didactical framework to foster students' need for proving.

The paper by Raman-Sunström and Öhman focuses on the notion of mathematical 'fit', with the goal of identifying some of its characteristics. In particular, their analysis leads to investigation of the relations between the 'mathematical fit', the notion of explanation and some issues related to the aesthetic aspects of proof.

Finally, two posters were presented. Pericleous discusses a study in a Cypriot classroom in the framework of Activity Theory. Vallejo and Ordoñez provide an example of proof-based teaching discussing knowledge construction in the field of natural numbers.

THEORETICAL AND PHILOSOPHICAL ISSUES, INCLUDING HABERMAS RATIONALITY

Three presentations were concerned with the 'scientific culture' in the classroom and in particular with analysis of different aspects based on Habermas' (1998) construct of rationality. Cramer investigates how Habermas' theory helps to explore obstacles and barriers to argumentation. Goizueta and Mariotti focus on the assessment of the validity of mathematical models in a problem-solving situation and underline the need for research to analyze epistemological aspects of the mathematical culture of the classroom.

Boero applies Habermas' theory to analyze a university student's attempt to prove an elementary theorem concerning continuous functions in epsilon-delta calculus.

The presentation of papers stimulated a rich discussion on Habermas' theory of rationality as a research tool which provides a 'dynamic vision' of mathematical activity, and as a general perspective for analyzing the epistemological dimension of classroom interactions and its socio-interactive roots.

The two posters presented in the session involve different frameworks that were discussed and compared with Habermas' rationality: the Toulmin (1958) model in the Ishii's poster, and a competence-based four step model set up by Süss-Stepancik and Götz.

ARGUMENTATION AND PROOF IN TEACHER EDUCATION

In recent years, the general interest in research in mathematics teacher education has stimulated many questions in research about argumentation and proof and teacher education. The presentations of papers in this session considered a variety of different tasks and activities.

Kempen and Biehler focus on perception of generic proofs in number theory and identify three different kinds of pre-service teachers' perceptions of proof: logical acceptance and psychological conviction, general acceptance of the concept and psychological uncertainty, and inappropriate understanding of the concept.

The paper by Buchbinder and Cook is concerned with learning opportunities for pre-service teachers. They suggest that proof construction can be fruitfully inspired by exploring unconventional computational algorithms presented through math-tricks.

From a different point of view, Erkek and Işıksal-Bostan's paper focuses on advantages and disadvantages of the use of GeoGebra in a study involving pre-service elementary mathematics teachers.

The poster by Modeste and Rojas discusses a research project that aims to build a model of mathematical activity that can be used in primary teacher education. The main issues discussed in the session were the design of proving tasks with the goal to avoid cultivating misconceptions in the teaching of proof, and to foster positive attitudes towards mathematics.

ARGUMENTATION AND PROOF IN TEXTBOOKS

Textbooks play a major role in everyday mathematics practice in many countries around the world and many teachers rely heavily on their textbooks that influence their decisions of which tasks to implement in the classroom, and how to implement them. Using different theoretical frameworks and adopting different approaches to the analysis, three papers investigate aspects related to argumentation and proof in textbooks in four different countries: Israel, Spain, Sweden and Finland.

Silverman and Even characterize justification and explanation for mathematical statements offered in 7th grade Israeli textbooks. The analysis revealed that the textbooks commonly used several modes of reasoning in explanations for each statement. Nearly every justification was deductive or empirical, yet different modes of reasoning were used for geometric and for algebraic statements.

Bergwall presents a framework for analyzing generality in proving tasks in calculus in Swedish and Finnish textbooks. The author discusses the usefulness of framework in analyzing and comparing textbooks and states that there is not necessarily a correlation between the number of general proving tasks and the opportunities for students to engage in reasoning about arbitrary functions.

Finally, Conejo, Arce and Ortega present the evolution of the proof schemes shown in grades 11 and 12 textbooks related to the theorems of limits. In particular, they develop a framework based on Harel and Sowder's (1998) notion of "proof schemes" and show a case study applying the framework to Spanish mathematical textbooks from the 70s until today.

The discussion focused on methodological aspects related to the unit of analysis (e.g. task, lesson, chapter, etc.) and on the difficulties identifying proof and argumentation tasks in textbooks (e.g. looking for keywords like "prove" or "show" might not be enough).

ARGUMENTATION AND PROOF AT THE UNIVERSITY LEVEL

Mathematics education at university level and, in particular, the teaching of proof and proving require specific methodological approaches and theoretical considerations that take into account the specific goals and the modality of teaching in this academic setting.

The theoretical paper presented by Annie Selden and John Selden suggests a perspective for understanding university students' proof constructions based on the ideas of conceptual and procedural knowledge, explicit and implicit learning, behavioral schemas, automaticity, working memory, consciousness, and two systems cognition.

One technique that future mathematicians should master is proof by reductio ad absurdum. Alvarado and González focus on it and present part of a research study in which college students performed a task which required application of this technique.

During the session, the discussion focused on the need for development of tasks, sequences of tasks and courses, as well as specific didactical approaches to support university students' proof production and comprehension. In this vein, Pfeiffer and Quinlan presented a paper on proof evaluation tasks in a university mathematics course. The responses to the task, in which students were asked to evaluate and rank different proposed proofs, provided rich opportunities for students to attend to the nature and functions of mathematical proofs; the task also revealed some interesting features of students' thinking. The authors argue that proof evaluation tasks can afford rich learning opportunities as well as enable novice students to participate in authentic mathematical practice.

PROOF REPRESENTATION

Contributions in this session discuss aspects of representation of proof, with particular attention to oral and written modes of representation, which involve different cognitive processes, and require careful consideration when one attempts to interpret research findings on students' conceptions of proof, and when comparing findings from different studies.

In particular, Andreas Stylianides focuses on the role of the mode of representation in students' argument constructions. He discusses findings from a classroom-based design experiment suggesting that the use of an oral mode of representation may be more likely, compared to a written mode, to support the construction of an argument that approximates or meets the standard of proof. This raises concern about the validity of research findings reported in the literature on students' conceptions of proof, and creates difficulties in comparing findings across different studies.

Azrou's paper deals with the writing of a proof text as the final step of the proving process. She describes university students' difficulties to get a satisfactory product, which frequently result in an unclear text in a disorganized form, in particular when students are asked to answer open questions.

The aim of Moulin's and Deloustal-Jorrand's work is to explore potential functions of stories in the learning of Science and Mathematics with the focus on potential connections between the mathematical space and the rhetorical space during problem solving activity. They characterize theoretically a processes-transferring space between the narrative activity and the problem solving activity. By analyzing oral and written products of children work, they show that the narration act supports students' mathematical reasoning.

PERFORMANCE, ASSESSMENT, ABILITIES

The main issues discussed in this session concerned the importance of a priori analysis of assessment tasks in order to understand their requirements and compare to students' mathematical histories, and the influence of the type of curriculum on students' proof performance.

In particular, Sears and Chávez examine students' performance on a proof task about corresponding parts of congruent triangles. Using data from 1936 students, they show that, regardless of curriculum type, students experience difficulty with constructing this type of proof.

Luz and Yerushalmy examine the design principles of e-assessment of understanding of geometric proofs. In particular, they review various proving task-design studies, looking for a template that incorporates interactive sketching that can be checked automatically.

Finally, the participants were involved in a debate on the question about the possibility, in mixed-ability lower secondary school classrooms, to engage all students in proof without compromising the development of the proof abilities of the most "talented" students. In particular, Moya, Gutiérrez and Jaime present a study on the ability to make proofs of mathematically talented secondary students attempting geometry proof problems.

CONCLUSIONS

We think that TWG on argumentation and proof has offered the participants the richness of diversity in this research domain and the opportunity of fruitful discussions. It also seemed to stimulate not only the interest of comparison but also the curiosity of undertaking a possible integration of different perspectives and the need of enhancing the development of international collaborations.

Proof by reductio ad absurdum: An experience with university students

Angelina Alvarado Monroy[1] and María Teresa González Astudillo[2]

1 Juárez University of the State of Durango, Durango, Mexico, angelina.alvarado@gmail.com

2 University of Salamanca, Faculty of Education, Salamanca, Spain, maite@usal.es

One technique that future mathematicians should dominate is proof by reductio ad absurdum. This paper presents part of a research study in which college students performed a task in which they needed to apply the knowledge gained using this technique. Small group discussions and a discussion led by the teacher were the methodology used in the classroom to solve the task. Both types of interactions were analyzed using the RBC-C model (Schwarz, Dreyfus, & Hershkowitz, 2009) to document how the construction process took place. It was found through consolidation of epistemic actions that although the students had to deal with difficulties associated with the proof, they were able to use the newly acquired knowledge.

Keywords: Proof, interaction, construction, knowledge.

INTRODUCTION

One of the main activities in mathematics is to prove. However, in recent years, some countries, such as Spain and Mexico have almost banished the practice of proofs from the school curriculum: "The idea of proving has changed over time; it depends on the context and cultural environment. Since the development of modern mathematics, which put too much emphasis on formal proofs, there has been a decline in their use in high school, this has strong implications for the transition to college"(Gómez-Chacón, 2009).

Possible reasons for the difficulties students face when having to develop a proof are a poor ability to formulate [and identify] mathematical statements, inappropriate concept images, a lack of training to generate and use their own examples and only an intuitive understanding of the concepts involved in the proof (Moore, 1994).

Everyday language is an obstacle for the learning of a mathematical proof because of the differences between this language and mathematical language (Epp, 2003). A conditional statement in every day language often admits various connotations of causality and temporality that makes its meaning quite different from the mathematical sense. Sometimes, ordinary language gives a different meaning to the statement caused by the tendency to deduce what is not said. In this sense, Epp (2003) suggests that the difference between everyday language and mathematical language can lead to committing the "reciprocal error" in accepting that "p only if q" is logically equivalent to "if p then q"; to difficulty in the interpretation of quantified propositions; and to the mistakes made in trying to deny the implications.

A lack of knowledge of proof techniques, how to choose the facts and theorems to be applied or when to use or not knowledge based solely on symbolic manipulation and the use of mathematical procedures are also perceived as problematic (Weber, 2001). Logic and proof are conceived separately; to avoid this, instruction must show the proof as a form of validation and the usefulness of language in developing and communicating proofs (Weber, 2001).

In this paper the process of solving a task using proof by reductio ad absurdum is analyzed in a study with university students in Mexico. This activity is part of a broader research study about the design of instructional tasks for teaching proofs and recording the advances made in the process of proving followed by the students as they solved these tasks. The solving process performed both in small groups and through guided interaction with the teacher are analyzed.

However, observation and detailed analysis of the process of construction of proofs in context can be very complicated when the data are massive and confusing. Hershkowitz, Hadas, Dreyfus, & Schwarz (2007) provides an example of research in which the flow of knowledge from one student to another is analyzed until they arrive at a common knowledge base. This type of research focuses on the process of construction and on the constructs at a given point until consolidation is acquired. The authors consider knowledge to be shared if the common knowledge base allows the group of students to continue building and updating knowledge collaboratively on the same topic. The authors acknowledge that they have relied on the work by Cobb (1995) in regard to collaborative learning.

CONCEPTUAL FRAMEWORK

Since students are expected to develop abstract mathematical knowledge, we consider Abstraction in Context (AiC) by Schwarz, Dreyfus, & Hershkowitz (2009) as the a suitable framework for analysis of the interaction. In AiC, abstraction is defined as "a vertical activity for the reorganization of previous mathematical constructs within mathematics and by mathematical meanings so as to lead to a construct that is new to the learner" (Schwarz, Dreyfus, & Hershkowitz, 2009, p. 24).

An abstraction process has three stages: the need for a new construct, emergence and consolidation. The abstraction cannot occur without the need for a new contruct; this need may arise from an intrinsic motivation to overcome contradictions, surprises, or uncertainty. The second stage is central and is where the new construct emerges. Three epistemic actions can be observed in this stage: R-actions (Recognizing), in which the learner recognizes that a specific prior construct is relevant to the situation at hand, B-actions (Building-with), with which the learner constructs recognized acts to achieve understanding of a situation or solve a problem; C-actions (Constructing), using B-actions and integrating previous actions to produce a new construct. The C-action refers to the first time that the learner uses or mentions a construct. In this process, R-actions are nested within B-actions and B-actions are nested within C-actions. C-actions can be nested in C-actions at a higher level. Finally, the third step, consolidation, is a long-term process which occurs when the construct is mentioned, constructed or used after a C-action. This stage is characterized by personal evidence, trust, immediacy, flexibility and care when working with the construct (Dreyfus & Tsamir, 2004) and also when the language is becoming more precise (Hershkowitz, Schwarz, & Dreyfus, 2001), although Kidron (2008) and Gilboa, Dreyfus, & Kidron (2011) consider that the increase in language precision is characteristic of the construction stage itself and not just the consolidation.

In AiC the epistemic actions referred to are known the as RBC model (Recognizing, Building with, Constructing) and the RBC-C model, with the second C corresponding to the second stage of consolidation.

The aim of this paper is to describe the process of students' proof construction and how they transfer the knowledge already acquired to solve new situations. We analyze the interaction of a group of five students and with the teacher using the AiC model (Hershkowitz, Schwarz, & Dreyfus, 2001). Therefore the research questions to be answered are: what are the epistemic actions that arise in the course of an interaction in a group and with the teacher during the process of proving a statement by reductio ad absurdum? And, are the students capable of consolidation during a long process of teaching of the concept of proof through a collaborative work effort?

METHODOLOGY

The activity described below is part of a broader research study about introducing mathematical proofs to university students in their first semester of the Bachelor of Applied Mathematics program of Juarez University of Durango State, Mexico. The average age of the students was 18. Specifically, the task presented in this paper pertains to the eleventh session and their participation was voluntary. The students had previously worked with other tasks about proofs such as the generation of definitions (Alvarado & González, 2013a), which gave them some preliminary knowledge about proofs, the identification of the parts of a mathematical proposition (Alvarado & González, 2013b), the use of logical connectives, the generation of examples and counterexamples, the formulation of conjectures and the proof by direct demonstration (Alvarado & Gonzalez, 2013c). In this session, the students were introduced to the process of proof by contradiction. The teacher began by explaining this technique with the following example: *Show that prime numbers never finish, there is always one more.* Different tasks were proposed to the students to prove some statements in the way shown by the teacher and once they had proved them, a challenge task, described in the next section, was proposed. The challenge task was to prove the following statement: *It is impossible to write numbers using each of the ten digits once so that their sum is 100*.

The classroom activity was conducted in a group with five students working on their own. Once they obtained an answer, an interaction with the teacher took place. Through collaborative dynamics the students were given the opportunity to develop knowledge together and express their ideas verbally. Planas & Morera (2011) argue that interaction is a skill that must be practiced by students and teachers in math class. This kind of an interaction is based on every participant's right to express their opinion and try to convince the others of the validity of their ideas.

The interactions can be effective if they feature a real and true exchange or communication. That is to say, if the participants: 1) undertake social interactions voluntarily with peers and with the teacher; 2) actively participate in interactions and engage with the task; 3) have developed the basis for sharing and receiving (taken-as-shared) in equal conditions; and 4) do not represent a mathematical authority in the course of the interaction. Cobb (1995) and Steffe & Wiefel (1992) consider points 3) and 4) necessary for small group interactions, for good communication and genuine collaborative learning in mathematics. In this sense it is expected that effective interaction will result in a product (definition, rationale, conjecture, method, argument, demonstration, illustration, etc.) agreed on by all participants.

During small group work, the teacher can see if students spend a long time looking for a way to approach the task. For this case the researchers had previously suggested that the teacher should interact with the students and give adequate support to their thinking. The teacher must take into account the four "teacher movements" (Jacobs & Ambrose, 2008) while the students continued working on the task. These movements are: a) ensure that students understand the task (what do they know about the problem?) and if necessary change the context to a more familiar one, b) change the problem to a similar one with simpler values, c) ask students what they have tried until that moment, and d) suggest using another strategy.

Discussions in the small group and with the teacher were videotaped and transcribed in their entirety. The analysis of interventions was made by identifying different units of analysis determined by the discussion of one aspect of the student's task. For each unit of analysis the epistemic actions evidenced were identified, and this identification was then triangulated between the researchers. To identify the epistemic actions, in this analysis R-actions were considered to be the epistemic actions that the students used to recognize the information assumed to be true, as well as the definitions and concepts involved, the B-actions were those that emerged from the statement by extraction of its meaning, or when calculations were performed to obtain deductions and to understand the meaning of the statement, to finally build the requested proof and organize it (C-action). The C-action occurred once the statement of the proposition and its proof were considered as a unit.

DATA ANALYSIS

Below we describe, characterize and analyze the process of solving this task which took place in the classroom during the interaction of a group with five students. We have differentiated two parts: the first one describes the work in the group and the second one the corresponding interaction with the teacher.

Group discussion

In the following dialogues only the students participated. We have not differentiated which student made each contribution because we are interested in the whole process as the overall production of the group. Each contribution is numbered indicating that it belongs to one of the students. The comments in brackets are comments made by the researchers.

The first *R-actions* served to recognize the assumptions or information available [2, 4], the conclusion [1 and 12] and the extraction of meaning from the data [5, 6]. As discussed below, students misinterpreted the information. They were considering a 10-digit number (all possible combinations) in which the digits 0 through 9 appear only once.

1	We must see that [a number] with the given conditions is impossible.
2	We have to use each of the 10 digits.
3	Yeah. It is impossible.
4	In P [the hypothesis] we have 10 digits.

5 We can put that we form a total of however many numbers but the digits 0 through 9 always appear.
6 You are going to do all such combinations. One would be 1234567890.

Following this misinterpretation, we can identify some *B-actions* (advances in the proof from the *R-actions*) in their arguments [7–9 and 14] i.e. the commutative property was applied. The students showed flexible thinking [10] using another *B-action* linked to the process of deducting from the back to the front "The only way you have 100 would be ..." and as a result some [12 and 13] *B-actions* took place to extend their peers' understanding.

7 [...] The sum will always be the same because the digits change places but not their value.
8 Good. P is that. Then P1 [the first deduction] which does not change the sum.
9 And by the property of the sum 0 + 1 + 2 + ... + 9
10 The only way you have 100 is with 10 places where the numbers were 10 and that's not possible.
11 I don't understand.
12 If the sum of all digits must give 100...
13 You are going to have a big number with 10 digits. Which you want without repeating. But their sum is not going to give 100.
14 [They read again] Well, the sum will always be equal using the commutative property.
15 But not different. It will always be the same.
16 See. It says that it is impossible.
17 How to build a contradiction?
18 Now, what must we prove?
19 That it's impossible that the sum is 100. That is Q [the conclusion] //.
20 Here's something missing. The sum will always be 45.

Another *B-action* occurred when formulating the negation of Q [21]. Finally [22 and 23] they found a contradiction and that was the step used to conclude that this was sufficient for proving the statement so this was the final *C-action*, i.e. the construction of a contradiction and thus the proof of the statement. It is important to mention that the statement did not appear in the conventional form "if P then Q", and the students did not realize that the numbers could be formed with any number of digits, but each digit from 0 to 9 could only appear once. This led them to prove a different proposition from the one requested.

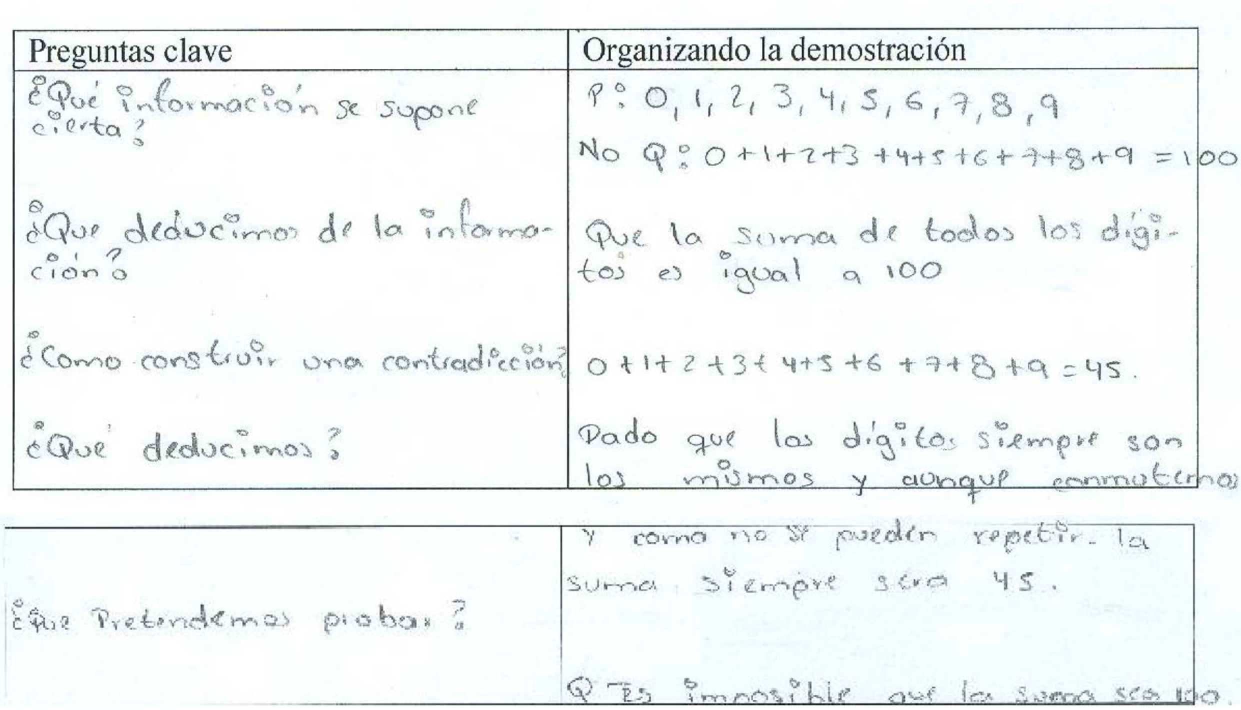
21 First there are 0, 1, ..., 9. Then assume that their sum is 100.
22 Now I do the sum 0 + 1 + ... + 9 and that gives me 45 different from 100.
23 Since the digits always add up to 45 although we change positions, then the sum can never be that, and therefore Q is impossible, that the sum would be 100.

The figure below shows the written production made by the students, well-organized by steps in order to clearly communicate their ideas, even though they have not proved the adequate proposition.

Interaction with the teacher

The teacher reread the proof written by the group. First, he clarified the misunderstanding of the proposition as students had thought they had to consider a single number with 10 digits and with each of the digits from 0 through 9 only once. In [24] the teacher presented an example involving two numbers [25]. The teacher [25] reframed the situation and students in *R-actions* [26 and 27] recognised the hypothesis and the negation of the conclusion [27] and implicitly the conclusion. They recognized [29] that they should move from hypothesis and NO Q to construct a contradiction. The teacher considered it important to verify that the interpretation of the task was suitable and asked for some examples [30]. They showed *B-actions* [31–35] to build examples with the aim of understanding the nature of numbers and the negation of the conclusion.

24 Teacher: [...] seems to be a confusion [...] Of course, if I write a number with the digits 0 to 9 each written once, their sum does not give me 100. But look. The exercise is the sum of numbers written with these digits used only once [He writes two numbers: 12345, 6789] what is the sum?
25 Teacher: Well I can write it this way [two numbers] but the digits can appear once. Let's see, what would be the way to reframe this situation? What do we know?
26 Students: The set of digits is 0, 1, 2, 3, 4, 5, 6, 7, 8, 9.



Preguntas clave	Organizando la demostración
¿Qué información se supone cierta?	P: 0, 1, 2, 3, 4, 5, 6, 7, 8, 9 No Q: 0+1+2+3+4+5+6+7+8+9 = 100
¿Que deducimos de la información?	Que la suma de todos los dígitos es igual a 100
¿Como construir una contradicción?	0+1+2+3+4+5+6+7+8+9 = 45.
¿Que deducimos?	Dado que los dígitos siempre son los mismos y aunque conmutemos y como no se pueden repetir la suma siempre será 45.
¿Que Pretendemos probar?	Q: Es imposible que la suma sea 100.

Figure 1: Students' written production

27 Students: The sum of them is equal to 100. That would be the negation [NO Q].

28 Teacher: How to build a contradiction?

29 Student: We must think of different numbers and their sum must be equal to 100.

30 Teacher: I have several numbers. I do not know how many. Their sum must be equal to 100. In addition, together they can contain no more than each digit once. See, what numbers would I use?

31 Student: So a_1, a_2 ... a_k should only have each digit once.

32 Teacher: That is, you may have one, two or more numbers, but if one digit is here in that number, you cannot use it in another number.

33 Student: Yes, [...] if I have 13, I cannot put 34 in another number [adding].

34 Student: But if in that case, we can obtain a sum even higher than 100.

35 Student: Yes, it may be higher, but we have assumed that it equals 100 [we must prove that it is impossible to add up to 100 and then its negation is that their sum is 100]

In the following excerpt, deductions were made from the hypothesis (they used numbers like 1245, 736 and 89) and the information derived from the negation of the conclusion. For the first deduction the teacher asked the students to analyze the digit of the units and think about what is required in this position so that the sum would be 100. They deduced with *B-actions* [37] that the sum of the digits of the units should give multiples of 10 or 20. They proposed examples of numbers to be in the position of the units [39–43] which is a *B-action* because it is a construction made by the students from the statement. Exploring with *B-actions*, they discovered that it was impossible to obtain the sum with 3-digit numbers [44–48]. When considering two-digit numbers [49] another *B-action* addressing the possibilities of the sum of the digits in the tens position [51] is given. They also gave an extreme example with the single case of a number with all digits. In this case the sum is itself [53 *B-action*] and greater than 100.

36 Teacher: Yes. It would be 100 [the sum], and what does that imply? For example, look at the numbers of units. What is needed to be 100?

37 Students: The units must give me a multiple of 10 [another student says]. Perhaps 10 or 20.

38 Teacher: What would it be? For example?

39–43 Students: 1 and 9 / 8 and 2 / 5, 2 and 3 / 7, 2 and 1 / 1, 4, 2 and 3.

44 Teacher: For example, in the case of 9 and 1, what happens? What about the other digits? Would they have a chance? If there were two numbers I would have

to accommodate the 8 digits left. Also if there were three-digit numbers the last digit of the third one would be 0.

45 Student: And I should accommodate 7 digits [2,3,4,5,6,7,8].

46 Teacher: So, at least on one of those three numbers we would have 3 locations to accommodate digits.

47 Students: Yes.

48 Teacher: But the sum is greater than 100, then that happens with numbers with more than three digits.

49 Students: One can do it if the number has two-digits, but I can't explain. Well, for example 5 two-digit numbers, using 0,1,2,3,4...

50 Teacher: For the units?

51 Student: Yeah, and then one must accommodate 5, 6, 7, 8, 9. We need to obtain in the tens, 9 [adding the units makes 10, therefore it accumulates 1 in the tens] and no ...

52 Teacher: Yes, well. I see.... Well, you can work on this idea. What matters to me is that you understand that the basic idea of reductio ad absurdum is to assume that the sum is 100 accompanied by the hypothesis. If I explore the possibilities and arrive at a contradiction, then we have proved the proposition.

53 Student: Well, if we think of a number with all digits the sum would not be 100 but rather greater.

Finally, the teacher stopped the discussion considering that the important thing is to understand the technique and the students must continue working later on the proof of the proposition on their own. As this took place in the last two days of school we were not able to collect the final evidence of the students' work on this proposition.

FINAL REMARKS

In this activity, a group discussion, the students' written production and the discussion led by the teacher to encourage knowledge construction from what they previously knew have allowed us to document the interactive generation of knowledge. The students recognized the hypothesis, the conclusion, and their role in the proof, they could construct the negation of the conclusion and from there, they proved the proposition although they made a misinterpretation of the statement. This is evidence of the consolidation of the knowledge acquired by the students.

They carefully managed the premises and constructed deductions from them, which is an indication of the consolidation of the new constructs as established in the RBC-C model and as shown by personal evidence. They also discussed the ideas they shared, showed confidence, immediacy, use of the construct when changing the context, working both in the group and with the teacher, seeking to clarify and refine their thinking, which may allow their language to increase in accuracy.

The RBC-C model allowed us to document and capture the complexity of group work for the construction of knowledge. Thanks to this model as a theoretical and methodological tool, we were able to identify the epistemic actions that occurred during the process. The group discussion with peers allowed students with the same level of knowledge to confront each other and identify some weaknesses, in this case comprehension of the task statement. The activity began with R-actions that progressed until a C-action. This activity sometimes required feedback to clarify to a classmate the reasoning performed, for example when a student says he does not understand. Throughout the task the students were persistent. They used examples in order to look at their structure, to understand their nature and to extract information in the construction of the contradiction.

Interaction with the teacher was essential in this case to clarify the meaning of the proposition. In relation to comprehension and application of proof by reductio ad absurdum, the students managed the technique, handled it properly and they understood the function of negation of the conclusion in this proof.

Proof writing at undergraduate level

Nadia Azrou

University of Medea, Medea, Algeria, nadiazrou@gmail.com

This paper deals with the writing of a proof text as the final step of the proving process. In particular, students' difficulties to get a satisfactory product, which frequently result in an unclear text in a disorganised form, are analysed. Differently from other difficulties related to proof and proving, we noticed this phenomenon particularly when third year university students were answering some open questions where the process has to be built up, differently from traditional questions of calculation or direct use of a mathematical result where the steps of the process are known, regardless the correctness of the proof. We'll try to identify the reasons behind writing an unclear, messy draft instead of a clear readable proof text; its consequences on students' making proofs at the university level will be considered.

Keywords: Proof, university, proof text, open tasks, meta-mathematics knowledge.

INTRODUCTION

The study reported in this paper is a part of a PhD research on proof and proving at the undergraduate level, focused on students' difficulties when making proofs within a course of Complex Analysis. Research concerns third year university students' productions while responding to tests during the academic year. These students are prepared to become engineers in a high level selective university in Algeria; the mathematics programme for them is the same as for mathematics majors in any other university, but with more time and more complete exercise activities. Each test contained three questions, chosen in order to investigate difficulties of students' proving. During the analysis of collected data (consisting of students' written productions) of the three tests, for a few students an expected difficulty emerged related to the production of the final written proof text; a fourth test was designed to explore that competence. In the first three tests, the questions were closed (like *'calculate', 'prove that'*), and most students' proof texts were quite clear, well organized and legible, regardless the correctness of the solution. In the fourth test, the questions were open (like *'why…', 'is it possible to have …'*) and students were required to justify their answers: we realized that in most cases the final proof text was written like a draft, in a messy form that makes it difficult to read, even though, most of the time the idea behind seemed to be correct.

We then decided to investigate the problem of writing a proof at the undergraduate level, because we think that it's a crucial skill and one of the factors that prevent students from making successful proofs or/and completing correctly a proof already began. When the first sentences are insufficiently developed and written like a draft in a disorganised style, they cannot be a strong base to develop a complete well organized proof and even to check the correctness of reasoning; moreover the students may misread what they wrote, thus they are misguided in their way through.

In a previous study (Azrou, 2013), performed with first year university students attending an algebra course, the findings indicated that most of the proofs given by the students in closed-type tasks, even the incorrect ones, were clearly written and could be read easily. The purpose of the study reported in this paper is to try to identify the reasons why many students produced those disorganised unreadable proof texts while answering open questions.

My hypothesis is that reasons might have been inherent: in the didactic contract that shapes the teacher-learners relationships; in the lack of meta-mathematical knowledge (in particular, as concerns proof); and in the cognitive difficulties inherent in moving from intuitions, knowledge and evidences elaborated at the inner or oral level, to a well-organized and clear written proof text, with an appropriate and correct use of mathematical language. Based on this working hypothesis, in the next section we will consider some theoretical elaborations concerning the above possible reasons, in order to address and deepen our analyses.

THEORETICAL BACKGROUND

The final proof text is a result of a process involving various components and is influenced by several factors. First of all, we will consider the relationship with the teaching and how proof texts are written by teachers; this will be explored using the construct of didactic contract (Brousseau, 1988) that concerns, in particular, the relationships between what teachers do and expect from the students, regarding knowledge that teachers have and intend to teach, and what students think that their teachers expect from them. Several teachers' expectations (concerning what students should do and learn) are not made explicit, or, when explicit, are not understood by students in the right way. On the contrary, the efficiency of a didactic relation assumes students having some intelligence about the intentions of the teacher (Mercier, 2010). In the case of proof, different teachers write different kinds of proofs at the blackboard according to their conceptions about what is relevant in a mathematical proof, and according to the needs of the moment. Some teachers write all the details, while others write only what seem to be important for them in that moment. Some teachers add special comments on proving, others write only a chain of symbolic statements and comment them orally. Students "by contract" might tend to provide proofs that are as close as possible to their teachers' ones.

At a meta-mathematical level, most students do not know what doing mathematics is, which means knowledge about mathematics as a science. By teaching only its contents, several teachers (especially school teachers) assume that over time, students will be able one day to acquire knowledge about that science and find out how it works. But it has been shown (see Morselli, 2007) that some university students' difficulties are still caused by lack of meta-mathematical knowledge, particularly as concerns proving, like: how to exploit a known theorem while proving another theorem; what is the difference between a definition and a theorem; what is a counter-example; thus, they ignore some important rules of the game. Moreover, as pointed out by Morselli (2007), frequently students confuse exploratory argumentation and proof; they produce written arguments that are different from a proof by writing their "proofs" when they are engaged in the exploratory phase. The problem is that teachers do not know that students ignore what exactly a proof and a complete proving process are, and thus they might tend to stick to models derived from their teachers' presentations of proof-models, which may be different from one teacher to another. We say briefly that, concerning proof, several students lack knowledge about it (which we consider as meta-knowledge about proof); and we hypothesize that this fact may result in a stronger influence of the didactic contract, which works as the only factor orienting their behaviour.

As concerns the writing of proof, it is also close to language and expression issues. The nature of mathematical language, with attention paid to the case of proof, was described in (Boero, Douek, & Ferrari, 2008), in particular as concerns the specific use of current verbal expressions in mathematics (with change of meanings, in comparison with ordinary language), and the integration of mathematical symbols within a verbal written text. In that paper, the authors also presented some results concerning university students engaged in problem-solving in an Algebra course; they found out that almost all those who, in an entrance test demanding verbal explanations, had produced answers with no verbal comment, or with rambling words and poorly organized sentences, failed the final exam. That paper is a general reference for our work: it offers a frame which provides a definition of mathematical language (pp. 265–266), a rich set of reflections and a wide perspective to deal with students' difficulties concerning mathematical language.

Finally, we'll also consider the logical structure of students' proof texts and how they link their written propositions together. For this, we'll make reference to Durand Guerrier's research work on the logical aspect of proving. In particular, students' use of '*then*' should be considered: it is currently used in mathematics to introduce a conclusion, to end a proof or set the desired result, and within the "*if…then…*" construct. Students may misuse it or not use it when they should, which makes a proof sound strange as there is no connection between the different propositions. In general students need to validate their different steps to carry on the proof process; if they are not able to do so because of difficulties related to logical symbols and connectives (cf. Boero et al., 2008; Durand Guerrier et al., 2012), their proof are likely to be vague and unclear, or mistaken.

METHODOLOGY

To study proof text, it's important to analyze students' proofs written individually. We have designed a test with open questions (thus not in the form: "prove that"), whose answers should not result from a standard procedure involving a mathematical result or a theorem, but rather engage students in a creative process. The test, administered to 98 students, proposes three simple short questions about a definition, a property or a result well known by the students, to be answered during thirty minutes. The degree of difficulty (complexity, connections to be established between known properties) of the questions was lower than in the case of some questions already tackled by the students during the exercises sessions. However, the questions were asked in a way unfamiliar to them, which put the students in a new situation that engaged them in gathering and linking their information and organizing them in order to build up a proof clearly written. This choice was aimed at identifying specific reasons influencing writing, and resulting in confused, unreadable proof texts.

The construct of didactic contract will be used to identify the relationships between students' productions, and how proofs were usually presented to the students by the two teachers (I'm one of them) during the course and the exercises sessions. Teaching the course consisted in two lecture sessions and one exercises session each week, all during a period of twelve weeks. There was no special focus on proofs even though all results are proved in lectures. The focus was rather on contents, statements of theorems, results and definitions and how students understand and use them; most of the exercises were about calculations, only some ones were about reasoning and links about concepts; time was not enough to develop in details every concept. There was no check of students' answers to questions (additional or not completely answered questions) posed to them, or of proofs written by them during the exercise sessions. Most of what students wrote was copying down what was already written by the teacher at the blackboard. The analysis will also consider students' oral expression ability during the academic year and how they managed to talk mathematically: as I know the students, I can tell about that for the students whose productions are analyzed.

The study will be focused on the organisation of the students' steps of reasoning in their proof texts; in order to better classify them, we will distinguish between three phases of proof production (Arzarello, 2006):

Step1: exploration and production of reasons for validating the statement.

Step2: organisation of reasoning into a cogent argumentation.

Step3: production of a standard deductive text.

Moreover, students' productions will be examined from a logical aspect, by exploring how they link the different steps and whether and how they deduce any written statement from the previous one, and what are the means used for that: are they, in particular, logical connectives, or symbols like the arrow implication, or other transition words like 'then', 'thus' or 'finally'?

A-PRIORI ANALYSIS OF THE FOURTH TEST

The questions of the fourth test were of open type and needed to be answered by producing the answer and building up a proof to validate it in an autonomous way (as concerns the whole process). The three questions were as follows:

1) *Is it possible to find a holomorphic function that admits 0 as a simple pole such that Residue* of f at *0* is *0 (Res (f, 0) =0)?*

2) *May the residue of a holomorphic function at the infinity be zero? Justify.*

3) *Why is the residue of a removable singularity zero?*

Like in the other tests, questions were related to properties and results that should have been well known by the students (and indeed other tests demonstrated that it was so). We aimed at ascertaining if the students were able to write down the argument, based on known definitions and theorems, in a well organised, clear mathematical form. Even if this kind of open questions was familiar for students in an oral form, it was quite new for them in a written form: they had never seen the written answers to such kind of question; they had never been engaged in producing written answers to them. Thus questions could have revealed the students' competence of *autono-*

mous proof writing (proof writing not induced by a stereotyped request) and the *consciousness* about its functions (related to the very nature of proof: shortly, as an unchaining of propositions aimed at validating a statement). The most interesting data have been collected through the first question.

The question is about some results concerning simple poles and residues (P ⇒ Q) and its negation (P and $\overline{Q}$) at the same time, which results in a contradiction: if a holomorphic function has a point 0 as a simple pole (P), it means that the residue of the function at this point (which is the coefficient of 1/*z* in its Laurent development) cannot be zero (Q); the reason is that, in the case at stake, the residue is calculated by the formula lim *zf(z)* when *z* → 0, which is exactly the coefficient of *1/z* already taken not zero. Logically speaking: the fact that the residue at a point is not 0 is a direct consequence of that point being a simple pole for the function. We have chosen to refer to the point 0 to simplify the formula. There was no doubt that students knew all these concepts because they had used them many times before, but always when performing calculations (to calculate the residue for a given point, to establish whether given points were simple poles, multiple poles or other singularities). However no request of identifying and exploring the links between concepts had been made especially in a written way.

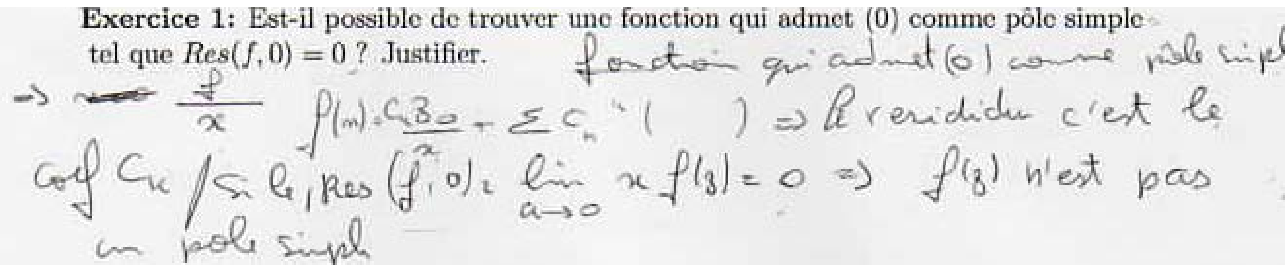
ANALYSIS OF SOME STUDENTS' PRODUCTIONS

We'll present and analyze two examples of students' productions (French is the ordinary used language) that consist of a disorganised, unreadable proof text. This will exemplify the work done on the collected productions, and how we got the conclusions reported in the next sections.

Student 1:

The student starts by rewriting the hypothesis of the question: '*a function admitting 0 as a simple pole*'. She continues at the beginning of the line by putting an implication arrow, followed by crossing out (*x=0);* then she writes *f/x*, adding the Laurent series of the function - not complete, with some blanks in it. Another implication arrow follows by stating the definition of the residue (that is the C_k coefficient). The student goes on by marking a slash, 'if the' and a comma; then she calculates the formula of the residue of *f* at *0* which is, according to the student, the limit when some non declared '*a*' goes to *0* of *xf(z)*, which is zero. With a last implication arrow, the student ends her proof by stating that *f(z)* is not a simple pole.

The proof in this production is not totally wrong but is not written correctly and not complete. This doesn't tell clearly if the student's reasoning is correct or is a result of a mere coincidence. The first thing to notice is that two variables are used: x and z. According to the student a function that admits *0* as a simple pole has a denominator with x, which is correct. She certainly meant to write f(x)=g(x)/x, but the way she expresses it is so odd, she writes *f/x*; she wanted probably to say that the principal part of the Laurent development contains only *1/x*. This shows how the student struggles to translate her intuitive vague idea about the formula into a mathematical expression with mathematical symbols. The writing of the student is confusing; she gives flashes of what seems important to her without taking into account how the proof should be presented to the reader and how the different steps and formulas should be linked, which indicates poor meta-knowledge about proof. Many variables like z_0, c_k, c_n and '*a*' are used without defining and specifying their meanings; we are not sure that their meanings are clear for her. At the end, she deduces, by an implication arrow, that *f(z)* cannot be a simple pole, and certainly she meant the point *0*. She writes down briefly how she remembers the related definitions and shows the main ingredients of the proof (one denominator with z, one coefficient is the residue and a non zero limit is for a simple pole).



Exercice 1: Est-il possible de trouver une fonction qui admet (0) comme pôle simple tel que $Res(f,0) = 0$? Justifier.

fonction qui admet (0) comme pôle simple

→ $\frac{f}{x}$ f(x) = C z₀ + Σ c_n ( ) ⇒ le residu c'est le coef C_k / si le, Res(f, 0) = $\lim_{a \to 0}$ x f(z) = 0 ⇒ f(z) n'est pas un pôle simple

Figure 1: Student 1

She works within the step 1, the exploratory phase and production of the reasons for validating the result.

We can see how the student' effort, influenced by the didactic contract, is aimed at showing to the teacher that she got the most important ideas related to the question, no matter if several details are mistaken or neglected. The text also allows to guess her own proof conception, which seems to be shaped by doing it for the teacher, who is supposed to understand the missing details and the unsaid words, according to the student. The logical links are not clear, particularly the implication used is not the logical one: it is more about shifting to another idea not necessarily and clearly connected to the previous one; moreover the student doesn't tell about her proof technique, which seems to be a proof by contradiction. From a language point of view, the student is one of those who showed real difficulty orally when expressing any question or a comment involving a mathematical idea. Her natural spoken language is confusing and poor, and lacks flexibility to express mathematical meanings (Boero et al., 2008).

Student 2

In this production, it's hard, first, to decipher the handwriting of the student and to follow the lines that are broken, so it's not clear where a line starts and where it continues and ends. He starts by explaining what means that a function admits *0* as a simple pole by putting one arrow, which is meant to be the implication arrow, oriented towards $f(z)$ expressed as $\varphi(z)/z$, φ being holomorphic. Then, the reader is puzzled where to continue reading, is it on the same line or beneath? At the same line, the student calculates the residue value by the limit formula, but it's indicated with z going to ∞ instead to *0*, even though the result is with z going to 0 which is $\varphi(0)$; this last result is declared to be different from *0,* without any justification, as an obvious fact. At the next line, he states that $\varphi(z)$ is $c_0 z$ with a hesitation on the power of z; at the next line, he adds that $f(z)$ is c_0/x plus a sum of c_n and something not clear; at the end, he concludes by writing 'then' *it is not pole*, without explicitly indicating what is '*it*'. With an unreadable handwriting presenting the proof like a sketch, the organisation fails to clarify what the student is exactly doing. However, after reading this text many times, the first part appears to be not totally incorrect. The student gives the definition of 0 being a simple pole and calculates the residue of the function, which is not 0, a valid step of reasoning, but this would need a conclusion: that is a contradiction to the question. The student gives the main idea: the formula of the function f is given by a holomorphic function ($\varphi(z)$) with z at the denominator in the case of having 0 as a simple pole, and then calculate the first element of the Laurent development of f, which should correspond to c_0, but fails to justify and make explicit the other details taken as obvious, like: why $c_0 \neq 0$, which is an important point in the proof. In doing so, the student is about showing to the teacher (or doing like the teacher) that he got the main idea of the proof, which seems more important than clarifying explicitly the "small details" which are clear for him. Leaving some blanks in the proving process makes inevitably the statements logically disconnected, especially because the student doesn't use logical connectors (except one 'then' at the end) to link a statement to another. I remember this student as one of the brilliant ones, but he is weak both orally and at writing. When he talks, no one understands him: he swallows his words, bubbles and repeats the same expression to say different meanings. On a cognitive level, he is very smart and most of the times he finds the good idea where all other students are stuck; it is rare that his answers are wrong, which makes his proof's idea possibly correct. For him, writing a proof text is writing a set of partial arguments presented in a disorganised way with incomplete formulas, far from how a proof should be.

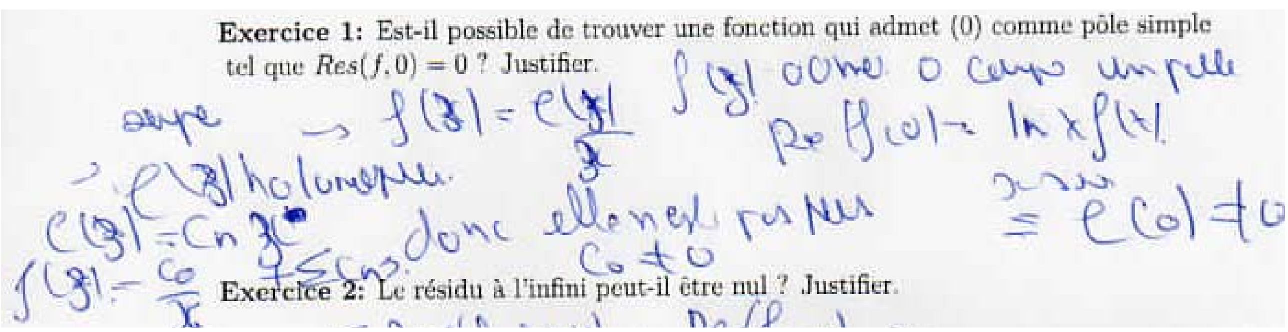


Figure 2: Student 2

RESULTS

Analysis indicates that students' difficulties concerning writing an organised and understandable proof text are originated in the didactic contract that substitutes the mathematically relevant aim of structuring and writing a clear proof text with the aim of imitating teacher' incomplete proofs. This results in a disorganised, poor text somehow similar to some sketches of proofs produced by teachers at the blackboard. Moreover, writing a proof is strongly influenced by students' engagement in showing to the teacher what they know (the relevant idea to achieve the proof), underestimating the importance of writing a complete, well organised proof text. The previous texts show that students fail to go through the three steps of the proving process; they only develop the first exploratory phase and write it down by presenting the main ideas and missing many details. Failing to engage in the second phase and reach the third phase of writing the proof text, logical links between statements remain unclear (student 1) and even missing (student 2); with misused logical connectors (the implication arrow for student 1 and 'then' for student 2), the logical structure of the proof text is totally disconnected. Such students' behaviors might be contrasted by a good meta-knowledge about proof, but as their meta-knowledge about proof is poor, what is suggested by the didactic contract becomes dominant. The poor proof texts show difficulties inherent in the mastery of natural language (for both students) in the mathematical register (Boero et al., 2008), particularly as concerns its logical features, which contributes to students' difficulties of logically connecting the steps of reasoning in an explicit and appropriate way, and to their using incomplete definitions and formulas (student 1 and 2). In some cases, disorganised proof texts have been produced by students with difficulties in mastering of natural language: students 1 and 2 are examples of them. Thus a flexible mastery of natural language (which cannot be achieved by means of every day-life experience alone, and requires specific interventions also concerning scientific communication) appears to be a necessary condition for mathematical proficiency (in agreement with (Boero et al., 2008), even for a course at the undergraduate level). The above presentation of the results of the analysis of students' productions suggests that the four components used to interpret the poor quality of the proof texts are not independent, but rather overlapping and intertwining.

DISCUSSION

Our hypothesis on difficulties of writing proofs to open tasks that require a creative construction of a proving process and writing clearly the logic structure of how links are created between different arguments and concepts were set on: lack of flexible mastery of natural language; lack of knowledge about proof at a meta-level; influence of the didactic contract; and weak consideration of logical proof structure. This led to the question of identifying the possible reasons for these results and suggesting some possible didactical implications to cope with these problems.

According to the didactic contract, we may hypothesize some links between the identified difficulties and our teaching of mathematics at the undergraduate level, which does not introduce learning of proofs and less writing a proof text. Moreover, during the grading of exams copies, we base our positive evaluation on correct ideas in students' proofs and give partial credit, even if they are not clearly and rigorously presented. As far as I'm concerned as a teacher, it happens that I write some of the proofs at the blackboard by giving the plan and the main idea, and devote the short available time to the full explanation of the concepts to be used, and the links between the ideas of the proof. I sometimes leave the final text to the initiative of the students, who feel satisfied by getting the main idea and the main details. Both students and I (as a teacher) have always held the assumption that when the main idea of the proof is clearly explained and understood, writing the proof details and organizing the proof text is a simple thing! However, the fourth test provides strong evidence that this is wrong. Most of the meta-mathematical knowledge about proof is absent in our teaching, in particular as concerns the relationships between the proving process and the proof text. The lack of this knowledge might explain why students write directly their final text at the same time when they explore the question: they have no mean to interpret and situate what their teachers do when they write a proof at the blackboard. We (teachers) generally write proofs in a direct linear way; knowing already the steps of the proof, we write them one after another, till the conclusion. We do not show the exploratory phase and how the partial arguments produced in that phase are re-considered and arranged to produce the final text (similar situation with mathematics textbooks). Students learn to do the same: when they first set some ideas about how to solve a problem, they write their first exploratory draft as a final text because they were never shown how to go further till the written proof text. Another component of the meta-knowledge about proof that would have helped to cope with the problem of writing the proof text is about the difference between argumentation and proof, which is not clear for the students especially from a structural perspective. The logical structure of an argumentation differs from the logical structure of a proof: while in a proof all steps are deductive, in an argumentation the steps may be of different nature: abductive steps or inductive steps (Peirce, 1960; Polya, 1962 cited in Pedemonte, 2007). In this case, the construction of a deductive proof requires a structural change: from abductive or inductive to deductive steps. This change is not always straightforward for students, but is usually necessary (Pedemonte, 2007). The results support the intrinsic cognitive difference between the open and the closed tasks, which implies different roles of verbal language. With closed tasks, proof text plays a narrative ritual function, while in the open ones, the text plays, in the first phase, a constructive creative function. With proofs for closed tasks, students go through a secure process, behaving in a conventional ritual way and showing a coherent reasoning guided by the didactic contract, according to teachers' and textbooks' models. The result is a clear, well organisation proof text (regardless the correctness of the proof). The use and control of meta-mathematics knowledge is needless in this case. On the contrary, in proofs for open tasks, a creative organisation of the arguments is needed, but lack of meta-mathematics knowledge about proof and some uncompleted proof text models offered by teachers lead students to write their proofs when reasoning (which is a nonlinear process). Failing to go through the two following phases, the text would look more like a draft. Furthermore, an in-depth analysis of students' mastery of their native language and of written French is needed to complete our study.

What instructional interventions can be effective in overcoming these difficulties? Teaching meta-mathematical knowledge and especially meta-knowledge about proof seems to be extremely important and effective for introducing the learning of proof. It should regard the differences between deductive, abductive and inductive reasoning, the logical structure of proof, and how to organize proof text. Introducing some open tasks, among the activities, would break the ritual pattern of proofs for closed tasks and encourage creativity. Explaining proofs and writing them directly fails to show students how really they are constructed in different phases; while some writing proof exercises proposed to students with hints and main idea of proof would enhance writing proof text.

On a generality framework for proving tasks

Andreas Bergwall

Örebro University, Örebro and Mälardalen University, Västerås, Sweden, andreas.bergwall@oru.se

In this paper I present an analytic framework for generality in textbook proving tasks that involve functions. The framework is discussed in relation to results obtained when analysing tasks in integral calculus. The results show that the frameworks' categories are easily distinguishable if the functions are explicitly described. The results are also promising regarding the possibility to clarify differences between textbooks. The analysed sections exemplify that there is not necessarily a correlation between the number of general proving tasks and the opportunities for students to engage in reasoning about arbitrary functions. Limitations and possible refinements of the framework are also discussed.

Keywords: Mathematical proof, mathematics textbook, upper secondary school, undergraduate mathematics, integral calculus.

INTRODUCTION

Research on the teaching and learning of proof often involves the distinction between specific and general arguments and properties. For instance, students' tendency to take specific cases as sufficient justification of general properties is well documented (Harel & Sowder, 2007). The distinction between specific and general has also been used to study how mathematics textbooks support proof-related activities and learning (e.g., Stylianides, 2008; Thompson, Senk, & Johnson, 2012).

In an ongoing study, we use the analytical framework of Thompson and colleagues (2012) to investigate Swedish and Finnish upper secondary textbooks. One part of the analysis consists of determining whether or not textbook tasks provide opportunities for general reasoning. When tasks involve functions, this distinction is not always obvious. Various combinations of dependent variables, independent variables and other parameters mean significant differences in the 'degree of generality' between tasks. This suggests that such a textbook analysis would benefit from a more fine-grained classification of generality. In this paper I will address this issue by discussing a tentative generality framework for proving tasks based on the 'size' of the set of functions that the tasks call for a proof about. I will refer to this as the *function generality framework*. By 'proving task', I mean a textbook exercise explicitly asking the student to prove or show a mathematical property.

The function generality framework is an answer to the first of three questions stated below, around which this paper is focused. By applying it to proving tasks in Swedish and Finnish textbooks, some results relating to the other two questions will be obtained. The questions are: (1) How can 'degree of generality' in proving tasks involving functions be framed? (2) What analytical difficulties arise when proving tasks are classified according to function generality? (3) What can classification according to function generality reveal about textbooks that a 'specific-or-general' classification cannot?

Some initial results concerning the analysed textbooks will also be discussed.

BACKGROUND

One characteristic feature of a mathematical proof is that it usually provides a valid justification for a *general* property. However, numerous studies (many of which are referred to in Harel and Sowder (2007)) show that students on most educational levels, even at university (e.g., Hemmi, 2008; Weber, 2001), have limited understanding of this aspect of proof. Typically, students justify general statements with specific examples, view counter-examples as exceptions, believe that counter-examples might exist even if there is a general proof etc. In the literature, this has been referred to as *empirical response* (Bell, 1976), *pragmatic justification* (Balacheff, 1988) and *empirical proof scheme* (Harel & Sowder, 1998). Central to all these frameworks is some kind of distinction between the general and the specific.

Even though no curriculum program is self-enacting, research has stressed the wide use of textbooks in classrooms and how they are crucial links between national curricula and teaching practice (e.g., Stein, Remillard, & Smith, 2007). In line with this research, mathematics textbooks can be seen as potential sources for opportunities to learn. Hence, textbooks' treatment of reasoning and proving is an important object of study. Historically, such studies are rare (Hanna & de Bruyn, 1999), but in the past decade a number of studies with this focus have been published (Nordström & Löfwall, 2005; Stylianides, 2008; Thompson et al., 2012). In an analysis of an American reform-based curriculum for middle school, it was found that 40% of the textbook tasks were designed to engage students in reasoning and proving, but only 12% of these offered opportunities to provide general proofs (Stylianides, 2008). Thompson and colleagues (2012) report on an extensive study of US textbooks for upper secondary school, concerning opportunities offered for students to engage in proof-related reasoning within the topics of exponents, logarithms and polynomials. Their study showed that about 50% of the properties stated in narratives were given some kind of justification; 30% with a general argument (i.e. a proof) and 20% with a specific case. About 5% of all exercises were considered proof-related, half of them of a general kind and half a specific kind. Approximately 1% of all exercises urged the student to develop a general argument.

The frameworks used by Stylianides (2008) and Thompson and colleagues (2012) are similar to (or inspired by) those used by Bell (1976), Balacheff (1988) and Harel and Sowder (1998). Hence, they also distinguish between specific and general aspects of textbook content. In an ongoing study, we have used the framework of Thompson and colleagues (2012) to analyse Swedish and Finnish textbooks. Traditionally, deductive reasoning has primarily been studied in geometry courses, but more recently it has been suggested that reasoning and proof are important in all content areas (e.g. NCTM, 2000). Therefore, Thompson and colleagues (2012) choose to focus on algebraic topics instead of geometry. For the same reason, and to further complement their study, we have focused on calculus. In this broader study we analyse all parts of textbooks: expository sections, worked examples, exercise sets, review exercises etc. It is during this work that I have encountered differences in generality that I have found difficult to capture with the earlier frameworks, and which I therefore address in this paper.

When functions are involved in mathematical tasks, there are dependent as well as independent variables. A task like "Prove that $Dx^2 = 2x$" is *general* in the sense that the student is asked to prove something for all x, but *specific* in the sense that it only concerns one particular function. The inclusion of more or less arbitrary functions, parameter families of functions and other parameters also means (potential) differences in the 'degree of generality'. Tasks like "Prove that $De^{kx} = ke^{kx}$" and "Prove that $Df(kx) = kf'(x)$" are both general in the sense that the identities hold for all x and all k, but the second one is obviously more general than the first since it also holds for any differentiable function f. This difference in generality also implies different content focus; while the first focuses on properties of a certain function, the second focuses on a fundamental property of differentiation itself. These examples show a need for a more fine-grained framing of generality based on properties of the functions involved in the tasks.

I have also found several tasks formulated as "Show that ..." but that were not general in any sense and only required a routine calculation. Sometimes it was the other way around: theoretically and cognitively demanding tasks that from a mathematical point of view concerned proving but were formulated in words like "Why is it ..." or "Motivate why ...". This relates to findings regarding proofs being "invisible" in textbooks (Nordström & Löfwall, 2005). While other studies (e.g., Stylianides, 2008; Thompson et al., 2012) look for opportunities to engage in reasoning and proving in a broad sense, it is therefore important to also look specifically at proving tasks.

METHODOLOGY

Topic, context and textbooks

For the pilot study reported here, I have restricted the analysis to proving tasks in integral calculus. Like differential calculus, this topic is central in upper secondary school as well as in introductory courses at universities. However, the theory of integrals is more complicated and proofs are often omitted. There is a tendency that the underlying theory is not treated in detail in introductory courses at universities but rather postponed to intermediate courses, due to students' difficulties with a theoretical approach (Hemmi, 2006). Thus, it is a real challenge for upper secondary textbook authors to incorporate elements of reasoning and proving within this topic, and it is of research interest to study how this is done.

To get a reasonably rich set of data, four different textbook sources were chosen (see Table 1 below): two Swedish upper secondary textbook series (referred to as SW1 & SW2), one Swedish undergraduate textbook (SWU), and one Finnish textbook for upper secondary school (FI1). Publishers are unwilling to reveal their market share, but it is well-known that SW1 and its predecessors have long dominated the Swedish market. In 2011, more than 80% of those entering engineering programs at Örebro University reported having used these textbooks. The main reason for choosing SW2 was that, while SW1 is a traditional Swedish textbook, SW2 is a newer one with more reform-oriented intentions and a stated focus on reasoning. FI1 is the only Finnish textbook series available in Swedish for use in the Swedish-speaking parts of Finland. Its Finnish original is probably the most widely used textbook in Finland. Finally, for the sake of curiosity, and to get an indication of the usefulness of the function generality framework on introductory calculus texts for the university level, SWU was included; this is a Swedish single-variable calculus textbook that has been around for several decades.

Swedish upper secondary school is course-based. There are five mathematics courses, of which the first four are often a prerequisite for university studies in science and technology. Integral calculus is treated in Courses 3 and 4. The first three courses exist in different versions, depending on whether they are part of a vocational program (Track a), a program in the social sciences (Track b) or a program in science and technology (Track c). For this study, only textbooks for Track c were chosen. In Finland there is a short mathematics course serving as preparation for university studies in, for example, the humanities, and a long course serving as preparation for university education involving higher mathematics. The long course is divided into 13 parts, the first ten of which are mandatory. Part 10 is devoted to integral calculus only (but this topic is further developed in Parts 12 and 13). This study only includes Part 10.

Method

First, all textbook sections specifically dealing with integral calculus were identified. All exercises in these sections were included in the analysis, as were the review exercises on integral calculus (which were typically placed at the end of the book). The only exception was exercises on continuous distributions, which were all omitted since only one of the textbooks treated probability theory within the sections on integrals. Concerning the unit of analysis, whenever an exercise was divided into an enumerated list of subtasks, each subtask was regarded as one task. This resulted in a total number of 1,739 textbook tasks to be analysed (see Table 1). Since the function generality framework is meant to be a tool for analysing the opportunities offered to students to associate 'proving' with general justifications, I next looked for tasks explicitly asking the student to 'show' or 'prove' something. Such tasks are referred to as *proving tasks*. In total there were 80 proving tasks, all of which could be interpreted as concerning functions.

In SW1, SW2 and SWU all proving tasks were formulated as "Show that ..."; i.e., the word 'prove' was

	Publisher	Series	Book	Total no. of	
				tasks	proving tasks
SW1	Liber	Matematik 5000	3c & 4	371	21 (6%)
SW2	Sanoma utbildning	Origo	3c & 4	450	13 (3%)
FI1	Schildts	Ellips	10	529	30 (6%)
SWU	Matematik-centrum, Lund	Analys i en variabel	Exercises	379	16 (4%)
				1,739	80 (5%)

Table 1: Textbooks, tasks and proving tasks within sections on integral calculus

never used. In FI1 'prove' was used as often as 'show'. On three occasions, all in SW1, 'show' was used in a non-mathematical way, as in "Show in detail how you calculate the integral ..." (SW1, Book 3c, p. 185, ex. 3412a). I chose to include them in the analysis since they play a role in forming what students will associate with the word 'show'.

For every proving task, a detailed account was made of the function(s) it concerned. This included information on whether the task concerned specific functions, parameter families of functions (including the number of parameters) or more general non-parametric classes of functions. Notes were taken about the kind of elementary functions involved (polynomial, trigonometric function, exponential etc.) or, in the more general cases, what classes of functions were involved (continuous, periodic, odd etc.). It was also noted if a task contained additional parameters (not connected to the functions), or if it could be seen as general in some other sense.

Analytical framework

One way to determine whether a proving task offers opportunities for general reasoning is to determine whether the property to prove itself is general or specific. Therefore, all proving tasks were categorized as *case-specific* or *case-general* following the framework of Thompson and colleagues (2012). As mentioned earlier, the distinction between specific and general is sometimes difficult to make for tasks involving functions. The general principle used in this paper is that if one can think of a more specific case than what is stated in the task, without substituting the independent variable with a specific number, then the task is considered case-general. This means that the presence of an independent variable is not enough for a property concerning functions to be deemed case-general – either there need to be other parameters involved, or the property must concern a class of functions. Thus, for example, a proving task about e^{2x} is usually considered case-specific (unless other parameters are involved), whereas a proving task about a^x or e^{kx} is considered case-general (see the *Results* section for further examples). I believe this is in line with how Thompson and colleagues (2012) would have distinguished between specific and general cases. To further clarify this notion, consider the following properties, which were all found (explicitly or implicitly) among the analysed proving tasks:

a) $\int_1^4 \sqrt{x}dx = \frac{14}{3}$
(SW1, Book 3c, p. 197, ex. 12a)

b) $\int_1^a \frac{1}{x^2}dx$ never exceeds π
(SW2, Book 4, p. 158, ex. 4371c)

c) $F(x) = \frac{a^x}{\ln a}$ is a primitive to $f(x) = a^x$
(SW2, Book 3c, p. 159 ex. 5124)

d) $\int_{-a}^a f(x)dx = 2\int_0^a f(x)dx$ if $f(x)$ is even
(FI1, p. 156, ex. F1)

Here (a) is case-specific, while (b)–(d) are all case-general due to the parameter . But, like the examples given in the *Background* section, there are differences in the 'degree of generality' between (b), (c) and (d). While (b) concerns one specific function, (c) holds for a one-parameter family of functions and (d) holds for all even functions, a class too large to be represented by use of a finite number of parameters. In order to capture these differences, I introduce the *function generality framework* with three subcategories: statements about a finite number of specific functions, like (b), will be called *non-general*; statements about parameter families of functions, like (c), will be called *finitely general* and measured by the number of parameters, as long as the number of parameters is finite; statements about more general sets of functions, like (d), which are too large to be represented by use of a finite number of parameters, will be called *infinitely general*.

From the student perspective, the difference between non-general and finitely general proving tasks is that in the latter case the student needs to distinguish the independent variable from other variables, and to be able to handle parameters when manipulating function expressions. But in both cases there are expressions available for algebraic manipulation. In the case of infinite generality, though, the student needs to find suitable ways to represent and use the relevant property (like the property 'being even' in (d)). Thus, I believe the three categories of function generality to be of educational relevance, even though it is sometimes easier to prove an infinitely general statement than a non-general one.

The classification of tasks according to function generality can be done independently of the classification of tasks as case-specific or case-general. But since all case-specific tasks will be non-general, nothing is gained by applying the function generality framework to case-specific tasks. I therefore only apply this framework to case-general tasks; i.e. I see function generality as a way to divide case-general tasks into subcategories.

During the analysis I soon discovered that proving tasks often express a relation between different classes of functions. In such cases, the task was classified according to the 'largest' of these classes. Examples are given in the *Results* section.

In our broader study, mentioned earlier, a second Finnish textbook series is included and parts of the analysis have been done independently by two researchers. During this work we have discussed and compared our coding and resolved all differences.

Finally, even though Examples (a)–(d) are from integral calculus, the ambition is for the framing of generality described here to be applicable to any topic involving functions. Aspects of generality that might be unique to integral calculus will be touched upon in the discussion.

RESULTS

In this section I will present a representative sample of the analysed proving tasks belonging to the different framework categories, as well as tasks that highlight the strengths and weaknesses of the framework as an analytical tool. A summary of the number of proving tasks, by textbook series and generality, is shown in Table 2. For example, SW2 had 13 proving tasks: three case-specific and ten case-general. When these ten were analysed according to function generality, three were found to be non-general, six finitely general, and one infinitely general.

In SW1 and SW2 (but not in FI1 or SWU) I found proving tasks that were case-general, even though they were non-general in the sense that they only concerned specific functions. This was always due to additional parameters, typically as limits of integration, as in Example (b) in the framework section.

Proving tasks of finite generality mostly concerned one- or two-parameter families of functions. SW2 also contained two tasks with three-parameter families. In FI1, six out of 13 finitely general tasks had the constant of integration as its only parameter, as in "Prove the integration formula $\int \sin x\, dx = -\cos x + C$" (FI1, p. 29, ex. 259a).

In SW1 there was no proving task of infinite generality, while in SW2 there was one: "Show that if $f(x)$ is continuous in $a \le x \le b$ then $\int_a^b f(x)dx = -\int_b^a f(x)dx$" (SW2, Book 4, p. 146, ex. 4340). About a third of the proving tasks in FI1 were infinitely general. Half of these were similar to "Prove the integration formula $\int f'(x)e^{f(x)}\, dx = e^{f(x)} + C$" (FI1, p. 35, ex. 271b); i.e., they were essentially related to the chain rule.

During the classification according to function generality, only three tasks proved somewhat difficult to categorize, all of them in FI1. The first reads as follows: "Show that all primitive functions to $g(x) = x^2(5 + 4x^3)^2$ are strictly increasing" (FI1, p. 25, ex. 250). In this task only one specific function is explicitly given, but the statement concerns the one-parametric class of its primitive functions. Therefore, I classified this task as finitely general. However, the proof need not take into account any parameters, since it mainly rests on the fact that $g(x) > 0$.

A similar difficulty concerns ex. 460, p. 112 in FI1, where the student is asked to prove a general formula for the area bounded by a parabola and a straight line. No explicit formulas are given for the two curves. However, since lines and parabolas are graphs of first- and second-degree polynomials, i.e. two- and three-parameter families of functions, I classified this task as finitely general.

	Proving tasks	Case-specific	Case-general			
			Total	Non-general	Finitely general	Infinitely general
SW1	21	15	6	1	5	0
SW2	13	3	10	3	6	1
FI1	30	8	22	0	13	9
SWU	16	13	3	0	1	2

Table 2: Numbers of proving tasks of different case and function generality

The third example connects to the uniqueness of primitive functions, but is actually a result of differential calculus, often referred to as *Rolle's theorem*: "If $f'(x) = 0$ everywhere then f is constant" (FI1, p. 156, ex. F3). The conclusion of this theorem means that the class of functions the theorem concerns is one-parametric. But in the proof, f must be handled as an *arbitrary* function with the property $f'(x) = 0$. I therefore considered this proving task to be infinitely general.

DISCUSSION

In the introduction I posed three questions. The first was how the 'degree of generality' in proving tasks involving functions could be framed. To answer this question, I have described a framework based on the 'size' of the class of functions under consideration. Applying this to proving tasks in integral calculus in four sets of textbooks has made it clear that proving tasks of all three kinds (non-general, finitely general and infinitely general) exist, and that the classification is straightforward as long as the proving tasks are explicit regarding which functions they concern. This indicates that for a generality analysis of upper secondary textbook proving tasks, the categories of the function generality framework are relevant and well-defined.

The second question concerned analytical difficulties. The three concluding examples in the *Results* section indicate that my framing of generality is less suitable when the functions under consideration are not explicitly given. In such tasks, the first step in providing a proof is often to find a suitable representation of the functions involved. One might therefore expect students to experience them as more general than our classification shows. This dimension of generality is not captured by my framework. The third example shows the difficulty in measuring generality in terms of the size of the class of functions when the statement itself is about this size. It is reasonable to believe that such difficulties arise more often when theoretically oriented textbooks are analysed, regardless of whether or not the topic is integral calculus.

The third question concerned the usefulness of the framework. Let us first look at the differences between the textbooks, shown in Table 2. A larger part of the proving tasks are case-general in SW2 than in SW1, and the same holds if we focus on function generality. But if we compare SW2 and FI1, the function generality framework reveals differences that cannot be seen simply by checking case generality. The proportion of case-specific to case-general proving tasks is approximately the same (1:3) for these textbooks. But while a third of the case-general proving tasks in SW2 turn out to be non-general when it comes to function generality, FI1 has no such non-general tasks. In addition, nine out of 30 proving tasks in FI1 are infinitely general (concerns 'any' function), while there is only one such proving task in SW2. The fact that SW1 has no infinitely general proving tasks and SW2 has only one also means that they provide few (if any) opportunities to associate the imperative 'prove' with the providing of a general argument valid for 'any' function. Since proving tasks concerning specific functions or parameter families of functions turn the attention to features specific to these functions and not to properties of integration in itself, the absence of proving tasks of infinite generality also means fewer opportunities for reification (Sfard, 1991) of the integral concept. Such information about textbooks may be of importance to teachers in planning and choosing complementary materials so they will be able to offer students sufficient opportunities to learn the generality aspects of reasoning and proof.

Since the analysis presented here only includes sections on integral calculus, we cannot draw any general conclusions about the analysed textbooks. What is said above only applies to the exercise sets in the integral sections. But the point here is that the results show that the function generality framework has the potential to reveal textbook properties of educational importance that a categorization of proving tasks as case-specific or case-general cannot. It is reasonable to believe that this holds true for other mathematical topics as well. As a first step, we plan to widen the analysis to differential calculus and to include tasks that are proof-related in a broader sense.

There are of course other aspects of proving that are not captured with this framework, and situations in which this framing of generality may be misleading. One topic-specific aspect concerns the constant of integration. As mentioned in the *Results* section, half of the finitely general proving tasks in FI1 had this constant as their only parameter. In such tasks, this parameter is seldom an essential part of the proof. Hence, the number of finitely general proving tasks can be misleading without further analysis of the parameters of the tasks. Another aspect relates to findings in the university textbook SWU. I was surprised to find so few general proving tasks in this book. On the other hand, my impression was that while proving tasks in the upper secondary textbooks often required only routine calculation (direct use of standard formulas for differentiation and integration), the proving tasks in SWU were more non-routine. They often concerned inequalities, and the proofs required that functions be estimated. One way to put it is that authors of upper secondary textbooks seem to want to acquaint students with the word 'show' by using it when one could just as well have asked them to calculate. This tendency is not evident in the university text. The extent to which proving tasks actually require reasoning and not simply standard symbolic manipulation is not covered by my framework, but would certainly be an important element of textbook proving tasks to investigate further.

Analyzing the transition to epsilon-delta Calculus: A case study

Paolo Boero

Genoa University, School of Social Sciences and Department of Mathematics, Genoa, Italy, boero@dima.unige.it

The purpose of this paper is to analyze and discuss a think-aloud production of a first year university student trying to prove an elementary theorem, concerning continuous functions, within the frame of the epsilon-delta Calculus. I will shortly consider current studies on the relationships between a visual justification, based on the graphical representation of a continuous function, and such epsilon-delta proving. Then I will try to show how a comprehensive theoretical framework (integrating different tools) based on Habermas' construct of rationality may account for the complexity of the whole process, for the difficulties met by the student in the transition from the visual-graphical to the epsilon-delta proving, and for the relevance of the visual-graphical reasoning to overcome them.

Keywords: Calculus proof, visual-graphical rationality, epsilon-delta rationality.

INTRODUCTION

The transition, in the first half of the nineteenth century, from Calculus based on the ideas of continuity and derivability of a function as continuity and smoothness of its graphical representation, to epsilon-delta Calculus (i.e. Calculus based on the epsilon-delta definitions of limit, and subsequently of continuity and derivative, usually also called the Cauchy-Weierstrass Calculus) has been dealt with by several authors in different disciplines (History of Mathematics, Epistemology of Mathematics, Psychology, Mathematics Education). In particular, the historical-epistemological analyses (see Grabiner, 1981; Jahnke, 2003) have shown the need of considering different reasons for that transition, like: the emergence of *monsters* and contradictions within the intuitive-visual treatment of continuous functions, when new types of functions not represented by ordinary formulas were considered; the nineteenth century movement towards formal set-theoretic rigour, particularly when proving was concerned (see also Tall and Katz, 2014); the need of dealing in a rigorous way with Calculus in many variables (where reference to visual – graphical evidence may be lost, as concerns the validation of statements); and also the increasing needs arising from the applications of Calculus (particularly stressed in Jahnke, 2003). As concerns the cognitive side, the general agreement about the fact that transition to epsilon-delta Calculus results in many difficulties for students does not correspond to an unique interpretation of those difficulties. For most past Authors difficulties mainly originate in the passage from an intuitive, visual conceptualization to a formal treatment of the same notions. More recently, researchers belonging to the embodied cognition stream of research (cf. Nunez, Edwards, & Matos, 1999) put into evidence the fact that the *natural* notion of continuity of a function and the epsilon-delta notion of continuity refer to very different grounding metaphors: a dynamic metaphor, for *natural continuity*; and three static metaphors (among which the *Preservation of closeness*), in the second case, which result in a hard to overcome conflict with the notions developed according to the dynamic metaphor underlying *natural continuity*. Nowadays, by integrating historical- epistemological studies on the origins and development of Calculus and cognitive analyses, Tall and Katz (2014) provide us with reasons for

> a re-evaluation of the relationship between the natural geometry and algebra of elementary calculus that continues to be used in applied mathematics, and the formal set theory of mathematical analysis that develops in pure mathematics and evolves into the logical development of non-standard analysis using infinitesimal concepts (p. 97).

During the nineties I had the opportunity, as teacher of an experimental course of calculus for first year university students in Mathematics, of collecting some interesting data (written texts, transcripts of oral think-aloud solving processes and notes taken by the observers concerning related gestures and attitudes). Students had been presented the intuitive, graphical notions of continuity and derivative for a real function defined on real numbers (or on an interval of real numbers), then the epsilon-delta definition of continuity at a point had been introduced. The derivative at a point had been introduced through the prolongation by continuity of the incremental ratio. Main theorems of calculus in one variable (in particular, the intermediate value theorem, IVT [1] in the following) had been presented with their epsilon-delta proofs; and some tasks demanding the epsilon-delta proof of easy properties by using those theorems had been proposed. Finally, the usual epsilon- delta notions of limit had been introduced (both in the case of finite and in the case of infinite limits) and applied to solve some exercises and to put into evidence how both continuity and derivative at a point were particular cases of the notion of limit.

Such an experimental approach somehow differed from the usual teaching of the epsilon-delta Calculus in Italy and in many other countries, based on the epsilon-delta definition of limit, because in our experiment the approach to the epsilon-delta reasoning referred to the intuitive notion of *regular* functions (smooth, continuous functions), according to the historical treatment of functions before the epsilon-delta revolution, and then moved to a formal description of *regularity* with the epsilon-delta language, and only at the end considered the epsilon-delta definition of limits.

Students were aware of the experimental character of that teaching of Calculus; they knew very well (thanks to elder students' experience) the difficulty of the subject matter, thus they were willing to engage in an alternative experience of teaching and learning, which possibly might have diminished the difficulties met in the ordinary learning of epsilon-delta calculus. Students volunteered in furnishing documents like private writings, informal drawings, oral reasoning in think-aloud situations.

I will not present the (modest) results of that teaching experiment, and I will not discuss the limitations and the heavy consequences on students of the usual teaching of Calculus focusing on the epsilon-delta systematization (cf. Nunez et al, 1999; Tall & Katz, 2014) – in the reality, the teaching experiment did not represent a radical alternative to it, and probably it is not possible to do more at the university level. I only wanted to introduce the document analyzed in this paper by describing its context of production, in order to open the reflection on it. It is a written and oral document produced by a brilliant student (we will call him Ivan), during a think-aloud problem solving session; it concerns the epsilon-delta validation of a rather elementary statement of calculus. The interest of the document depends on the very detailed presentation offered in it of the mental path followed by Ivan to get the proof and on the fact that the difficulties met (and overcome) by him are very frequent (and frequently not overcome!) among students when they want to validate a statement according to the epsilon-delta criteria.

The aim of the research reported in this paper is to build a suitable theoretical framework to account for what happened during Ivan's problem solving, and to put into evidence the role played there by the visual – graphical treatment of the problem and its importance in the students' approach to epsilon-delta proving.

THE DOCUMENT

Myself as the teacher of the course and a Master Degree student of mine took notes about what we observed, and then compared and completed those field notes, finally integrating them in the transcript of the student's speech. The document is faithfully reported here. (...) for pauses of at least 5"; *italic* for sentences written by Ivan.

> f: R→R is a continuous function;
> $\lim_{x\to+\infty} f(x) = +\infty$; $\lim_{x\to-\infty} f(x) = -\infty$.
>
> The problem:
>
> Prove that there is at least one point c such that $f(c)=0$

Ivan reads the text and after a few seconds draws the x and y axes, and two arrows, upwards on the right, downwards on the left; then he makes a gesture joining with a finger the two arrows and slowly and repeatedly crossing the x-axis; finally Ivan joins the two arrows by drawing an "oscillating" line.

1 Well, it seems to me that (...) yes, it is a case of the IVT.

2 IVT says that I may find c such that $f(c)=0$ (...)

3 yes, but how to find a and b? First, I have to find a and b (...)

4 and to exploit continuity

Ivan comes back to look at the drawing; two index fingers are placed on the upwards and downward arrows.

5 Yes, the limit perhaps says something.

Ivan makes an horizontal movement with his right index finger and crosses the right upwards arrow.

6 If I take *a* value of y, the function must be over that value when x is enough big. But how to choose a value of x? (...)

7 Before I need to choose a value of y. But the value of y is whichever (...)

8 Whichever M, I take M and I may find T such that for every $x>T$ (...)

Ivan makes again a horizontal movement with his right index finger and crosses the right upwards arrow.

9 This might be the value of M, the value of y, then I find the value of x, the value of x which is b, such that if $x>b$ then $f(x)>M$

10 But I have $f(x)>M$, not $f(x)=M$

11 Is it $f(b)=M$? (...)

12 Not sure! (...)

13 I might take one point x' such that $f(x')>M$; that point is the extremity of the interval on the right!

14 But why $f(x')>0$?

15 Yes, I need to take $M>0$! M is a number, whichever number!

16 On the left it is the same: I find x'' such that $f(x'')<0$.

17 The interval for the IVT is (x'', x'). Let us write the proof:

Ivan speaks and writes at the same time, by dictating to himself what he says

18 *Thanks to continuity of f and IVT, $f(x'')f(x')<0$ implies that c exists in (x'',x') such that $f(c)=0$.*

19 Not, it does not work! First, I need to find x' and x''.

20 *Thanks to hypotheses on limits, given $x'>0$ I find $f(x')>0$.*

21 Not, still it does not work! I need to come back to how I could find $x'>o$ such that! No, not how, why I could find it! Because of limits! How to write it well?

22 *Thanks to the hypothesis on limits, given $M>0$ I may find $x'>0$ such that* (...)

23 Not: I may find x_M such that for every $x>x_M$ I have $f(x)>M$.

Ivan puts a strikethrough over all what he had already written, and starts again to dictate to himself and to write down:

24 *Thanks to the hypothesis on limits, given $M>0$ I may find x_M such that for every $x>x_M$ I have $f(x)>M$. I take one point $x'>x_M$. $f(x')>M>0$.*

25 Well, now it works.

26 *In the same way I find x'' such that $f(x'')<0$.* (...)

27 *There is a point c, $x''<c<x'$, such that $f(c)=0$* (...)

28 Not, this is the conclusion, before it I must write the hypothesis and then the conclusion.

Ivan puts a strikethrough over the last line, named 27 above, and dictates to himself and writes down:

29 *Now I may apply the IVT to the function f in the interval (x'', x'): $f(x'')f(x')<0$, thus c exists in the interval (x'', x'), such that $f(c)=0$*

When the document was analyzed, the complexity of the student's behaviour and the analytical tools available in that moment (1995) did not allow to perform an exhaustive, in-depth description and interpretation of the difficulties met by the student and of how he was able to overcome them. At that time we were only able to find some elements that could qualify as mature Ivan's mastery of the visual-graphical notion of continuity and infinite limits at the infinity, his identification of IVT as the theorem which might have allowed him to perform a rigorous validation of the statement, the immediate reference to the problem of finding the extremities of the interval where to apply IVT, and the identification of the epsilon-delta definition of infinite limits at infinity as the crucial tool to solve the problem. Then Ivan enters the epsilon-delta reasoning and the situation seems to become more and more confuse: the search for the extremities of the interval where to apply IVT results in an apparently messy sequence of steps of reasoning to get the abscissa of a point where the function is positive. When the interval to apply IVT is constructed, a further problem concerns the organization of the text in order to satisfy the textual and logical constraints of a proof text. This description is a pure narration of Ivan problem solving process. It does not allow to account for:

- the functional relationships between Ivan inner questioning (see steps 3, 6, 11, 14, 21) and the different kinds of answers (sometimes a decision concerning how to go on, sometimes the control of a proposition or a chain of propositions);

- the nature of the difficulty met in the central part of the process (from 6 to 17), and what allowed to overcome them;

- the nature of the difficulties met in the last part of the process (from 18 to 29).

THE NEED FOR A COMPREHENSIVE FRAMEWORK: THE HABERMAS CONSTRUCT OF RATIONALITY

The document does not speak by itself; we need theoretical tools to make Ivan's voice understandable by us, and possibly identify an intentionality that might drive Ivan's towards the final result, in spite of the superficial impression of "*a random walk luckily resulting in a good conclusion*" (according to the evaluation of the document by a colleague of mine who teaches Calculus for first year university students). We need also to understand why apparently so obvious steps (like finding a point x where f(x)>0, given the hypothesis of +∞ limit at +∞) become so difficult when the path moves through the epsilon-delta forest.

The first need suggested us to try and adapt Habermas' construct of rational behavior to Ivan's problem solving (as a process driven by intentionality to get a correct result by enchaining correct steps of reasoning, and to communicate it in an understandable way in a given community). The second need was satisfied by integrating, within the use of Habermas' construct, an analysis of some phases of Ivan problem solving process in terms of *mental dynamics* related to the treatment of propositions and the mastery of logical constraints, according to the Guala and Boero's elaboration on mental dynamics in problem solving (see Guala & Boero, 1999). They consider "mind times" that may be generated during the problem solving process: e.g. when imagining to move back from an hypothetically attained goal to a previous situation; or when going back and retrieving some information from memory, and projecting it in an imagined, future situation; etc.

Habermas' construct of rational behavior deals with the complexity of discursive practices according to three interrelated elements: knowledge at play (epistemic rationality); action and its goals (teleological rationality); communication and related choices (communicative rationality). Thus, it seems suitable for being applied to mathematical activities like proving and modeling that move along between epistemic validity, strategic choices and communicative requirements. The following aspects of Habermas' elaboration (1998, pp. 310–316) are relevant for us.

Concerning epistemic rationality

> We know facts and have knowledge of them only when simultaneously know why the corresponding judgments are true. (...) Someone is irrational if she puts forward her beliefs dogmatically, clinging to them although she sees that she cannot justify them. In order to qualify a belief as rational, it is sufficient that it can be held to be true on the basis of good reasons in the relevant context of justification (...) The rationality of a judgment does not imply its truth but merely its justified acceptability in a given context. (p. 312)

The intentional character of rational behavior on the epistemic side emerges from these remarks in a perspective of progressive development of knowledge (the qualifying element being the tension towards knowing "*why the corresponding judgments are true*"). In Habermas' elaboration, the exercise of epistemic rationality is strictly intertwined with speech and with action (i.e. teleological rationality)— the latter resulting in the evolutionary character of knowledge:

> Of course, the reflexive character of true judgments would not be possible if we could not represent our knowledge, that is, if we could not express it in sentences, and if we could not correct it and expand it; and this means: if we were not able also to learn from our practical dealings with a reality that resists us. To this extent, epistemic rationality is entwined with action and the use of language. (p. 312)

We will see how this way of conceiving the interplay between knowledge, speech, and action will account for some relevant aspects of Ivan's proving.

Concerning teleological rationality

> Once again, the rationality of an action is proportionate not to whether the state actually occurring in the world as a result of the action coincides with the intended state and satisfies the corresponding conditions of success, but rather to whether the actor has achieved this result on the basis of the deliberately selected and implemented means (or, in accurately perceived circumstances, could normally have done so). (p. 313)

Let us consider problem solving in its widest meaning (including conjecturing, proving, modeling, finding counter-examples, generalizing, and so on): the above sentence highlights the quality of a process, which may be qualified as rational (on the teleological side) even if the original aim is not attained. The intentionality of action (including the choice and use of the means to achieve the goal) and the reflective attitude towards it are two relevant features of teleological rationality.

> A successful actor has acted rationally only if he (i) knows why he was successful (or why he could have realized the set goal in normal circumstances) and if (ii) this knowledge motivates the actor (at least in part) in such a way that he carries out his action for reasons that can at the same time explain its possible success. (pp. 313–314)

Concerning communicative rationality

> (...) communicative rationality is expressed in the unifying force of speech oriented toward reaching understanding, which secures for the participating speakers an intersubjectively shared lifeworld (...). (p. 314)

The above sentence illustrates an ideal practice of communicative rationality, and the related values. Then Habermas presents a condition that qualifies an actual individual behavior as rational on the communicative side:

> (...) The rationality of the use of language oriented toward reaching understanding then depends on whether the speech acts are sufficiently comprehensible and acceptable for the speaker to achieve illocutionary success with them (or for him to be able to do so in normal circumstances). (p. 314)

Even in the above sentence the intentional, reflective character is pointed out (for the specific case of communicative rationality).

Habermas' construct offers a model to deal (after adaptation) with important aspects of mathematical activity, without capturing *all* the aspects (see Boero & Planas, 2014, pp. 207–208 for a brief presentation of some of its intrinsic limitations). It has been initially used as a tool to analyse students' rational behavior in proving activities according to the researchers' (and teachers') expectations (see Boero, 2006; Morselli & Boero, 2011). Its application to analyses that also use other constructs gradually resulted in a rich toolkit with various applications (see Boero & Planas, 2014).

ANALYSIS OF THE DOCUMENT [2]

In the perspective of the Habermas' construct of rationality, integrated with Guala and Boero's elaboration on mental dynamics, the document provides us with the opportunity to analyze and interpret Ivan's proving as a *rational* enterprise. It also offers an occasion (based on that analysis) to reflect on some crucial aspects of a successful approach to what we may call the *epsilon-delta rationality*. Indeed in the reported document we may identify:

- the continuously renewing, conscious interplay, driven by an inner questioning (steps 3, 6, 11, 14, 21), between the need of performing strategic choices (*teleological rationality*) aimed at getting the elements to move forth, and the epistemic control on how they fit (or do not fit) the requirements of *epistemic rationality*;

- some mental dynamics (cf. Guala & Boero, 2009) related to Ivan's strategic choices (*teleological rational-*

ity) performed to meet *epistemic* requirements. We may observe how in the first part of Ivan's work he follows (as the movements of his hands show – see description before step 1) the time ordering of the text of the task, moving from the hypothesis on limits to the visual-physical search of the points of intersection with the x axis. Then an abductive shift is made to the IVT, which should guarantee the same result within the theory: this means a shift to a different *epistemic rationality*. At that point, a reverse mental movement is made, from focusing on the existence of the intersection point (step 2), to the search for the interval to which the IVT should be applied (step 3). This movement means moving back from the time of the solved problem to the time of the hypotheses that guarantee the solution. A similar movement will be replicated later (step 7), and expressed through a temporal adverb ("*before*", "*prima*" in Italian). In both cases an inner question related to how to validate (*epistemic rationality*) a partial result got during the development of the problem solving process suggests to go back to the condition that ensures its validity. Let us consider now what we might call the *quantifiers game,* played from step 7 to step 15 and then at least partially echoed in the writing phase (steps 18 to 24, where the *epistemic rationality* and the *communicative rationality* constraints are intertwined). From the satisfied condition of infinite limit at the infinity: *for every M there is* x_M *such that if* $x > x_M$ *then* $f(x)>M$ it is necessary to move to: *in particular, I choose M≥0 and then I get x' such that f(x')>M≥0*, with a change of logical status: from general quantification and consequent existential quantification and subsequent universal quantification, to particularization of the generality of M in order to get a point where the function is positive. Focus must move from the general condition of limit to a specific implication of it. The condition to be satisfied becomes f(x')>0, thus M must be chosen as M≥0. The Mind times toolkit, applied to a micro-analysis of this phase of the process, allows to interpret the mental weight inherent in this phase and its difficulty: a projection in the future time of the application of the IVT results in the choice of a *particular* value of M, at the beginning of the logical and mentally temporal chain of quantifiers, suitable to get the *appropriate* value of x';

- the full mastery of the logical and temporal structure of a theorem, interfaced with the above change of focus; this is evident in the steps 18 to 24;

- the need to satisfy the requirements of *communicative rationality*, consciously related to the *epistemic* requirements. *Communicative rationality* must account for satisfied *epistemic* requirements in the outer speech/writing, while epistemic requirements drive the inner dialogue towards consequent actions: this emerges in the steps 23–29, with communicative constraints particularly evident in the steps 27–29.

REFLECTIONS ON THE ANALYSIS OF THE DOCUMENT

The adaptation of the Habermas' construct to Mathematics Education offers the opportunity to qualify the visual-graphical Calculus as fully *rational*. Indeed that pre-Cauchy Calculus, when dealing with "ordinary" functions, has its own criteria of epistemic validity, its own strategies to solve problems, its own means of intentional communication. This is reflected in the first part of Ivan's elaboration: requirements of *epistemic validity* are of visual nature, and the chosen strategy to solve the problem consists in the translation of the verbal hypotheses of the statement into visual-graphical hypotheses, which will be connected to the thesis through the gesture of the finger that crosses the x axis in order to connect downwards and upwards arrows. Also inner and outer communication is mainly visual (through the signs on the sheet of paper and the gestures). This is not new (cf. some remarks by Nunez et al., 1999, and by Tall & Katz, 2014), but the use of Habermas' construct of rationality suggests us to reflect on how that system of thinking (with its specific epistemic, teleological and communicative characters), relevant in the history of mathematics, may work today not only as an intuitive first step when moving towards the epsilon-delta proving, but also as a resource during the epsilon-delta proving to support some of the most delicate student's actions (in the case of Ivan, this is particularly evident, thanks to his gestures, in the descriptions after the steps 4, 5 and 8).

In Ivan's elaboration, the statement of the IVT "represents" what is already clear in his first approach, and guaranteed by a gesture (see above); it also opens the way to its formal treatment by orienting the search for the interval in which it can be applied, based on the formal definition of infinite limit at infinity. We may interpret IVT as a pivot in Ivan's transition from the visual-graphical rationality to the epsilon-delta rationality in the treatment of the problem.

In terms of mental dynamics, we may better understand the complex relationships between the visual-graphical rationality and the epsilon-delta rationality, and the difficulties to manage the latter. On one side, the management of mind times in the epsilon-delta Calculus implies the necessity of changing the temporal and logical order of quantifiers, moving from $f(x) > M$ (whichever M) to the choice of a value of M such that we can get x' and $f(x') > M$. This suggests a perspective (alternative to Nunez, Edwards and Matos elaboration) to interpret why it is so difficult to move from visual-graphical to epsilon-delta calculus. On the other side, on the *teleological* dimension, the visual-graphical rationality provides Ivan with the visual and gestural support to bear the weight of the complex logical and temporal operations needed to construct the (x'', x') interval where to apply the IVT. Indeed the movement of his right index finger not only suggests the existence of a point where the function is positive, but also provides Ivan with the opportunity of "seeing" how to move from a general quantification on M, to the choice of a particular M in order to get a value x' such that $f(x') > 0$, thus orienting Ivan's mental dynamics.

CONCLUSIONS

The case of Ivan's think-aloud proving of a simple theorem of epsilon-delta Calculus was an occasion to search for a comprehensive framework to deal with the problem of analyzing the transition from visual-graphical proving, to epsilon-delta proving in Calculus. The Habermas' construct of rationality, integrated with an analysis of the proving process in terms of mental dynamics, suggests a solution, which in the case of Ivan accounts for his intentional work and his difficulties. It also suggests to reconsider the visual-graphical treatment of proving not only as a heuristic starting point, but also as a consistent *rationality* and, as such, a permanent, sure reference when students move within the forest of the epsilon-delta proving during the approach to the epsilon-delta Calculus as taught in most universities.

ENDNOTES

1. Precisely, by IVT we mean the theorem whose statement in Ivan's textbook is: "If f is a continuous function in an interval (a,b) and $f(a) \cdot f(b) < 0$, then at least one point c exists in the interval (a,b) such that $f(c) = 0$."

2. In the Turin international symposium (November, 21, 2014) on "Mathematics Education as a transversal discipline", Ferdinando Arzarello presented an alternative analysis of the same protocol, based on an integration of the Habermas construct with analytical tools derived from Hintikka's Logic of inquiry, with some points of contact with the analysis presented in this paper as concerns the teleological dimension of rationality.

Pre-service teachers' construction of algebraic proof through exploration of math-tricks

Orly Buchbinder[1] and Alice Cook[2]

1 University of New Hampshire, Durham, USA, orly.buchbinder@unh.edu

2 University of Maryland, College Park, USA

This paper contributes to the ongoing effort to create rich learning opportunities for prospective teachers to engage with reasoning and proving. Twenty elementary and middle school pre-service teachers completed individual projects in which they explored "math-tricks" – unconventional computational algorithms – as a part of an undergraduate proof course. Our findings suggest that the task evoked uncertainty with respect to why the tricks work and motivation to resolve the uncertainty by means of algebraic proof. We discuss the potential of this task to create rich opportunities for prospective teachers to conduct explorations, construct algebraic proofs and reflect on their experience from learner's perspective.

Key words: Proof, pre-service teachers, uncertainty, algebraic reasoning.

INTRODUCTION

The central role of reasoning and proof in teaching and learning mathematics has been long recognized by mathematics education community and by policy makers. In recent years there has been a movement in the United States towards making proof an integral part of mathematics curriculum not just for students in high-school geometry but across all grade levels (NCTM, 2000; CCSSO, 2010). This trend is also associated with growing demand for deeper conceptual knowledge of number sense and algebraic reasoning (CCSSO, 2010).

In order to provide students with learning environments that emphasize reasoning and proof, teachers themselves need to have strong subject matter knowledge and a solid understanding of proof (e.g., Knuth, 2002, Stylianides & Ball, 2008). However, research studies consistently show that pre-service teachers (PSTs) have inadequate conceptions of proof, and experience difficulties in distinguishing between empirical and deductive arguments and in understanding the different roles of proof in mathematics (e.g., Martin & Harel, 1989; Ko, 2010).

In recognizing the impact of teachers' knowledge of proof on students' experiences with proof, many teacher education programs have designed courses and instructional activities oriented towards developing pre-service teachers' conceptions of proof, especially at the elementary and middle school levels (e.g. Stylianides & Stylianides, 2009). According to Ball, Hill and Bass (2005) teachers need to experience mathematics from the learner's perspective in order to gain appreciation of mathematical ideas, develop better understanding of the ways students interact with them and become aware of the difficulties students encounter. With respect to proving, this might entail engaging PSTs in mathematical exploration, conjecturing, and proof construction. However, designing such tasks for elementary and middle school teachers is a pedagogical challenge for teacher educators. Teachers' prior knowledge of mathematical content might hinder their ability to grasp the complexity of underlying mathematical ideas or their ability to consider students' perspective. It also might reinforce an inadequate view of proof as a routine exercise of justifying well-known and prior established facts (Knuth, 2002).

Several approaches to address this issue have been suggested. For example, Barkai and colleagues (2002) asked elementary PSTs to analyse students' arguments in elementary number theory. Stylianides and Stylianides (2009) suggested a "construction-evaluation" model in which elementary teacher candidates were asked to write a proof of a given statement and then to evaluate the validity and generality of their arguments. Despite the reported success of these approaches, Ko (2010) points to the need for more research on strategies for developing PSTs' conceptions of proof and adequate knowledge of proving.

With this paper we aim to contribute to the ongoing effort of the field to create learning opportunities for teacher candidates to engage with reasoning and proving. We report on one task that was developed and implemented in our undergraduate course titled "Reasoning, Justification and Proof for elementary and middle school teachers". The task aimed at promoting PSTs' understanding of algebraic proof through analysis of unconventional computational algorithms (math-tricks) and through reflection on their proving experiences. Qualitative methods were used to analyse the types of student-generated proofs, their spontaneous use of algebraic proof and/or of algebraic notation in it, and to explore cognitive and affective aspects of the ways in which prospective teachers' coped with the task from the students' perspective.

THEORETICAL CONSIDERATIONS

Our approach for designing the task "exploration of math-tricks" is grounded in several theoretical notions. First, we build on Harel's (2007) premise that instruction should appeal to and foster students' *intellectual need to prove*. Implementation of this principle entails creating learning situations in which the need for proof arises intrinsically. One possible way to achieve this is by creating uncertainty regarding whether a certain mathematical phenomenon is true or false. Research studies have shown that such tasks generated a need to resolve the evoked uncertainty by means of argumentation, explanation, convincing and proving (e.g. Buchbinder & Zaslavsky, 2011; Hadass, Hershkowitz, & Schwarz 2000).

Zazkis (1999) suggests that uncertainty can be evoked by exploration of "non-conventional" mathematical objects such as number systems other than base 10 or non-Cartesian coordinate systems. Building on this approach, we created a task that invited PSTs to evaluate non-conventional computational algorithms, or math-tricks, and either prove or refute them. Thus, prospective teachers could explore unfamiliar mathematical phenomena embedded within familiar content.

Finally, our work is grounded in the research that highlights the importance of teachers' reflection on their own thinking from the learner's perspective. According to Zaslavsky and Sullivan (2011) the process of resolving uncertainty combined with reflection on personal experience can lead teachers to revaluate and refine their understanding of mathematical content of the task, and promote teachers' awareness of difficulties students might experience while engaging with this content.

THE SETTING

Twenty elementary and middle school PSTs participated in the course on mathematical reasoning and proof which most students took during the 3rd or the 4th year of their program. The task "Exploration of math-tricks" was given to PSTs as individual project and asked them to (a) watch, understand and describe a math-trick presented in a video in their own words; (b) analyse the math-trick and either prove that it works or disprove it by a counterexample; (c) compare the math-trick to the corresponding convention algorithm and discuss similarities and differences between them; and finally (d) write a reflection on the exploration and proving process in this task. The students were given four weeks to complete the project. They were encouraged to cooperate with each other, but required to submit their original work.

Task analysis

The content to which we refer as "math-tricks" is a collection of short videos which we found on the web[1]. Each video presents an unconventional, albeit correct under limitations, algorithm for one of: multiplication, division, calculation of square or cube roots, solving systems of linear equations and many others. Due to space constrains we present here a short description of two such math-tricks (Figure 1).

These algorithms can be regarded as unconventional since they differ substantially from standard algorithms found in mathematical textbooks both in content and in presentation style. In the video, the presenter used several numeric examples to illustrate each algorithm, describing them as "faster, easier and smarter ways", "math-tricks", and "pure magic", without any expectation on the part of the

1 It is not our intent to either criticize or promote this online content for any purpose beyond described in this paper.

Trick #1: Special trick for multiplication
Suppose you want to multiply two two-digit numbers that have the same tens digits and the sum of their unit digits is 10. For example, consider: 36×34. First, multiply the tens digit of a multiplicand by next counting number: $3\times(3+1)=3\times 4=12$. These are the first two digits of the product. To obtain the last two digits of the product simply multiply the unit digits, e.g. $6\times 4=24$. Thus, the product is: $36\times 34=1224$.

Trick #2: *Trick for squaring numbers 10 – 19*
Suppose you want to square a number between 10 and 19, e.g. 17^2. To find the first two digits of the product add the unit digit to the original number: $(17+7)=24$. To find the last digit, square the unit digit of the original number $7^2=49$ and add it to the number obtained before, carrying forward the 4 and ensuring that 9 remains the units digit: $24\square + 49 = 289$. Thus, $17^2 = 289$.

Figure 1: Description of two "math-tricks" as presented in the video

viewer to understand why these algorithms produce correct results. However, as shown in Figure 2, when represented algebraically, the "tricks" appear to be just special cases of multiplication of two two-digit numbers. Thus, the math tricks could be analysed with algebraic techniques accessible to pre-service elementary teachers.

a proper justification. For example, students in this category merely restated the algorithm or wrote that it works because of its similarity to conventional algorithm. Two other categories were *Partial general argument* - unfinished general argument or missing details, and *Valid proof*. For the second criterion, use of algebraic notation, we identified the following categories: *No algebraic notation*– students used only numeric examples or described their thinking in words; *Semi-algebraic notation* – although some variables and algebraic symbols were present in student work, they were not used meaningfully or were not functional for proof construction; and *Correct algebraic notation*. The latter category was further divided into two sub-categories: *Standard algebraic notation*, such as using $(10a + b)$ to represent a two-digit number; and *Self-invented notation,* meaning that students came up with their own correct algebraic representations.

Conventional multiplication of two-digit numbers	Special trick for multiplication	Trick for squaring numbers 11-19
a, b, c, d digits	$a=c,\ b+d=10$	$a=c=1,\ b=d$
$(10a+b)(10c+d)=$ $100ac+10(ad+bc)+bd$	$(10a+b)(10a+d)=$ $100a^2+10a(b+d)\ +bd=$ $100a^2+100a+bd=$ $100a(a+1)+bd$	$(10+b)(10+b)=$ $100+10(b+b)\ +b^2=$ $10[(10+b)+b]+b^2$

Figure 2: Algebraic representation of the conventional multiplication and two "math-tricks"[2]

Data and analytic techniques

The data for this paper come from 20 student project papers on 13 different math-tricks. In order to explore the students' proof production, their mathematical arguments were analysed through open coding (Staruss, 1987). Two major criteria emerged, along with corresponding categories focusing on algebraic notation and proof justification. For the first criterion – proof production - the following categories emerged: *Invalid justification* – students either relied solely on empirical evidence or did not produce

When analysing students' written reflections we looked for evidence of uncertainty evoked by the task and students' approaches to resolve it. We also identified and examined instances of students reflecting on their proof experiences as learners, their mathemati-

2 Note that the constrains on variables in both tricks account for the place value of the digits in the product in such way that adding the unit digits can be described as "placing" them in the units place.

Representing the trick with algebraic notation: $\prod x \bullet y = a \bullet (a+1), b_1 \bullet b_2$

Where x is the multiplicand, y is the multiplier, a is the first digit of the multiplicand, b_1 is the last digit of the multiplicand and b_2 is the last digit of the multiplier. The comma is to separate portions of final product.

Why it works: The math trick works because the requirements are extremely narrow. Since both beginning portions of the multiplicand and multiplier must be the same, it allows for consistency between the parts of the algorithm. The last digits being multiplied by each other happens in both the conventional algorithm and the math trick. By adding the following consecutive integer to the first digit of the multiplicand, it covers the part of the conventional algorithm that incorporates the addition of the problem.

Figure 4: Melanie's analysis and justification of *Special trick for multiplication*

cal struggle, and connections to their future teaching. Due to the space constraints not all categories will be reported herein.

RESULTS

Students' mathematical arguments

First we report on the kinds of PSTs' mathematical arguments and their use of algebraic notation. This section illustrates some of the categories described above with examples of students' arguments and excerpts from their reflections. Figure 3 below summarizes distribution of students' arguments across all categories.

Our data suggests that success with proof production was strongly related to use of algebraic representation. PSTs who used correct algebraic notation were able to either produce valid proofs or partial general arguments that could potentially be turned into proofs. Interestingly, only 3 PSTs used standard algebraic notation, while 8 students invented their own representations (see examples below). Five students used, what we call, semi-algebraic notation, meaning that their use of variables was insufficient or not functional and did not result in production of valid proofs. Nevertheless, 3 students provided additional written explanations and produced partial general arguments. Four students whose arguments were categorized as invalid either relied solely on empirical evidence or used semi-algebraic notation. Only one of them seemed to be aware of limitations of such a line of reasoning.

Examples of students' work

Melanie's work on the *Special trick for multiplication* (Figure 4) illustrates the category of arguments that used semi-algebraic notation and produced invalid justification.

Melanie recognised the similarity between the conventional algorithm and the math-trick, and tried convey it in her explanation. She described her observations eloquently, but provided little insight on *why* the trick works. For example, it is not clear from her explanation *how* the similarity of "both beginning portions" of the two factors "allows for consistency between the parts of the algorithm". In her reflection, Melanie described the challenges she encountered in representing the trick algebraically and in explaining why it works. She also referred to her experiences as student and difficulties in understanding algorithms in general:

> *.... creating an algebraic notation was very challenging [...] I found it very challenging to under-*

Use of algebraic notation / Type of argument	No algebraic notation	Semi-algebraic notation	Correct algebraic notation	
			Self-invented	Standard
Invalid justification	2	2	--	--
Partial general argument	2	3	2	--
Valid proof	--	--	6	3

Figure 3: Distribution of teacher candidates' mathematical arguments (N=20)

Why it works?

Let's look at this algebraically: If we look at $ab \times ac$, we can see that a is the tens digit, so if your numbers were 22 and 28 then a would equal 20. Since we are adding 1 to the tens digit, we are essentially adding 10 to 20. This gives us the $a(a+10)$. I needed to incorporate the rule that the sum of b and c is 10, so I made $b = 10 - c$.

$$(a+b)(a+c)=a(a+10)+bc$$
$$(a+10-c)(a+c)=a(a+10)+(10-c)c$$
$$a^2+10a-ac+ac+10c-c^2=a^2+10a+10c-c^2$$
$$a^2+10a+10c-c^2=a^2+10a+10c-c^2$$

Figure 5: Thomas's analysis and justification of *Special trick for multiplication*

> *stand why the trick works as a whole, although I can understand how to do it and its limitations. I have personally never been one very strong in understanding the functioning of algorithms at the core so it did not surprise me that I had difficulty understanding how the trick worked.*

Another student, Thomas, who analysed the same trick, came up with his own way to represent two-digit numbers and used it to produce a valid proof (Figure 5).

Thomas represented a two-digit number using notation somewhat similar to the standard, as $(a+b)$, where a represents tens. He then used the distributive property to show that the product of two two-digit numbers yields the same algebraic expression as described in the math-trick. One disadvantage to Thomas's notation is the need to remember that the variables a and c in the final expression represent different things: tens and units respectively—a detail imperative to account for place value of the product's digits. Thomas's reflection is a detailed account of his thinking process, his initial frustration and feeling of excitement when the proof was completed:

> *I was impressed with this trick from the beginning, but I struggled expressing it algebraically. It seems simple now, but at the time it was very frustrating. During the process of writing my equation I kept treating a like it was a single digit number instead of treating it like the place value that it held. [...] I am not sure why it clicked, but I realized a was the tens digit, while b and c were the ones digits [...] It has been quite some time since I have been as excited as I was when all of this clicked. It took me analyzing and breaking down both the trick and the conventional algorithm to create my equation.*

Another student, Cindy, also came up with her own version of base 10 notation to analyse the *Trick for squaring numbers 10 – 19* (Figure 1) and was able to produce a valid proof for this trick. Cindy used n to denote the entire two-digit number between 10 and 19, and used $(n-10)$ to represent the units digit (Figure 5).

Cindy's reflection reveals both cognitive and affective sides of the process she went through in her exploration. Although the exploration of math-trick was not an easy task for Cindy she persevered and was able to solve it correctly. She wrote:

> *This task was a little time consuming and confusing at first. [...] I did this by trial and error, until I realized a key element I was missing. My "aha" moment was when writing the general rule. [...] I kept trying to manipulate the equation in different ways, and finally realized that I need to account that we are solving for the first 2 digits in a 3-digit number. Therefore, I need to multiply the first portion of the equation by 10 to account for the 10's and 100's digits.*

To find the first two digits of n^2: $10[n+(n-10)]$

To find the last digit of n^2: $(n-10)^2$

Conjecture: For all whole numbers from 10 to 19: $n^2 = 10[n+(n-10)]+(n-10)^2$

Check the conjecture using appropriate algebraic notation:

$$n^2 = 10[n+(n-10)]+(n-10)^2$$
$$n^2 = 20n-100+n^2-20n+100 \longrightarrow \boxed{n^2} = \cancel{20n} \cancel{-100} + \boxed{n^2} \cancel{-20n} \cancel{+100}$$
$$n^2 = n^2.$$

Figure 5: Cindy's analysis and justification of "*Trick for squaring numbers 10–19*"

Cindy and Thomas's reflection shows that the analysis of an unconventional algorithm led them to consider more carefully the standard multiplication algorithm and place value. This was a recurring theme in most of students' reflections, including students who eventually were not successful in producing valid proofs.

Students' reflections on the exploration process

In our analysis of PSTs' reflections we identified evidence for the uncertainty evoked by the task, expressions of students' interest in the math-trick project and their consideration of the task from the leaner's perspective. This analysis was overlaid onto an analysis of students' mathematical arguments. Not surprisingly, students who produced valid proofs or partial general arguments described feelings of accomplishment and satisfaction with the project (including the two students who produced invalid arguments but were unaware of this). Although the degree of uncertainty evoked by the task varied within the group, almost all PSTs indicated that they were surprised by the math-tricks. PSTs distinguished between challenges involved in understanding the steps of the trick, *why* it works, and constructing a proof. Some PSTs who understood the trick relatively easily, but struggled with proving, tended to describe the task as frustrating, or hard. For example, Lisa wrote:

> *It was easy for me to see how the trick was connected to the conventional method and to see that it would always work. The hard part was explaining it because I cannot think of a way to put this trick in algebraic notation and it is very hard to visualize the math using words.*

Other students felt initially perplexed by the algorithms, but felt more comfortable once they represented them algebraically. For instance, Helen wrote:

> *Understanding how to complete the trick wasn't too complicated, but understanding why it works was a difficult task. [...] for me, the "Aha" moment was once I thought of using variables. Seeing the steps in variable form, instead of using numbers made it very clear to me how the process worked.*

For the majority of PSTs, transitioning from empirical exploration to algebraic representation was not a straightforward process. Aside from 3 students who felt comfortable with it, the group reported on difficulties they encountered, the strategies employed to resolve the impasse and their "Aha!" moments. Students like Melanie or Lisa, who felt that they did not resolve the uncertainty, shared feelings of frustration and lesser competence in their mathematical ability. This might have been avoided or reduced by encouraging greater collaboration and sharing ideas among students.

Several students reflected on their exploration of math-tricks from both learner and future teacher perspectives. Following is an excerpt from Natalie's project paper, with the original emphasis:

> *This process was different for me because my role was to be both a student and a teacher. When I was a student in this process I had to figure out how the trick worked, but when I was a teacher in this process, I had to explain why the trick worked. As a student, this involved noticing patterns, and as a teacher, this involved synthesizing and explaining the real math behind the trick.*

CONCLUSION

In this paper we described the design and implementation of the task "Exploration of math-tricks" with elementary and middle school pre-service teachers. The task aimed to enhance PSTs' appreciation of proof and highlight its exploratory function through investigation of unconventional computational algorithms – "math-tricks". Our data show that, as anticipated, the task evoked uncertainty regarding how and why these algorithms function, which most of the students resolved through proving. The majority of students in our course used standard or self-invented algebraic representations to produce proofs or partial general arguments. Not surprisingly, prospective teachers who felt less proficient with algebra were less successful in producing proofs and in resolving uncertainty as evident from their comments. Nevertheless, exploration of unconventional algorithms allowed teacher candidates to review and refine their knowledge of standard computational algorithms and algebraic techniques. Our findings concur with theoretical notions underlying the role of uncertainty in fostering a need for proving and with empirical studies which utilized exploration of unconventional mathematical objects in instructional tasks with PSTs (e.g., Buchbinder & Zaslavsky, 2011; Zaslavsly, 2005; Zazkis, 1999).

Our analysis of PSTs' reflections revealed a complex account of cognitive and affective aspects of engagement with exploration of math-tricks; while some PSTs described difficulties in transitioning from informal argument to algebraic proof, others felt that algebraic notation aided in expressing their mathematical ideas. PSTs reported on mixed feelings of initial challenge and struggle with the task; but also on their excitement after successful (in their view) production of proof, or frustration when failed to produce one. We conclude that exploration of math-tricks combined with reflection on their own proving process allowed PSTs to evaluate this experience from learners' perspective and, in some cases, consider difficulties students might encounter with the concept of place value in multi-digit arithmetic. Furthermore, it seems that engaging in exploration and proving of math-tricks can provide pre-service teachers with the valuable opportunity to consider the role of both student and teacher.

A case study: How textbooks of a Spanish publisher justify results related to limits from the 70's until today

Laura Conejo, Matías Arce and Tomás Ortega

University of Valladolid, Valladolid, Spain, lconejo@am.uva.es

In this paper we present the evolution of the proof schemes shown in grades 11 and 12 textbooks of a Spanish publisher related to the theorems of limits. In order to analyse this evolution, we use a framework developed from the definitions of proof schemes, preformal proofs and functions of proofs. Firstly, we describe our framework and then we show a case study applying the framework to textbooks (from the 70s until today) of a Spanish publisher. Some results and reflections about the analysis are described at the end as well as consequences for further studies.

Keywords: Proof schemes, preformal proofs, textbooks, limits.

INTRODUCTION

The main goal of a mathematical proof is to verify the correctness of mathematical statements. Under the perspective of mathematical education research we agree with Hanna (1995), who claims that mathematical proof promotes understanding. Moreover, Hanna & Barbeau (2010) think that proofs are bearers of mathematical knowledge in the classroom because proofs embody "methods, tools, strategies and concepts for solving problems" (Rav, 1999, p. 6) which is the essence of mathematics. Textbooks (that is, any book used by teachers and students, during a scholar year, in a teaching and learning process of a certain subject, González, 2002) are important elements in the teaching and learning process. Schubring (1987) claims that „teaching practice is not so much determined by ministerial decrees and official syllabuses as by the textbooks used for teaching" (p. 41). In addition, analysis of textbooks give us information about the mathematical knowledge that a society considers relevant in a particular historical moment (González, 2002) because they affect what and how students should learn (García-Rodeja, 1997). Spanish Educational System is an example of the effect described by Schubring (1987) because textbooks at pre-university education are usually the main reference material for teachers and students during the scholar year. Since the 70s, several changes of the Spanish Educational Law have occurred so a large amount of textbooks have been published and they have evolved in how they present mathematics.

The limit of a function is one of the most difficult and important concepts which are introduced at pre-university school in Spain. Research about this concept has shown that its learning involves a lot of difficulties. There are different studies which investigate how this concept could be taught at pre-university school: in an intuitive way (Henning & Hoffkamp, 2013), exploiting graphs of functions (Gunčaga, 2009),… Blázquez, Gatica & Ortega (2007) consider that students will be able to understand the ε-δ definition once they have understood the concept of limit as a tendency and approximation. We also think that proving results related to limits contributes to students' understanding of the concept, so we are interested in how textbooks present the concept of limit and justify the results related to them. Closer to our study, several researches have been developed about proving in secondary school textbooks in other countries but due to the limitation of space we do not include a detailed description of them but we will compare them with our own work in the future. For example, Nordströn & Löfwall (2005), who studied proof in Swedish textbooks, noticed that the frequency of proof items is low but they often exist invisible in the textbooks and this is a bit similar in Spanish textbooks. Ibañes & Ortega (2001) studied the student's proof schemes in the last courses of Secondary school and they conclude that students have difficulties in understanding proofs. Dos Santos (2010) noticed that mathematical proofs are disappearing in textbooks, that is, the newer a textbook is, the less number of mathematical proofs are in it. We claim that mathematical proofs is important in the understanding of mathematics, so it must be included in textbooks and for that we want to know how textbooks deal with this element of mathematics. The main goal of this study is to analyse the evolution of mathematical proof in textbooks and if they use other alternative justification procedures. To achieve this goal, we will try to answer some questions: are mathematical proofs replaced by other processes of justification? What kinds of justifications are used? Are all functions of mathematical proofs considered? Here we present a case study about the evolution of the treatment of mathematical proof in textbooks belonging to a Spanish publisher since the 70s until the present.

THEORETICAL FRAMEWORK

The aim of our study is to analyse the processes found in textbooks than could be used to convey students about the validity of the mathematical statements formulated in them. We use the concept of personal proof scheme (PPS) defined by Harel & Sowder (1998) because it includes other kinds of justification apart from mathematical formal proofs. Ibañes & Ortega (2001) studied the grade 11 students' proof schemes and they noticed that students accept any kind of proof schemes as a justification of a mathematical result, and some of these kinds of proof schemes could be found in textbooks. We are conscious that we do not know the intentionality of the publishers/editors. However, we want to classify the processes shown in textbooks according to the characteristics of personal proof schemes that they exhibit because these processes establish different levels of comprehension of the proofs. For that reason, we have adapted the definition of PPS to textbooks in the following way:

> *Proof scheme (PS) of textbooks: it consists of what is showed in the textbook which can constitute ascertaining and persuading for a generic reader of this textbook (here, a math student of the grade of the textbook), meaning by ascertaining the process showed in the textbook which could allow the reader to remove her or his own doubts about the truth of an assertion and meaning by persuading the process showed in the textbook that the reader could employ to remove other's doubts about the truth of an assertion.*

The processes of persuading and ascertaining are complementary, and both together constitute a PS. Regarding this definition, we have adapted the categories of classification developed by Harel & Sowder (1998) and Ibañes & Ortega (2001), including a new category using the concept of preformal proof (Van Asch, 1993).

> *PS0: there are no procedures of justification of the theorem.*
>
> *Inductive PS of 1 case (IPS1): we convey anyone about the validity of a conjecture by illustrating an example.*
>
> *Inductive PS of several cases (IPSs): as in the previous case, but now we verify several different examples.*
>
> *Inductive systematic PS (IsPS): as in the previous cases, but now examples are chosen in a systematic way, out different possible cases.*
>
> *Transformational PS (TPS): it is done by transformations of elements in a deductive way.*
>
> *Axiomatic PS (APS): the theorem is proved using axioms, meaning by axioms any primary results and other results which have been deduced previously.*
>
> *Preformal Proof (PP): a line of reasoning which can be formalised to a formal proof, by in which the essential idea is already present. It takes the same character of axiomatic and transformational PS.*

Figure 1 shows an example of inductive systematic PS. Something can be classified like an inductive PS if the textbook shows something which suggests that the example could be generalized to any other case. If not, it could be only considered like an application example of the theorem.

Transformational and axiomatic PS are the closest categories to a formal mathematical proof. Sometimes, we could find that a proof scheme has characteristics of both kinds of proof schemes, so they could be classified in both categories. Anyway, we classify the proof schemes found in textbooks only in the predom-

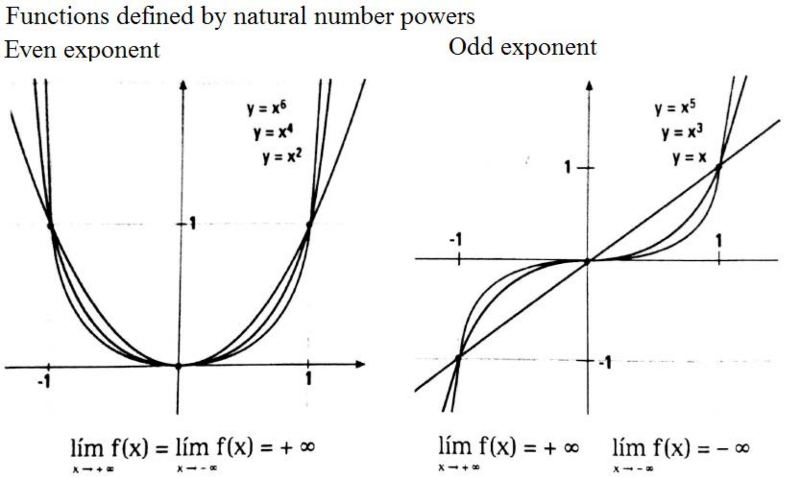

Figure 1: Example of inductive systematic PS to show the limits of functions defined by natural number powers (translated from the textbook LOGSE 11, 1998)

inant category to make their first count easier. Figure 2 shows some steps of an example of transformational proof scheme, although it uses some results which make it to be also considered as an axiomatic proof scheme. We classify it as a TPS because the author shows mainly transformations to justify the result. In the example, the justification ends by calculating the areas described below and comparing.

In the category of axiomatic PS we classify any formal mathematical proof. This kind of proof scheme uses always other theorems that were established before and they use deductive reasoning to prove the theorem. One well-known example of axiomatic PS could be the ε-δ proof to establish the uniqueness of the limit of a function if it exists.

Finally, we show an example of preformal proof. These kinds of justifications are rarely used but we think that they could be useful at these educational levels because they allow the students to understand a deductive reasoning without doing the abstraction of using a general case. In the example (LOGSE 11, 1998), the author justifies that the limit of a polynomial function at infinity is equal to the limit of the dominant term of the polynomial. The author shows the steps of the formal proof in a specific function instead in a general polynomial function, so the students only need to substitute by the general function to reach the formal proof.

> *Let be $P(x) = 2x^3 - 5x^2 + 8x - 12$. We study the ratio of $P(x)$ by its dominant term $2x^3$:*
>
> $$\frac{P(x)}{2x^3} = 1 - \frac{2}{2x} + \frac{8}{2x^2} - \frac{12}{2x^3} \xrightarrow{x\to\pm\infty} 1$$
>
> *Except number 1, when $x\to\pm\infty$ any addend approach to 0. For that reason, the limit is 1.*

Other important aspects that we consider are functions of mathematical proofs which are shown in the text. For that, we consider De Villiers (1990) model functions of proof (verification, explanation, systematization, discovery and communication). As Ibañes & Ortega (2001) defend, we also believe that the greatest worth of proofs is their function of explanation, although it is not their only value, and formal proofs could be exchanged for other kind of proofs. Apart from these classifications, we consider other aspects of proof in our broader study, but due to the limitation of space, we will not describe these items.

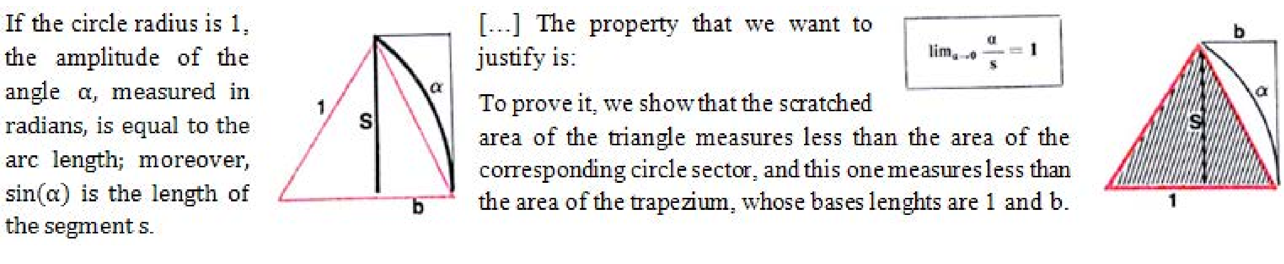

Figure 2: Example of transformational PS of "the limit at zero of $f(x) = x/\sin(x)$ is 1" (translated from the textbook LGE 10, 1980)

METHODOLOGY

Our research problem is related to the teaching and learning process of mathematical proof. We want to know how proofs have been treated in Spanish textbooks since the 70s. In the 70s it was enacted the first Spanish Educational Law which structures all the Spanish Educational System for the first time, they appeared the first common curricula and the government made control of the published textbooks. After that, there have been two changes in the Educational Law, and also in the curricula. As Dos Santos (2010) claims, we think that proofs are disappearing of Secondary School textbooks. In Spain, textbooks are used by almost every teacher and in almost every classroom of pre-university education, so the analysis of textbooks gives us information about the teaching of mathematics of a special moment. Due to the historical character of our work, we have combined two methods which are appropriate to this kind of work, the method of historical research on education (Ruiz-Berrio, 1976) and the research process on education described by Fox (1969). The combination of both methods gives us a method but here we only show a part of the general study, considering the analysis items of proof schemes and preformal proofs. By using these analysis items, we have classified the justifications which appear in textbooks according to them. Then, we have compared the different PS or PP used in each textbooks and their evolution along the time.

Although we are analysing textbooks of four different Spanish publishers (selected according to two criteria: publishers that have been widely used by Spanish mathematics teachers and those which exist since the 70's), here we show the analysis of one of them as a case study. We focus on proofs of theorems related to limits which are taught at pre-university levels, that is, the last courses of Secondary School (grades 11 and 12, 16–17 and 17–18-year-old students). The textbooks of this publisher correspond to three different education laws: the first one, LGE, was promulgated in 1970, the second one, LOGSE, in 1990, and the third one, LOE, in 2006, and it is still in force for the considered courses. The sample is composed by seven textbooks: one corresponding to LGE (grade 10; limits do not appear in grades 11 and 12), four corresponding to LOGSE (we have found two different collections corresponding to different years which differ on the treatment given to limits, and we have the textbooks of grades 11 and 12 of both collections) and two related to LOE (grade 11 and grade 12). We will use the code *Law G (Year)* for each textbook to simplify the notation, where "*Law*" denotes the Law of the textbook, "*G*", the grade, and "*Year*", the year of edition. In the Table 1 we show a summary of our sample.

ANALYSIS RESULTS

Each textbook considers a different treatment of the concept of limit and different ways of justifying the results that they show. We have only found some similitude in the presentation of the concept and its properties between textbooks of the same collection. For example, LGE 10 (1980) considers an unusual way to present limits: it firstly defines the continuity of a function and it presents limits in the chapter of derivability (in fact, it uses a description of limit in the definition of continuity). In the study of limits, the textbook shows the behaviour of functions in points of discontinuity and then, it defines the concept of limit of a function.

Textbooks corresponding to second period (LOGSE) present limits in a different way depending on the collection: the older collection (textbooks from 1998 and 1999) presents limits like a tool to study functions and their graphics; for example, they give a description of limit using an example and then, they give examples and describe the properties of the limit of a function. The newer collection (textbooks from 2003 and 2004) makes a more traditional presentation of limits: they do not present limits like a tool to study functions but they give formal definitions, the one in terms of sequences and the one in terms of absolute value (but they don't justify the equivalence between different definitions). Textbooks corresponding to the third period (LOE) give a simpler treatment of limits: firstly

Education Law	*LGE (1970–90)*	*LOGSE (1990–2006)*	*LOE (2006–14)*
Textbook	LGE 10 (1980)	LOGSE 11 (1998) LOGSE 12 (1999) LOGSE 11 (2003) LOGSE 12 (2004)	LOE 11 (2008) LOE 12 (2009)

Table 1: Sample of textbooks analysed

Textbook	Proof schemes							*Total results*
	PS0	*IPS1*	*IPSs*	*IsPS*	*TPS*	*APS*	*PP*	
LGE 10 (1980)	21	0	0	0	2	3	0	26
LOGSE 11 (1998)	16	4	3	0	1	0	1	25
LOGSE 12 (1999)	35	3	1	1	7	1	1	49
LOGSE 11 (2003)	9	0	2	0	0	0	0	11
LOGSE 12 (2004)	23	0	0	0	0	0	0	23
LOE 11 (2008)	9	2	0	0	0	0	0	11
LOE 12 (2009)	9	2	0	0	1	0	0	12

Table 2: Proof schemes used by textbooks

they consider all the definitions of limit of a function (finite limits, infinite limits, limits at a point or limits at the infinite) and then they formulate the arithmetic properties of limits. The differences between grade 11 and 12 are that in grade 12 definitions are formal (it gives the ε-δ definition) instead the intuitive definition of grade 11 (*we say that the limit of a function f*(*x*) *at the point* a *is* L *if the function f*(*x*) *approach to* L *as much as we want, whenever we take a value for x sufficiently close to the value*, LOE 11, 2008) and it goes deeper in the calculus of limits than the textbook corresponding to grade 11.

As we have seen before, there are significant differences in how textbooks deal with the concept of limit and the definitions that they use (formal, intuitive, no definition,...) These differences in how to present and define the concept affect the kind of proofs which can be used (informal definitions do not allow the editor to make formal proofs). Regarding the properties of limits, the uniqueness is only formulated in LGE 10 (1980); one-sided limits always appeared in these textbooks (they are necessary in the study of functions) but they are not always used to characterise the limit of a function: LOGSE 11 (1998) and LOGSE 12 (1999) are textbooks that do not link the existence and equality of one-sided limits to the existence of the limit of a function at a point. The arithmetic of limits is formulated in all textbooks but it is never justify except in one textbook (LGE 10, 1980). Indeterminate forms are always presented in the textbooks so, that let us think that textbooks are more oriented to promote mechanical calculus of limits than understanding of the concept. However, some textbooks give justifications of some cases of indeterminate forms, so we think that this indicates the consideration of the explanation function of proof in some cases.

Table 2 shows a summary of the proof schemes used in textbooks to justify the results corresponding to limits. We notice a big difference on the number of results considered in each textbook. It is due to the different ways in which the textbooks present the properties of limits: some of them consider separately the arithmetic of finite limits at a point, of finite limits at the infinity, of infinity limits at a point and of infinity limits at infinity; other ones consider only the difference between finite and infinity limits; there are textbooks which study the limits of families of basic functions, and consider them like theorems... This diversity in what a textbook considers as a result affects the amount of results presented in textbooks. Regarding the kind of proof schemes used, we notice that there is a significant change after 1999: the amount of results is smaller than in the previous years, but the number of justifications too. The predominant behaviour in all textbooks is not to justify the results (77.7% of results are classified as PS0). Among the different categories of justifications, it depends on the textbooks: LGE 10 (1980) only uses transformational and axiomatic PS; the textbooks of the older collection of LOGSE use all kind of justifications, but the predominant PS are inductive PS of 1 case in grade 11 (16%) and transformational PS in grade 12 (14.3%); on the contrary, the newer collection does not justify except two inductive PS of several cases in grade 11; finally, textbooks of LOE mainly use inductive PS of 1 case (18.2% in grade 11 and 16.7% in grade 12).

The results justified by textbooks are generally related to limits of any kind of functions (potential, polynomial, rational, logarithmic or exponential functions). Textbooks never justify the properties related to arithmetic of limits (except the addition in LGE 10 (1980)). Moreover, this one is the textbook which uses more axiomatic PS, although it is not the one which shows more results. We specify the results

Textbooks	*Proof schemes*
LGE 10 (1980)	TPS: equivalent infinitesimals, limit at zero of $f(x) = x/\sin(x)$ APS: uniqueness of limit, addition of finite limits at a point, limit at infinity of logarithmic function
LOGSE 11 (1998)	IPS1: limits of types $\to k/\to\infty$ and $\to k/\to 0$, limits at infinity of polynomial functions, limit of exponential functions IPSs: limits at infinity of $f(x) = x^n$, $g(x) = x^{-n}$, $h(x) = x^{1/n}$ TPS: limit at zero of $f(x) = x/\sin(x)$ PP: limits at infinity of rational functions
LOGSE 12 (1999)	IPS1: limit at infinity of $f(x) = x^2$+k, limits of exponential and logarithmic functions IPSs: limit at infinity of $f(x) = 1/x^n$ IsPS: limit at infinity of $f(x) = x^n$ TPS: limits at a point of rational functions ($\to 0/\to 0$), limit at zero of $f(x) = \sin(x)/x$, addition of infinities, equivalent infinities, equivalent infinitesimals, limits of $(1 + f(x))^{1/f(x)}$ and $f(x)^{g(x)}$ (when they contain indeterminate forms, $\to 1^{\to\infty}$) APS: limits at infinity of rational functions PP: limits at infinity of polynomial functions
LOGSE 11 (2003)	IPSs: limits at infinity of polynomial and exponential functions
LOE 11 (2008)	IPS1: equivalence of existence and equality of one-sided limits and the definition of limit, limits at infinity of rational functions
LOE 12 (2009)	IPS1: equivalence of existence and equality of one-sided limits and the definition of limit, limits at infinity of rational functions TPS: limit at zero of $f(x) = \sin(x)/x$

Table 3: Results related to the proof schemes used

which are proved in each textbook in Table 3. Due to the number of inductive PS found in textbooks, we think that authors try to convince students about the validity of the results from intuition and not from mathematical reasoning.

Regarding the functions of proofs, the kind of results that are justified and the kind of PS used let us think that the predominant function that is showed in textbooks is communication. We also consider the function of verification in the justifications classified like axiomatic or transformational PS. The function of explanation could be noticed in some textbooks which select examples that contribute to explain why the result is true, but we do not notice this function especially in proofs but in the application examples of theorems. Indeed, this function appears in results related to calculus of limits (indeterminate forms or the arithmetic of limits).

FINAL REMARKS AND QUESTIONS FOR FUTURE RESEARCH

As we have seen, there is not a significant fall of the number of mathematical proofs in textbooks since the 70's in this publisher. That is because there are only three axiomatic PS and two transformational PS in the first book and there are four axiomatic PS and eleven transformational PS in all of them. However, we have noticed that the number of justifications have dropped along the time. It can be due to diversity in how textbooks deal with limits: for example, the newer collection of the LOGSE period does not show formal definitions, so they do not justify. Textbooks make few references to the justifications procedures used, only in some cases they specify that they are justifying. We think that more justifications must be included in textbooks and it should be indicated that this is a justification and what kind it is. We conjecture that all textbooks (except LGE 10, 1980) have the intention of teaching students to calculate limits but they are not so interested in the understanding of the concept. We will go deeply in this aspect in future research.

The analysis shown in this paper gives a first insight in this topic, but there are a lot of open questions. For example, we have said that the differences of justifications founded in textbooks probably depend on the way that these textbooks introduce the concept of limit, so it is necessary to study how it affects to proofs. Other future questions to answer are: Which is the best way (from a didactical point of view) to present and develop this concept? Is it better to consider intuitive definitions of the concept than a formal one? We think that a good way to present limits is to adopt a rigorous (but not formal) definition of limit in the sense defined by Blázquez, Gatica & Ortega (2007) and then, introduce the formal definitions. An example of these authors' definition is: *the limit of a function f(x) at a point* a *is* L *if, for every approximation* K *of* L, K≠L, *there exist a punctured neighborhood of* a *such that the images of all its points are closer to* L *than* K. We also recommend using preformal proofs, as a way to introduce formal reasoning, using specific functions that allow students to understand the mathematical reasoning without abstraction. This kind of reasoning is also preferred by students as it is claimed in González (2012). Finally, this case study is not enough to know how textbooks deal with the concept of limit and the justifications, but it let us realize of the difficulties of this kind of analysis (for example, how to compare among proofs when results are organizing or formulated in different ways), and that will help us in our future work.

Argumentation below expectation: A double-threefold Habermas explanation

Jenny Christine Cramer

University of Bremen, Bremen, Germany, cramerj@math.uni-bremen.de

Teaching mathematical argumentation is a challenging task, and how to teach argumentation to students from all backgrounds remains an open question. It is especially difficult to say why some situations evoke the vivid exchange of arguments, while other situations completely fail to engage students in argumentation. This paper points out how two related concepts from Habermas' theory of communicative action may help to explore possible barriers and obstacles to argumentation: The rules of discourse ethics for argumentation processes, procedures and products and the consideration of rationality from the epistemic, the teleological and the communicational perspective. Both approaches help to recognize that mathematical argumentation requires more than mathematical content knowledge.

Keywords: Argumentation, Habermas, rationality, discourse ethics.

INTRODUCTION

Argumentation is highly relevant for the learning of mathematics, and may even be seen as a prerequisite for learning (Krummheuer, 1995). Besides argumentative learning, Knipping and Reid (2015) point to learning argumentation as an important research interest. In order to learn argumentation and proving, Boero states that (2011, p. 120, italics in original) "the best didactical choice is to exploit *suitable mathematical activities* of argumentation and proof". Learning argumentation is a good starting point in school, because as Douek (1999) highlights: if an emphasis is put on proving this can be a restraint to argumentation. But beyond the question of how to find suitable mathematical activities for fostering mathematical argumentation there remains the open question of how to ensure that all students may participate in argumentation, regardless of their socioeconomic or linguistic background. In the light of research results for problem solving and modelling activities, Knipping (2012, p.1) warns that: "classroom argumentation could become a social filter" if this question does not remain in focus. Gaining a better understanding of argumentation in general is a good first step towards identifying possible filtering effects.

Knipping and Reid (2015) point out that analysing argumentation in the mathematics classroom is important in order to gain a better understanding of its characteristics. Situations in which argumentation remains below expectation in that it either does not happen at all or not in the way anticipated by the teacher are equally interesting to consider if we want to shed a light on the difficulties argumentation entails for students. In this paper I consider a lesson from my research work in which argumentation did not happen in the intended way. Two related parts of Habermas' theory of communicative action are used to identify obstacles and barriers to argumentation: Habermas' view on argumentation as a process, procedure and product from his work on discourse ethics as introduced in Cramer (2014a) and the threefold perspective on communicative, teleological and epistemic rationality as introduced to mathematics education by Boero (2006). In the first part of the analysis, I consider moments in which a student does not engage in argumentation. By means of Habermas' discourse ethics I analyse the situational conditions and present a possible explanation by identifying subjectively perceived barriers. In a second analysis I focus on rudimentary arguments, which either broke off or did not provide a contribution to the solution of the task. Communicative, teleological and epistemic aspects are considered to identify obstacles within the argumentation process. Benefits and limits of the double approach are discussed in the end.

THE IMPORTANCE OF (LEARNING) ARGUMENTATION

Proof lies at the heart of mathematics as an academic discipline, and argumentation is vitally important for the development of mathematical understanding. Krummheuer (1995) even considers participation in collective argumentation processes as the social precondition for learning. Argumentation, proof and their "complex, productive and unavoidable relationship" (Boero, 1999) have been central to mathematics education research for several decades. In my research, I adopt Habermas' (1981, p.38) definition of argumentation as a type of speech in which participants discuss controversial claims and support or criticise these by arguments containing reasons which are rationally connected to the claim. Proving processes lie within this definition of argumentation. Proof as the goal of classroom activity can be a restraint for the development of argumentation, according to Douek (1999). Therefore, argumentation in general is the focus of my research, including, but not limited to, deductive reasoning as the path towards proving.

The learning of mathematics is tightly interwoven with, if not even dependent on, student participation in argumentation processes. Taking this into consideration, the emphasis on mathematical arguments in NCTM and other national standards documents is a welcome development. It is, however, unclear how to achieve involvement of all students in argumentation. Lubienski (2000) has shown that children from lower socioeconomic backgrounds benefit less from the reform-based emphasis on problem solving. Concerning the achievement of children in high-stakes tests, Prediger and colleagues (2013) have pointed out that language proficiency is the main predictor for success. Knipping (2012) highlights the necessity of decontextualized language in argumentation. To avoid the looming filtering effect of argumentation she envisages that a thorough analysis of unsuccessful attempts at including argumentation in class could be helpful. In the following, I choose the term "barrier" for occasions in which argumentation did not develop, whereas "obstacle" is used when argumentation is begun but breaks off. I distinguish these two terms because they are different in nature. I will clarify the distinction by exploring two different threefold concepts from Habermas' theory of communicative action for the analysis of situations when argumentation remained below the teacher's expectations. By the analysis, I hope to better understand what makes access to argumentation difficult.

A TWOFOLD HABERMAS RESEARCH TOOL

The foundation for my analyses is laid in Habermas' theory of communicative action (1981) and related works. Within this framework, Habermas (1983) describes communicative action and strategic action as two opposed forms of social conduct. Whereas in strategic action the speaker's intention is to enforce a claim regardless of means, speakers who act communicatively seek consent by supporting their claim with suitable arguments. These arguments are exchanged in discourse. To foster vivid discussions and active argumentation in the mathematics classroom, discourse opportunities must be created.

Barriers arising from argumentation as process, procedure and product

Discourse is described by Habermas (1983) as a communicative situation shaped by argumentation. New knowledge is inferred from shared common knowledge. Habermas (1983) describes rules for argumentation from the interwoven perspectives of processes, procedures and products. These rules need to be subjectively fulfilled for speakers to engage in argumentation. In the following I present a translated adaptation of these rules for the mathematics classroom (cf. Cramer 2014a).

The first of the three interwoven perspectives Habermas presents is the view on argumentation as a *process*, traditionally considered by the science of *rhetoric*. Characterizing features of argumentation processes are the exclusion of force and the reliance on nothing but the best argument. The process rules are:

(R1) Everyone may participate in discussions.

(R2) The topics to be discussed are conjointly determined.

(R3) There are equal rights and no compulsion to participate in communication.

Argumentation can also be seen as a *procedure* of hypothetically checking claims by giving reasons, free from any immediate pressure to action. This view on argumentation is traditionally rooted in the science of *dialectics*. Its rules are:

(D1) A speaker is only allowed to claim what he or she believes to be true.

(D2) Shared knowledge may not be attacked without reasons.

Arguments are the *products* of argumentation. Their structure is governed by the rules of *logic* and Habermas gives three rules from this perspective:

(L1) No speaker may contradict himself.

(L2) Who uses a warrant in one situation must be willing to use it in analogous cases.

(L3) Expressions need to have shared meanings.

These three perspectives must not be regarded as separate entities. According to Habermas, they are all equally important preconditions for argumentation. For participation, all of the rules have to be subjectively fulfilled. Of course, perfectly equal positions and the conjoint determination of topics in school are virtually impossible to achieve. However, I have explored before (Cramer, 2014b) how the *subjective* fulfilment of these rules can be shown in the situation of a logical game in which argumentation was successfully evoked. The focus of this paper is on communicative situations where argumentation unexpectedly did not develop. My interpretations of the students' subjective interpretations of the situational preconditions are based on their contributions and the detailed analysis of the situation as a whole. Within these, I try to identify barriers resulting from the subjective non-fulfilment of the rules for argumentation processes, procedures or products, as Habermas claims that subjective fulfilment of these criteria is a prerequisite for engaging in argumentation.

Obstacles arising from epistemic, teleologic and communicative rationality

Boero (2006) introduced Habermas' threefold perspective on rationality into mathematics education research to account for students' rational behaviour in proving activities. As Boero and Planas (2014) remark, epistemic, teleological and communicative perspectives on rationality gradually became a toolkit for many different aspects of research in mathematics education. I use Habermas' elaborations on rationality to account for obstacles that students may encounter in argumentation processes, leading to breakdowns or failures in reaching the pursued goal.

According to Habermas (2009), a person's behaviour can be described as rational if that person can account for his or her behaviour from three different but interwoven perspectives. *Epistemic rationality* is concerned with the propositional structure of knowledge. In order to act rationally from the epistemic point of view, an interlocutor needs to be aware not only of whether he or she holds certain statements to be true, but also of the reasons he or she has to justify this belief. In discourse, epistemic rationality leads to the possibility of negotiating and transferring knowledge, as the speakers are not only capable of sharing their convictions and beliefs, but also their justifications. Rational action is furthermore characterized by the actors' conscious choices of strategies and tools to help them arrive at mutual or even shared understanding. This conscious choice of strategies according to the aim the actor is following is called *teleologic rationality*. It implies that there are reasons for the actor why he prefers one tool to another, and that these reasons justify the actor's belief that he can achieve his aim under certain preconditions. In mathematical argumentation, actions are usually expressed with words. Language serves as the link between knowledge, aims and the communicative situation. Language is not, however, rational in itself (Habermas, 1996). *Communicative rationality* is located within the use of speech in discourse to develop a common understanding. This uniting power of speech secures the continuity of shared knowledge and the frame within which all interlocutors can refer to it.

The practice of argumentation unifies and requires all three forms of rationality (Habermas, 2009, p. 17). Obstacles may be encountered on the epistemic, teleologic or communicative rationality layer. In contrast to the aforementioned barriers, these obstacles occur after a student has begun to engage in argumentation. They can cause the argumentation to break off, which makes them an interesting analysis approach.

GREY AND WHITE BOXES

The analyses in this paper are based on data from my dissertation project in which I worked as a teacher-researcher with a group of five 15-year-old girls, all of whom are non-native German speakers from different schools. The lesson took place one week into the project; it was the first content lesson after an introductory interview in the preceding week. Before the project, the girls knew neither me as their teacher, nor each other. In the lesson considered, four girls were present. They worked in pairs with very little teacher guidance in order to foster the creation of their own arguments. The following problem was given to the students:

> In a square of grey boxes you are supposed to place white boxes. The grey boxes must no longer touch afterwards. Example for 16 squares:

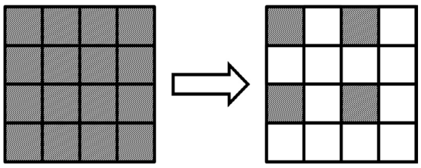

Figure 1

> How many white boxes do you need if the square consists of 36, 100, 1024 grey boxes?

The tasks allows for many different solutions (splitting the square into 2 × 2 squares with three white boxes each, recognizing that every second column and half of every second row are filled with white boxes, etc.). The desired outcome was that the students find a pattern that allows them to deduce that for even side lengths, 0.75 times the number of grey boxes is the solution. In the following, I describe episodes from Ayla and Jawahir's pair work process to illustrate how the two approaches from Habermas' work may help to identify barriers and obstacles. A combination of descriptions and transcript excerpts is used for clarity.

Getting started: argumentation barriers

After distribution of the problem, some introductory teacher comments and further clarification of the task, the girls start to work on the task individually and in silence. Only few comments are exchanged; both girls are visibly engaged in drawing and counting activities. Some minutes after Ayla instructed Jawahir to draw a 6x6 square for the 36 boxes task, they exchange results. Both arrived at 27 white squares as the correct answer by drawing and counting. Hardly any other verbal exchange takes place. Four minutes after their comparison and 17 minutes after the problem was given, the first longer conversation takes place. The transcript of this episode about the number of white boxes for 100 grey boxes is given in the following.

3	Ayla:	Did you just do one hundred? (...)
4	Jawahir:	I have six rows here, here.
5	Ayla:	But why six?
6	Jawahir:	I wanted five, I did f/, I did six. (..)
7	Ayla:	But look, (..) you did six here, didn't you? Do //four//
8	Jawahir:	//Mh// (affirmatory).
9	Ayla:	f/, no.
10	Jawahir:	It is supposed to be hundred, ehm
11	Ayla:	Yes yes but look, you can just do it like this (takes piece of paper) simply ten here (points in one direction with a pen) and ten here (points to another direction with a pen). Then you have hundred in here.
12	Jawahir:	(....) I hate maths.

In this exchange, Ayla inquires about Jawahir's approach to the task. She wants to know why Jawahir chose six as the side length of her "square". Jawahir does not respond with an argument for her approach, but states that she had originally planned to work with a side length of five (6). Ayla questions her approach by pointing to the preceding task where Jawahir had used six as the side length (7). It is not clear if she names four as the side length of the example on the worksheet or if she wants to tell Jawahir to enlarge the number of rows and columns by four. Jawahir responds by recalling the task (10). Finally, Ayla takes over and gives the argument that a ten by ten square contains 100 grey boxes (11). Jawahir neither reacts to justify her solution, nor does she articulate agreement with Ayla's justification. Instead, after a short pause, she claims to hate maths (12). Two minutes after this exchange, Jawahir says, "I am stupid" in the middle of her work.

In the situation at hand, Ayla is trying to enter into a social process of argumentation with Jawahir, while Jawahir does not enter into the discourse. Regarding Habermas' preconditions we can deduce from Ayla's behaviour that she does not meet any barriers that prevent her from requiring or giving arguments. She justifies her choice of ten as the side length of the square, she questions Jawahir's approach to the task and substantiates her doubts by referring to the former task where six already served as the side length for the 36 boxes square (7). Jawahir, on the other hand, does not justify her solutions nor does she ask for reasons when Ayla presents her approach.

In the following, I speculate on possible barriers for Jawahir's participation in argumentation. From the *process* perspective on argumentation, there are several possible subjective limiting factors. Jawahir does not participate in the discussion. It is therefore possible that she does not feel welcome to contribute (R1). Her statement that she "hates math" makes mathematical content an unlikely choice of discussion topic for her (R2). Furthermore, her claim "I am stupid" suggests that she does not perceive herself as an equal discussion partner (R3). The same claim also shows a lack of confidence in her mathematical abilities. It is well possible that this presents a barrier inherent in the *procedure* precondition that speakers are only allowed to claim what they believe to be true (D1). No knowledge is exchanged, so nothing can be deduced about shared knowledge (D2). As no arguments are produced, the barriers arising from the *product* perspective can hardly be assessed. Speculations are that mathematical insecurity might lead to self-contradiction (L1), deficiencies in the knowledge of mathematical structures and concepts may lead to problems with identifying analogous situations where warrants can be transferred (L2), and a lack of conceptual knowledge could lead to differing usages of expressions (L3).

Although it is difficult to nail down exactly what it is that kept her from entering into discourse, it is clear that Jawahir in contrast to Ayla did not engage in argumentation in the situation at hand. A lack of mathematical content knowledge probably contributes to the problem, but self-perception seems to be equally relevant. A deficiency in deductive reasoning skills can be excluded as the cause of her silence, as Jawahir produced highly sophisticated arguments in other situations (cf. Cramer 2014b). Within the complex interplay of situational constraints, Habermas' discourse ethics rules provide a tool that can account for some barriers for participation.

Spontaneous breakdowns: argumentation obstacles.
Several minutes later, the girls are still engaged in drawing boxes and counting. No exchange about patterns or generalities has been observed so far. The teacher directs the attention towards the side length of the 1024 square. Following some hints, Ayla finds out that the solution is connected to the calculation of square roots. She is used to working with a table of square roots from her text book (she calls it "clever book"). After she has looked up the square roots of 36 and 100, this exchange takes place:

40	Teacher:	So why does that match the side lengths?
41	Ayla:	Because it is the same, isn't it, this way (hand from bottom to top) and this way (hand from left to right).

The table in her book only contains numbers below 1000, so the teacher uses a calculator and shows 32, the square root of 1024 to Ayla and Jawahir. Afterwards, Jawahir starts conversation by asking the teacher for a way to solve the task:

60	Jawahir:	How does the thousand work, I mean this (points at worksheet) here?
61	Teacher:	Think about that together. (...) Ayla already found the side length of that thing. (..) And maybe you see something HERE (points to the worksheet) that you can (.) carry on (.) somehow. Something this and this here (.) have in common. If you look at them all next to each other, this and this and this.
62	Ayla:	Yes, there always is one, and then not, and then one, and then not.
63	Teacher:	Yes, exactly. And then there for example is a row where there is nothing.
64	Ayla:	Mhm. (Affirmatory)
65	Teacher:	And that is actually kind of the same everywhere. And maybe you find something general (.) how you can find it out WITHOUT COUNTING.

The teacher leaves the table. 50 seconds later, Ayla starts talking:

66	Ayla:	So if thirty (..) times thirty is nine hundred (..) nine hundred thirty, (..) nine hundred thirty, thirt/ (5 sec), nine hundred sixty. It has to be nine hundred sixty. See (.) write that down. (..) I will now draw these boxes, if nine hundred sixty comes out I was (..) right.

After this monologue, Ayla and Jawahir start to create a 32x32 square by gluing together various pieces of paper. Some interesting comments during this activity:

67 Ayla: Wow, how many boxes ARE THERE? (..) I think this (.) is this one thousand-thingy, isn't it, isn't it, isn't it?

Due to the limited time, their drawing remains incomplete. During the whole-group comparison, Ayla presents 960 as their solution. She justifies her answer as follows:

81 Ayla: We first (.) calculated the square root with you. And then ehm, we arrived at thirty-two. Then we tried (.) to do thirty-two boxes, top and bottom. We didn't manage to. Yes, and we got to nine hundred sixty, because we calculated it.
82 Teacher: So what did you calculate to get to the nine hundred sixty?
83 Ayla: Yes well, because the book said ehm (.) thirty by thirty is nine hundred, and then we calculated a bit.

This longer episode is very interesting from the perspective of rationality. From the *epistemic* perspective, it is observable that Ayla has understood the concept of square root as possibility to calculate the side length of a square (41). She does, however, appear surprised at discovering the huge number of boxes in the 32x32 square they create (67). A possible explanation for her surprise is that she does not see squaring as a reverse operation to calculating the square root. This can be seen an epistemic obstacle. It leads both to difficulties in her calculation attempt for 32 squared (66) and to her disbelief faced with the enormous number of boxes in the 32 by 32 square.

Her abovementioned lack of understanding square roots can also be considered a *teleologic* obstacle, as it goes hand in hand with her strategy of multiplying seemingly random numbers. Ayla multiplies 30, the highest number in her multiplication table, by 32, the result for the square root of 1024 given by the calculator (66). Even when asked (82), Ayla does not give any reasons for the appropriateness of her strategy. Ayla's identification of the pattern (62) sheds light on another obstacle in her teleologic rationality. Although she recognizes an overarching structure for the differently sized squares, she cannot transfer this insight into a useable tool towards finding a mathematical solution. Finally, Ayla's justifications "because the book said" and "we calculated a bit" (83) show obstacles in her *communicative* rationality. Ayla does not seem to know how to justify her solutions in a mathematically acceptable manner. Furthermore, she does not or cannot use algebra as a tool to represent the pattern she discovered (62), "one, and then not, and then one, and then not".

Possible obstacles can be identified on all three levels of rationality and provide a possible explanation for why Ayla did not arrive at a mathematically correct solution to the task despite her willingness to engage in argumentation. Identifying these obstacles for argumentation can however provide teachers with a tool to work on better support for their students. In Ayla's case, working on calculating square roots and squaring as reversing each other could be beneficial, but also a fostering of using algebra to express patterns might prove helpful.

OUTLOOK AND DISCUSSION

In this paper, I have elaborated on two different but related concepts from Habermas' theory of communicative action that can help to cast a new light on barriers and obstacles for argumentation. The subjective fulfilment of Habermas' rules for argumentation as process, procedure and product can help to identify barriers leading to non-participation in argumentation. The threefold perspective on epistemic, teleologic and communicative rationality on the other hand provides a tool for the detailed analysis of obstacles leading to unsuccessful argumentation.

Both approaches are united in that they take a perspective that simultaneously highlights and limits the importance of mathematical content knowledge for argumentation. A lack of knowledge can be both a barrier to engaging in, and an obstacle for being successful at argumentation. However, among other influences, the social situation, feelings of inequality, availability of suitable strategies and knowledge about communicative practices are equally important to consider if we want all students to engage in argumentation, especially in the light of looming effects of social and linguistic disparities. Habermas' considerations underline the importance of perceived equality, shared meanings and the absence of force for engaging in argumentation. He also shows that the awareness of justifications, suitable tools and means of communication is essential both to start and to continue argumentation. More research on barriers and obstacles for argumentation may help to finally overcome them and enable participation in argumentation to all students.

Is the use of GeoGebra advantageous in the process of argumentation?

Özlem Erkek and Mine Işıksal-Bostan

Middle East Technical University in Ankara, Faculty of Education, Ankara, Turkey, ozdursun@metu.edu.tr

The purpose of this study was to investigate the advantages and disadvantages of using GeoGebra in an argumentative application. For this purpose, the data were collected from eight prospective elementary mathematics teachers via video recordings, reflection papers and interviews. Data were analyzed through qualitative data analysis methods. According to the results, making accurate drawings, creating confident justifications based on exact measurements, dragging objects to see relationships and saving time were the main advantages of GeoGebra in argumentation. On the other hand, not attending class discussion and not reasoning the relationships after measuring with GeoGebra were the disadvantages for argumentation.

Keywords: Argumentation, GeoGebra, geometry, advantageous, disadvantageous.

INTRODUCTION

Argumentation is defined as "a process of establishing or validating a conclusion on the basis of reasons or the act of proposing, supporting, evaluating and refining the process, context, or products of an inquiry (Sampson & Clark, 2011, p. 66). Toulmin (1958), the pioneer of this multidisciplinary trend in literature, proposed the Argumentation Model, which is used to determine arguments in numerous scientific studies. In this model, an argument comprises three elements which are claim, data and warrant (Toulmin, 1958). Claim is a statement to be supported. The other element data corresponds to evidence presented for supporting the claim. Warrant is an inference rule enabling data to be connected to the claim. In addition to these elements, Toulmin (1958) also asserted that qualifier, rebuttal and backing may also be needed to describe an argument. While qualifier refers to the strength of the argument, the rebuttal expresses a counter-argument. Backing corresponds to additional support for the warrant of an argument. Although, Inglis, Mejia-Ramos and Simpson (2007) asserted that the full version of the Toulmin model need to be used in mathematics, backings, modal qualifiers and rebuttals are less often used in the studies related to mathematics education corresponding to the nature of mathematics. Toulmin's (1958) argumentation scheme was represented in the Figure 1.

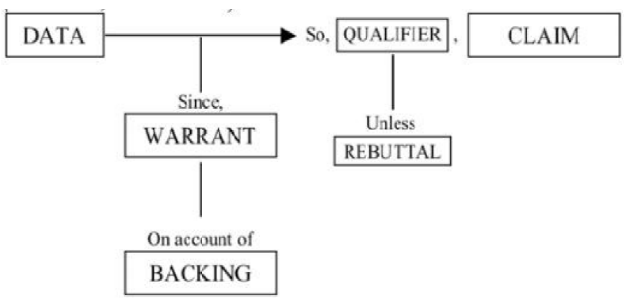

Figure 1: Toulmin's (1958) Model of Argumentation (p. 104)

The importance of argumentation has increased gradually in learning and education and many researchers implied that the students should participate in discussions for mathematics learning (Krummheuer, 1995; Stein, Engle, Smith, & Hughes, 2008). Inglis and colleagues (2007) pointed out that the first researcher who integrated Toulmin's argumentation scheme into the mathematics field was Krummheuer (1995) who analyzed classroom-based mathematical arguments. Krummheuer (1995) used the term collective argumentation and defined it as "a social phenomenon when cooperating individuals tried to adjust their intentions and interpretations by verbally presenting the rationale of their actions" (p. 229). After this first attempt, the number of studies related to the applications of argumentation into mathematics has increased (Inglis et al., 2007; Pedemonte, 2007; Wentworth, 2009). For instance, Wentworth (2009)'s study include technology allowing online synchronous and asynchronous discussion to explore argumentation of prospective teachers and secondary school students. The results indicated that it is difficult for participants to write all their arguments and it is difficult to detect and follow their reasoning process only from their writings (Wentworth, 2009). In the same way, mathematics educators are aware of the fact that logical inferences and formal justifications are not always convincing and comprehensible so they propose that additional informal justification ways, like dynamic geometry tools, are necessary (Prusak, Hershkowitz, & Schwarz, 2012). Thus, mathematics educators have developed dynamic geometry tools allowing inquiry-based environment and encourage argumentation in geometry (Prusak et al., 2012). Furthermore, researchers emphasized the importance of dragging in conjecturing in many studies (Arzarello, Olivero, Paolo, & Robutti, 2002; Baccaglini-Frank & Mariotti, 2010). For instance, Arzarello and colleagues (2002) stated that dragging encourages conjecturing and exploring since individuals have the chance of observing the invariant properties after changing the shapes. Obtaining immediate feedbacks was claimed to be helpful for discovering and proving invariant properties of drawings (Arzarello et al., 2002). Dynamic geometry software allows students to construct and experiment with geometrical objects to make conjectures and interpretations (Healy & Hoyles, 2001). Since conjecturing is a crucial action in argumentation, it is worth to study the advantages and disadvantages of dynamic geometry program (GeoGebra) in argumentation process. It is claimed that it is not only the technology that brings an educational change but also the teacher (Arzarello et al., 2002). However, few studies analyzed the prospective elementary mathematics teachers' argumentation in geometry. The prospective teachers' argumentation skills are important to be searched because they are the people who will facilitate and manage the whole class discussions, ask questions, listen to students who will develop mathematical understanding in the future (Stigler & Hiebert, 1999). Their own proficiency in developing arguments has also great importance for their future performances in argumentation applications. Therefore, the investigation of the argumentation process with dynamic geometry program, GeoGebra, will be beneficial to determine the critical issues to be considered by prospective teachers.

This study is significant since the results would provide insight to prospective teachers and teachers who want to integrate GeoGebra and argumentation into their geometry lessons. In addition, the results would provide a clear picture of possible benefits and problems that prospective elementary mathematics teachers may confront while experiencing argumentation with GeoGebra. Based on the rationale mentioned above, the purpose of the present study was to investigate advantages and disadvantages of using GeoGebra in argumentation while solving geometry tasks. The following research question has guided the study: What are the advantages and disadvantages of using GeoGebra in argumentation process?

METHODOLOGY

This study is a qualitative case study. Purposeful sampling was used to identify the participants. The researchers selected 8 prospective teachers enrolled in Elementary Mathematics Education program of a public university in Ankara, Turkey. All participants were 4th grade students who have completed almost all courses related to elementary mathematics education program. The four participants in GeoGebra group were voluntary students who have taken the elective course called "Exploring geometry with dynamic geometry applications". In this way, there is no need to teach them how to use GeoGebra program. The other four participants in Paper-pencil group were the communicative students who have not taken the course. The application was done in one session for each group and it lasted 2 hours to solve three geometry tasks.

To triangulate data, we utilized multiple data sources. Data collection took place in the spring semester of 2012–2013 education year through video and audio recordings of the two applications, reflection papers and interviews. Interviews were also recorded with a camera.

The researcher who was the participant observer in the classroom settings started the application by giving some information about argumentation in each group. The purpose of this was to give an idea to the participants about the application process and to encourage them to justify their claims as much as possible. Also, the researcher asked them to think aloud in pair-work to share their ideas with their partners. Moreover, the researcher asked participants to concentrate on the discussion on the board in order to encourage all students' contribution to the classroom discussion. There were 3 geometry tasks in the application. The first geometry task was like a warm-up

Geometry Task 1

1. A recreational park has a rectangular shape. At each vertex of the rectangular park there is an attraction. The manager of the park decided to locate the ticket booth at an equal distance from the four attractions. Find the point in the rectangle which fits for the ticket booth.
2. Another park has the shape of an equilateral triangle. At each vertex of this park there is an attraction. The manager of the park decided to locate the ticket booth at an equal distance from the three attractions. Find the point in the triangle which fits for the ticket booth.
3. What if the recreational park has the shape of a scalene triangle? Find the point (if any) in this triangle which fits for the ticket booth.

Geometry Task 2

In any ABC triangle D and E points are midpoints of the sides |AB| and |AC|. F and G points are placed on side |BC| so as to be |BG|=|CF|. |DG| and |EF| intersects at point H.

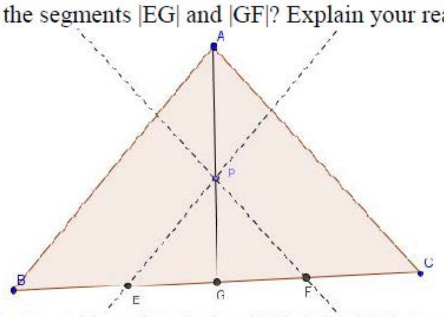
When does |AH| become angle bisector of the angle A? (Think about all triangle types)

Explain your reasoning and justify your solutions.

Geometry Task 3

Let P be any point on the median of |AG| of a triangle ABC. Let m and n parallel lines through P to the sides |AB| and |AC| of the triangle.

1. What relation is there between the segments |EG| and |GF|? Explain your reasoning.
2. What if the triangle ABC is equilateral or isosceles triangle? Can any generalization be made for the relation between the segments |EG| and |GF|? Explain your reasoning.



3. Where must be the point P positioned such that |BE|=|EF|=|FC|. Justify your solution.

Figure 2: Geometry tasks

task which was discussed in pairs and then the class discussion began. After getting all different solutions, the researcher moved to the second task's pair discussion. In the same way, the third task was discussed in pairs and later with the whole class. The researcher reworded the claims of students in order to provide a collective argumentation environment and to make it clear for other participants. In addition, the researcher asked probing questions such as "Why do you think so? Are you sure about that? What is your justification for that? Do you all agree with your friend's claim?". That is, the researcher motivated students to justify why a conjecture is true or false and convince others. The subsequent class discussions focused on student reasoning and argumentation.

In GeoGebra group there were two pairs of students and each pair had one computer and one worksheet to study together. In Paper-pencil group there were two pairs of students and they had a ruler, a compass and a protractor to be able to draw accurate shapes and one worksheet to study collaboratively. After the participants solved the tasks in each group, one voluntary pair was interviewed; the other pair wrote a reflection paper in order to collect more information about their experiences regarding the benefits and the drawbacks of using GeoGebra in argumentation.

For the data analysis, the recorded dialogues of the participants were transcribed. Toulmin (1958)'s Argumentation Model was used to determine the arguments of the participants. By using the Toulmin's (1958) predefined argument elements, the researcher had the chance of organizing the arguments of the GeoGebra and the Paper-pencil groups in such a way that they are comparable because they discussed the same geometry tasks. Two experts assisted with the researcher determining the argument schemas from video recordings. An inter-rater reliability agreement was 90%. In addition, the reflection papers and interviews were also open coded for triangulation of the data to detect advantages and disadvantages of using GeoGebra in argumentation.

Data collection tools

Three geometry tasks about triangles (see Figure 2) were selected for the argumentation application based on the criteria such that the tasks should be suitable for the discussion and argumentation, have alternative solutions, and be able to be solved via GeoGebra and paper-pencil. After getting permissions from the authors, the tasks were translated into Turkish. Expert opinions were taken for the statements to be clear for the participants. The first task was about the circumcircle and taken from the study of Prusak and colleagues (2012, p. 28). The second task was prepared by Ceylan (2012) and it was adapted by the researcher to be able to be suitable for argumentation. The third task was prepared by Domenech (2009) for high school students.

The researcher prepared interview questions for the voluntary pair just after watching the video of the application. The day after the implementations the interviews were conducted. If the participants did not remember some details about their arguments, the video record of that part was shown to make them remember what they did in the application. The aims of implementing interview were to obtain the ideas of participants about the advantages and disadvantages of GeoGebra while solving geometry tasks through argumentation and to clarify their arguments. Some components of arguments may be missing in discussion when the discussion flows to different directions. In some situations, the participants may not explain their reasoning but imply it somehow. The researchers asked those parts to the participants through interviews in order to make correct interpretations.

RESULTS AND DISCUSSION

After the applications, the schemas of all the arguments of the participants were drawn and then the arguments of GeoGebra group and Paper-pencil group were compared in terms of the number of arguments, the existence of argument elements and the contents of argument elements. Considering Inglis and colleagues' (2007) suggestion the elements of the full model of Toulmin were searched but it was detected that few modal qualifiers and rebuttals and no backings were expressed by the participants. In addition to this, some arguments were generated by more than one student during the class discussion. That is, claim was stated by one student while the warrant of that claim was stated by another student. By comparing these arguments, the researcher concluded that GeoGebra was both advantageous and disadvantageous in argumentation depending on the educational goals of teachers and the nature of tasks.

Advantages of using geogebra in argumentation

One of the advantages was that the participants in GeoGebra group were able to made accurate and dynamic drawings for the tasks. In this way, they could see the relationships easily, became more confident in their arguments, and went on forming justifications and inferences. However, in Paper-pencil group, they were not sure about their conjectures or made wrong conjectures because of their inaccurate drawings. The conversation and argument schema below in paper-pencil group exemplifies such a situation.

Teacher: How can we find the circumcenter of any triangle?

S2: We could not remember the rule so we could not determine the lines which intersect and generate circumcenter.

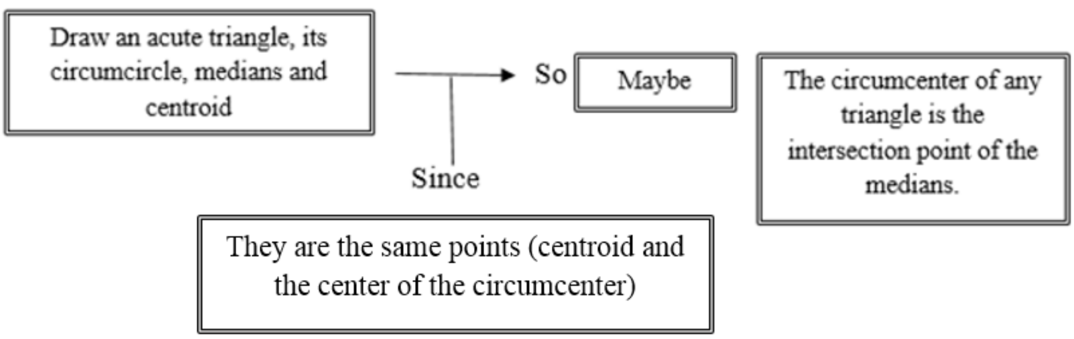


Figure 3: A Sample Argument Schema for the conversation

Maybe it can be the intersection point of medians. Let me try it.

(S2 drew an acute triangle, a circumcircle and medians of the triangle on the board and saw that the centroid approximately seems to be the center of the circumcircle)

S2: Oh they are the same points. I think we can find circumcenter by intersecting medians of a triangle.

In the conversation above, S2 concluded that the circumcenter of a triangle may be the intersection point of the medians, centroid. This was a wrong argument and the reasons for the mistake were approximate drawing and not thinking all triangle types. S2 thought that centroid and circumcenter are the same point but in fact they were very close to each other in an acute triangle that she draw. The other students were also satisfied with the drawing and they did not discuss the solution further. Then the instructor asked whether that was valid for an obtuse triangle or not? This question helped participants to think other triangle types. However, in GeoGebra group, the students drew the medians and found the centroid and compared it with the circumcenter in different triangle types. In this way they did not generate wrong arguments. Therefore, they formed further arguments and found different solutions.

Another advantage of the use of GeoGebra in argumentation can be the dragging option which enables maintaining some geometrical properties of a figure and exploring the relationships. The students in GeoGebra group used dragging option effectively and made generalizations easily which support conceptual understanding. Moreover, they were more motivated to discuss and to find alternative solutions to the problem. For instance, when they saw any relationship in an equilateral triangle, they could check whether the relationship was valid for other triangles by dragging the vertices of the triangle and changing its properties. However, in Paper-pencil group, participants did not have such an opportunity. They got stuck while they were drawing the new shape again and again on the paper with materials such as ruler, protractor and compass. Therefore, the participants had difficulties in focusing on the relationships between the unchanging properties of different shapes, because of repetitive drawings and their motivation for discussion decreased. For instance, in GeoGebra group while participants were discussing the geometry task 2, they noticed that |AH| is angle bisector when |DE| is perpendicular to |AH| (see Figure 4). In addition, they investigated that |AH| is angle bisector when ADHE is deltoid. Then they analyzed whether |AH| is angle bisector when ADHE is any other type of quadrilateral. They used dragging option and see the relationships in a short time. In the end, they concluded that |AH| is angle bisector when ADHE is deltoid and rhombus. However, in Paper-pencil group, participants concluded that |AH| is angle bisector when ADHE is only deltoid since they could not move F and G points to obtain different quadrilaterals on the paper.

It can be said that dragging option in GeoGebra was beneficial in argumentation because the participants could see the relations that they could not see on fixed shapes drawn on the paper and they justified willingly

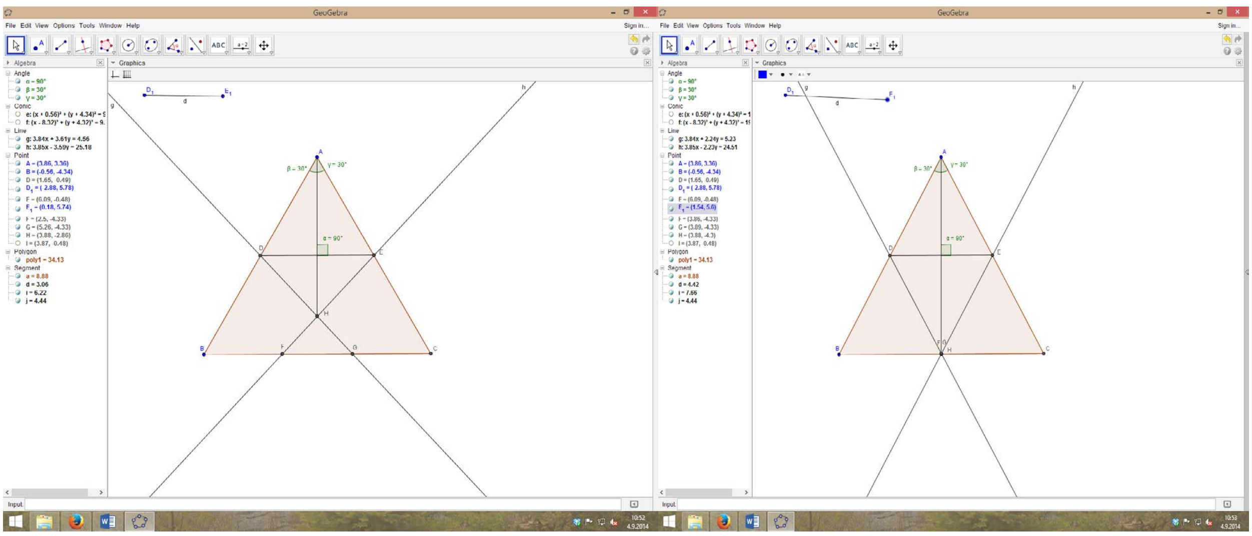

Figure 4: A drawing for task 2 in GeoGebra group class discussion

their reasoning based on the properties of the different shapes composed by dragging.

Based on the findings, the other advantage of GeoGebra is time issue. The participants drew shapes easily and quickly with GeoGebra options such as measuring angle, measuring side, drawing circle, drawing perpendicular or parallel line etc. In GeoGebra group, the participants did not spend too much time on drawings but they used most of their time for reasoning and argumentation. However, it was time consuming for Paper-pencil group to measure angle, to draw angle bisector, to draw circle with compass… etc. They sometimes had to draw the shape again because of wrong conjectures and the argumentation paused very often. In a similar situation, the GeoGebra group members had the chance of going back on the screen with "Ctrl+Z" and continue to draw on the same shape. Thus, GeoGebra was useful in order to save time and to retain the argumentation.

Dynamic geometry software were developed in order to engage inquiry based strategies and argumentation in geometry (Prusak et al., 2012). In argumentation, the participation of all students is crucial because all students should evaluate others' arguments and contribute to their solutions. At the same time, they should convince others by justifying their claims. As for the advantages, Geogebra allowed the participants to use dragging option, to construct accurate drawings such as segments, angles, angle bisectors, parallel lines, perpendicular lines. In line with the results of Prusak and colleagues' (2012) study, dragging option gave students the opportunity to see relationships visually (Healy & Hoyles, 2001) and check whether their conjectures are valid. Thus, they could obtain immediate feedback and enable rethinking and making new conjectures and geometrical analysis to solve problems (Prusak et al., 2012) which promoted their argumentation. In this way, the reasoning process of participants could be followed by the instructor clearly with the help of their arguments in classroom interactions and their products with GeoGebra. Moreover, GeoGebra was time saving for drawings and motivating for students to discuss the task. When the teachers do not want to spend much time for drawing shapes but to promote reasoning on the task, they can integrate Geogebra into their lessons so that students will draw the accurate shapes quickly and discuss on the properties of the shapes more.

Disadvantages of using GeoGebra in argumentation

The results indicated that there were some disadvantages of the use of GeoGebra in argumentation. One of them was that all students were not at the same pace in using GeoGebra and interpreting the drawings. Therefore, it was difficult to control all participants and to make them participate in the class discussion. When one of the students came to the board to show her solution, some of the students who were thinking on their own drawings did not follow the discussion and did not make comments for the solution. However, all participants should have followed and contributed to the arguments of others in collective argumentation process in order to reach a conclusion. When all students could not follow the discussion, there may be some missing points in their understanding. In the collective argumentation, the arguments are developed through two or more students' participation (Krummheuer, 1995). In order to critically make sense of the arguments developed, the interaction with other students was stated to be crucial in collective argumentation (Yackel, 2002). Thus, teachers should promote student interactions by rewording their claims and asking probing "Why" questions during the argumentation.

Another disadvantage was that the task may not be compatible with the GeoGebra usage so students who obtain feedbacks from GeoGebra immediately may generalize easily without reasoning. De Villiers (2003) asserted continuous transformations of objects with dynamic geometry software made students convinced easily with general validity of a conjecture. For instance, in the second task, they said that "I measured with GeoGebra and dragged point A to check for other triangles. The lengths are equal for all triangles." In such a situation the teacher asked the reason why these lengths are equal and made them justify their solution. In the class discussion, the teacher directed participants to think about the reasons for this equality to obtain their justifications. However, in Paper-pencil group, participants started to reason whenever they see the worksheet and their discussion was more productive and they formed more arguments. This is because the geometry task 2 was not suitable for GeoGebra use since the measurement tool in GeoGebra program stopped the argumentation of the participants. It is stated that conjecturing and justifying has a great importance in argumentation (AEC, 1991). However, the tasks should be suitable for conjecturing and the use of Geogebra to find different solutions. Otherwise, the participants will solve the task on their worksheet and use GeoGebra only for checking the solution by dragging or measuring. That is, the tasks that can be solved with some measurements via GeoGebra may terminate the argumentation. This may not promote their argumentation and they may not justify their claims so that they do not state warrants. When the geometry task requires conjecturing and dragging to recognize the relationships and teacher needs to hear students' justifications to decide whether they conceptually understand the topic or not, the GeoGebra might be advantageous for students. Otherwise, the students might not think critically on the task so the argumentation might not be effective. Thus, it was suggested that the teachers should select GeoGebra tasks carefully and determine whether Geogebra should be used or not in their argumentation based geometry lessons considering the objectives of the lessons and the needs of their students.

Constructing validity in classroom conversations

Manuel Goizueta[1] and Maria Alessandra Mariotti[2]

1 Universitat Autònoma de Barcelona, Barcelona, Spain, mgoizueta@gmail.com

2 Università degli Studi di Siena, Siena, Italy, mariotti21@unisi.it

We account for different strategies used by a group of students to talk about and assess the validity of mathematical models while working in a problem-solving task. Two main competing strategies are described, one centred in ritualized uses of well-known mathematical constructs as a means to cope with perceived didactical expectations and a second strategy centred in the assessment of the representativeness of mathematical models when accounting for the proposed empirical situation. The interactions analyzed exemplify the difficulties students and teachers experience when dealing with epistemological aspects of knowledge being constructed in classroom conversations. Our findings point to the need for research to focus on epistemological aspects of the mathematical culture of the classroom.

Keywords: Validity, argumentation, mathematics classroom epistemology, classroom culture.

INTRODUCTION

It is widely accepted that argumentative competencies should be developed within the mathematical activity in the classroom, both as a product of this activity and as a means to support it. We share Boero's (2011) idea that a 'culture of argumentation' is to be developed in the classroom and that it should include practices on the production of conjectures, meta-mathematical knowledge about the acceptability of references advanced for the validation (acceptance/rejection) of claims and knowledge about the role of counter-examples and generality. It should include elements for evaluation of mathematical productions and general ideas about the use of all this knowledge within argumentative practices, along with the needed awareness to allow deliberate and autonomous control of the process.

In order to promote such a culture, the processes by which students actually construct and validate mathematical knowledge in classroom activities, as well as the meta-mathematical knowledge underpinning this processes, should be better understood. This report is part of a series in which we argue that it is worth characterizing this processes in terms of validity conditions emergence and fulfilment in order to account for the epistemological dimension of classroom interaction and its socio-interactive roots (see Goizueta, Mariotti, & Planas, 2014). Our main interest is to investigate the epistemological basis of argumentative practices in the mathematics classroom and, particularly, how is validity interactively negotiated in rich problem-solving mathematical activities. In this occasion, we compare different strategies for validation of mathematical models observed in a secondary mathematics classroom. We account for the epistemological complexity of these strategies and explain, from this point of view, the difficulties students face to discuss the validity of mathematical models.

THEORETICAL FRAMEWORK

According to Habermas (1998), accepting a validity claim is tantamount to accepting that its legitimacy may be adequately justified, that is, that conditions for validity may be fulfilled. Validity conditions are not restricted to absolute standards; instead, they are contingent constraints that emerge to accommodate elements considered suitable for validity appraisal in a given context (Goizueta, Mariotti, & Planas, 2014). They embody what are intersubjectively considered good reasons in a particular context of justification. Thus, validity relates to acceptance based on contingent validity conditions fulfilment. This implies that validity is not a property of claims themselves, but emerges from the mode they are contextually dealt with. It should be stressed that whatever is considered as a good reason, must not necessarily be explicit or even stateable, nor the individuals must be aware of it in a conscious way, it might be enacted implicitly in successful social participation (Ernest, 1998).

According to Habermas' construct of rational behavior (Habermas, 1998) and its adaptation by Boero and colleagues (2010), in the students' argumentative practices we can distinguish an epistemic dimension (inherent in the epistemologically constrained construction and control of propositions, justifications and validations), a teleological dimension (inherent in the strategic decision-making processes embedded in the goal-oriented classroom environment) and a communicative dimension (inherent in the selection of suitable registers and semiotic means to communicate within the given mathematical culture). Such a distinction reveals useful to reconstruct the origin of specific validity conditions. For instance, focusing on the epistemological dimension and following Steinbring (2005), we assume that a "specific social epistemology of mathematical knowledge is constituted in classroom interaction and this assumption influences the possibilities and the manner of how to analyse and interpret mathematical communication" (p. 35). Within this socially constituted mathematics classroom epistemology a criterion of mathematical validity is interactively negotiated between the participants. A central consequence of these assumptions is the basic necessity for interpretative research to reconstruct the situated conditions in which (and from which) mathematical validity emerges as part of the interactive development of mathematical knowledge. Although 'conditions' might be considered in a broader sense, we are particularly interested in the epistemological assumptions at stake, the references (mathematical and not) that might be considered as relevant and the social environment in which the process is embedded.

In the context of the mathematics classroom, the general relation between classroom epistemology, mathematical activity and social environment must be considered under the light of a specific, content-related didactical contract (Brousseau, 1997). Mathematical acceptability of students' explanations is linked to the reciprocal expectations and obligations perceived within the didactical situation by the teacher and the students and to the mathematical contents at stake (or perceived as being at stake). Thus, when faced with a problem, the didactical contract may indicate relevant mathematical knowledge and references to the students, according to the proposed didactical situation. However, not all the emerging references are linkable to well established and intersubjectively shared mathematical knowledge. We might also need to consider other references (statements, visual and experimental evidence, physical constraints, etc.) that are not part of institutionalized corpora, such as scholar mathematics, but (nevertheless) are used de facto as taken-as-shared, unquestionable knowledge (Douek, 2007). This corpus of references might be tacitly and operatively used by students to make sense of the task, semantically ground their mathematical activity and back their arguments. Accounting for the reference corpus at stake might be particularly relevant when considering problem-solving settings in which empirical references are to be considered as part of the proposed milieu.

PARTICIPANTS, TASK AND DATA COLLECTION

The participants in our design experiment were thirty 14/15-year-old students and their teacher in two lessons in a secondary school mathematics classroom in Barcelona, Spain. It was a problem-solving setting, with time for small group work and whole-class discussion. The researchers suggested the following task:

Two players are flipping a coin in such a way that the first one wins a point with every head and the other wins a point with every tail. Each is betting €3 and they agree that the first to reach 8 points gets the €6. Unexpectedly, they are asked to interrupt the game when one of them has 7 points and the other 5. How should they split the bet? Justify your answer.

As we ascertained in a pilot experiment, this task can be approached and solved using arithmetical tools, without having been taught formal probability contents, which was the case of this group. The teacher was explicitly asked to avoid showing approval or disapproval to the students' numerical answers and proposed models. Instead of hint-guiding the students towards a correct answer, she was asked to foster the emergence of competing models and their discussion. By avoiding directive guidance, teacher's interventions were meant to foster autonomous processes of validation within the students' mathematical activity. Models observed during the pilot were discussed with the teacher and numerical variations of the problem were designed in order to help her problematize these models when and if necessary.

We were aware of the high complexity of the problem as a modelling task. The construction by the students of a situation model (in the sense of Blum & Borromeo-

Ferri, 2009) is related to some well-known epistemological obstacles regarding probability-thinking development (García Cruz, 2000; Wilensky, 1997). This circumstance, along with reports on the use of this problem in the classroom (García Cruz, 2000), suggested it might be a good candidate to promote a rich argumentative environment and to foster the discussion of mathematical, but also meta-mathematical issues. The novelty of the task was expected to prevent students from using mechanical approaches based on well-established solving strategies. Different situation models were expected to emerge and, consequently, a variety of mathematization processes. The need to compare competing mathematical models was expected to foster the emergence of different arguments to validate them.

For data collection, three small groups were videotaped and written protocols were collected. The data were analysed and coded with the aid of qualitative data analysis software. By constant comparison of similarly interpreted situations and triangulation with other research team members' perspective, key aspects of the classroom mathematical work were inductively inferred. This process was iterated for analysis refinement and confirmation.

DATA ANALYSIS AND RESULTS

Constructing a situation model: Initial validity conditions

Whether explicitly or implicitly students bring to the discussion taken as shared references about the proposed empirical situation. In so doing, they often describe it as a 'random game' and use words associated with this notion in informal ways. An example is the following intervention by a student, Anna, during the first session:

Anna Obviously, because it's random, the game (...) A does have more chances of winning but B could win as well (...) From what we've got so far, A would have to get more money, because he's got more points.

These taken as shared references, a cluster of empirical information, beliefs and words to talk about the situation, conform part of the reference corpus the students resort to in order to semantically and empirically ground the task, understand the problem and conform (often in a tacit way) an associated situation model. Observed in all groups and illustrated by Anna, a validity condition emerges expressing the need for the winning player to get more money. Any possibly valid mathematical model, within which an acceptable answer can be constructed, should fulfil this requirement, so we categorize it as a validity condition. Students' choices also indicate adherence to common clauses of the didactical contract: they tend to disregard and discard solutions that appear spontaneously but are not considered mathematics-related (e.g., 'each one gets his money back because the game did not come to an end'). A common clause of the didactical contract constrains them to actually do some mathematics in order to solve the problem. The need for the solution to be mathematics-related acts as a validity condition that students take into account to decide on the model's validity.

Often, the first numerical answer students propose roots on models associated to typical school problems about proportional costs, which tend to be solved by manipulating the numerical data appearing in the wording. A ritualized way of presenting this solution may be paraphrased as: 'if by winning 8 points a player gets €6, for each point won a player should get €0.75'. The students quickly realize that the amounts of money distributed according to this model, namely €5,25 and €3,75, do not add up to six euros, what, according to them, falsifies the model. The necessity for 'adding up to six' emerges as a validity condition that any numerical answer, and the model within which it is constructed, should fulfil.

The emergence of these validity conditions (namely the need for the winning player to get more money, the need for the distributed amounts of money to add up to six euros and the need for the solution to be mathematics-related) was observed in all groups, as well as the resorting to them as means for validity appraisal. While the need for the solution to be mathematics-related derives from expectations related to the didactical contract, the other validity conditions relate to the need for any possible valid model to account for the empirical references considered by the students. This stance accounts for both the epistemic and the teleological dimensions of the students' activity: a mathematical model that satisfies the validity conditions considered must be constructed; it should be acceptable in the context of the mathematics classroom and lead to an acceptable solution for the game.

The proportional solution

In the following we focus on the case of the group of Lyn, Ely, Tim and Lucy.

After ascertaining that the initial model does not fulfil the validity conditions, Tim considers the twelve points won by both players and proposes a second model: give away the bet proportionally to the points won: €3.50 for the winning player and €2.50 for the other; what corresponds to 7/12 and 5/12 of the bet respectively. Let us call it, from now on, 'the proportional solution'[1].

41 Tim Look, we add the points, right? We take the money and divide it by the number of points, then we get how much is one point worth out of these twelve points that we have. Then we divide it and we get zero point five.

42 Lyn No, because seven plus five is not eight!

43 Tim Three point five plus two point five is six! One gets three point five and the other two point five.

44 Lyn OK, but listen: seven plus five is not eight. OK?

45 Tim It is twelve.

46 Lyn Right, and the six euros were for eight points.

47 Tim Yeah, but, because that was not right [referring to the '€0,75 per point' model], we distribute it this way. 'Cos they couldn't finish, we must distribute it this way!

By focusing in a well-known procedure [41] Tim is suggesting that proportionality might be an adequate model to solve the problem. He infers from the numerical information the "correct numbers" to introduce in the model: it is not eight but twelve what they should use. Lyn [42] does not address Tim's proposal in a straightforward manner; it is just by looking at her three utterances that we may try to understand what she is actually talking about. Lyn focuses [46] on the rules of the game: a player wins by winning eight points and by no other circumstances. We conjecture that Lyn objects taking twelve points into consideration because this action does not represent these rules. This interpretation will be confirmed later (see [63] below). Tim responds [43] by focusing on a validity condition: the amounts of money distributed according to this model 'add up to six'. We infer that, for him, this indicates some degree of certainty about the validity of the model and the numerical solution, although the epistemic status is not addressed in an intelligible way. We observe the emergence and fulfilment of validity conditions as a means for validation. The shift of foci in Tim's utterances [41] and [43] and the disconnected answer in [45] might indicate that he is simply not understanding Lyn's objection. It is just after Lyn's clarification [47] that Tim seems to address it, but rejecting it in a rather authoritarian way. Noticeably, on the one hand Tim does not take care of Lyn's objection about the representativeness of his model, on the other hand Lyn seems not be able to make her objection explicit or even clear. It is not possible to infer from these utterances whether Tim does not understand the objection or does not find it relevant.

The teacher's intervention

The teacher comes and the following conversation takes place:

54 Lyn Ok, if there are just six euros to distribute... and six euros are for eight points but there are twelve points in total... Do we have to forget that six euros are for eight points?

55 Teacher No! You should never forget. You are confusing things; six euros are for eight points of one single person. When you say twelve points, the twelve points were obtained by two persons. All right?

56 Lyn I know, but distributing means giving to both...

57 Teacher No. Because the first arriving to eight gets everything; the whole six euros (...) The problem is that, because the game couldn't be finished, we have to distribute.

58 Tim I have given to the twelve points, the six euros, and then one gets three point five and the other two point five. And it would be fair.

59 Lyn But that doesn't make sense, 'cos...

60 Teacher Why it doesn't make sense? That's a possible solution. I agree. A criterion to divide the money is what Tim just

1 For the case of Anna's group we describe the emergence of this model in (Goizueta, Mariotti, & Planas, 2014).

said. Now Lyn says it doesn't make sense. You should give me an argument why it doesn't.

61 Lyn Because… I mean… No, no, no. Because the six euros are for eight points. And what he is doing is picking the six euros and dividing by all the points.

62 Teacher He's done that exactly.

63 Lyn No, no, no. I mean… That is not like the rules we have.

64 Teacher To see if our solution is consistent, what we can do is to change how the game ended up. Let's imagine six-two. They are six-two when the game is interrupted. Let's check how to split the money and check if it's fair or not.

Lyn refers in a highly condensed way [54] to what they have done to this point and to their current dispute. If we consider this intervention as continuing the students' conversation, it provides the group with new elements to understand Lyn's objection: dividing the money by twelve entails "forgetting" that it corresponds to eight points. The teacher, who is interacting with this group for the first time, seems not capable of inferring the precedents and thus of understanding the epistemological complexity of the discussion. She interprets [55] Lyn's intervention as a mere confusion. The following utterances [56] [57] confirm the ineffectiveness of the exchange. Tim interrupts with his explanation [58], focusing on a procedure and the numerical answer it yields, which surely reveals to the teacher the proportional solution. Lyn addresses [59] the problem of the representativeness of the model again, but still in a rather unintelligible way for the teacher, who reacts to Lyn's objection [60] by apparently supporting Tim and asking Lyn for a justificatory argument. Although it is not clear how the students might interpret the teacher's utterance, it is in line with the didactical planning of the session: fostering the emergence of competing models and students' discussion of them. By saying "a possible solution" and "a criterion" she is implying that other models and criteria could be considered as well. The following utterances by Lyn [61] [63] seem to reveal that the teacher interventions do not help her better frame the problem of the representativeness of the model. Even when she tries to reformulate the issue [63], the teacher does not address it directly. Instead, she sticks again to the planning and proposes [64] to consider a numerical variation of the problem along with a hint. It is difficult to decide how the students might interpret the words 'consistent' and 'fair', but the teacher seems to suggest that the model's validity can be assessed by assessing the 'fairness' of the solutions it yields. The epistemological status of such a link is not made clear, but the teacher is tacitly indicating a new objective to the students: to explore this validity criterion for the situation model that they intend to exploit.

Lyn and Tim's actions suggest different epistemological and teleological stances underlining and shaping their arguments. Lyn seems to understand their immediate task as assessing the relation between the proposed mathematical model and the implicit situation model; thus her intention (as we interpret it) is to put in evidence the lack of representativeness of Tim's mathematical model. Tim seems to focus the solution of the task on the identification and skilful execution of well-known, suitable mathematical procedures; by evoking proportionality in a rather ritualistic way and proposing a numerical result, he copes with that demand. While Lyn's activity suggests the need for a reflective approach, Tim's suggests a reproductive one.

A shift of attention: Towards a probabilistic model

After working for some minutes alone, Lyn proposes a new idea:

87 Lyn Look, I don't know where I want to get to with this, but to arrive to where you get six, this needs just one and this needs three. So, based on that… let's see how to distribute the eight. But I don't know how.

Lyn shifts the focus of attention from the actual score, the base of the proportional solution, to the potential scores, the base of a probability related solution. Although we have observed this shift in other groups, Lyn's case is exceptional in that it is not the response to teacher's regulative interventions (in fact it involves disregarding them); hence it is not a case of perceived expectations fulfilment. It seems to be a genuine, autonomous attempt to investigate elements of the empirical situation in order to construct a situation model and look for a representative mathematical one.

95 Lyn If we divide six euro by this, that is what is missing [writes down '3 + 1 = 4' and '6/4 = 1,5']. We get one point five. [writes down

'3 x 1,5 = 4,5' and '1 x 1,5 = 1,5'] But we should give more to this [winning player], 'cos he's closer than this [losing player]. So, what I would do is to give this ['4,5'] crossed to this [winning player] and this ['1,5'] crossed to this [losing player]. I don't know why!

96	Ely	That looks OK!
97	Lyn	But, why?
98	Ely	'Cos it's proportional. I think it's OK.
104	Lyn	I think it makes sense. But I don't know why!
105	Ely	If you add them up you get six.

Lyn's argument [95] develops through relating the data '3' and '1' (points needed to win) to the loosing and wining players respectively. By simple extension, the product '4,5' ends up to be associated to the losing player while the product '1,5' does to the winning one, what does not conform to what she considers a validity condition. She proposes a 'crossed association', but recognizes it as arbitrary by stressing that she does not find a reason to do so. Instead, Ely supports this solution [96] [98] [105] by referring it to well-known validity conditions: the soundness of proportionality as an adequate mathematical construct to solve the task and the two distributed amounts of money adding up to six. However, such support does not fit Lyn's fundamental need for validating the mathematical model according to its representativeness of the empirical situation [95] [97] [104]. We observe again different epistemological and teleological stances underlying students' arguments. Lyn subordinates the validity of the mathematical model, she proposes establishing a relation between it and the implicit situation model. Instead, Ely positively assesses the validity of the mathematical model on the basis of the soundness of proportionality, to which she associates it, and the fulfilment of previously considered validity conditions.

CONCLUDING DISCUSSION

As observed throughout the analysis, the students seem to be unable of explaining to each other the base on which they claim or challenge the validity of the models they propose. This may be interpreted referring to the difference between the teleological and epistemological stances they adopt. Tim and Ely seem to understand the task as the need for identifying some known, relevant mathematical construct to produce a sound answer that is consistent with shared expectation of the didactical contract. Accordingly, the goal they are pursuing is that of producing a numerical solution through a proportional model, tacitly linked to the problem through its ritualistic use in situations of distribution. It is this link and the fulfilment of the related validity conditions what seems to confer validity to the model. However, the evaluation of the model always remains implicit. Lyn's activity reveals a different stance: the mathematical model must represent the empirical situation if it is to be considered valid, thus her immediate goal when discussing Tim's model and her own is assessing their representativeness.

Both cases illustrate how different epistemological perspectives may influence students' teleological stances and thus students' attitudes towards validating the models they produce, but also how undeveloped is this attitude and far from a desirable culture of argumentation. In the case of Lyn, although she clearly focuses on validating the model with respect to how accurately it represents the proposed situation, she seems unable to share her ideas with her peers in an intelligible way. Meanwhile, Tim and Ely prove incapable of interpreting her stance and seemingly unaware of the necessity of linking the validity of the model to its representativeness. Even the teacher seems unable to perceive the tension between the different stances and help the students fruitfully discuss it.

From our point of view, this experience illustrates a more general situation, namely that students and teachers do not always have the tools to deal with, or talk about, the epistemological complexity of mathematical knowledge in the classroom. If a desirable culture of argumentation is to be fostered in the classroom to allow students to autonomously construct and validate mathematical knowledge, some awareness about one's and other's epistemological stances should be developed as a condition for a critical, reflexive account of one's and other's actions. It should not only be about producing valid arguments that satisfy conventional communicative requirements, but also about being aware of and able to discuss the grounds for their validity in their context of justification. Suitably fostering such discussions in the classroom should be the teleological counterpart of such epistemological stance. We suggest that more attention should be paid to the mechanisms that regulate the emergence of the mathematics classroom epistemology in order to provide teachers with adequate means to plan and control its development as part of a desirable culture of argumentation. To this regard, we claim that the interpretation of classroom mathematical activity in terms of validity conditions emergence and fulfilment might be worthwhile in order to reveal epistemological aspects of classroom interaction and their socio-interactive roots. This interpretation might help researchers describe and model the advocated development of a culture of argumentation.

ACKNOWLEDGEMENT

This report is part of the research funded by Project EDU2012-31464, Ministry of Science and Competitiveness, Spain; co-funded by AGAUR, Generalitat de Catalunya, through the grant 2014-SGR-972 granted to GIPEAM-Grupo de Investigación en Práctica Educativa y Actividad Matemática (Grup de Recerca Consolidat de la Generalitat de Catalunya). It has been possible due to a PIF-Grant granted by Universitat Autònoma de Barcelona to the first author.

Pre-service teachers' perceptions of generic proofs in elementary number theory

Leander Kempen and Rolf Biehler

University of Paderborn, Paderborn, Germany, kempen@khdm.de

In this paper, we present our concept of the usage of four different types of proofs to engage students in the proving process: the generic proof (with numbers), the generic proof in the context of figurate numbers, the so-called "formal proof", and the proof in the context of figurate numbers using "geometric variables". Further, we report from our case study, where 12 pre-service teachers were interviewed after attending our bridging-course, which had a focus on argumentation and proof. We investigated students' perceptions of the generic proof with numbers. Our findings suggest the classification of perceptions in three categories: "Logical acceptance and psychological conviction", "general acceptance of the concept and psychological uncertainty", and "inappropriate understanding of the concept".

Keywords: Generic proof, conviction, transition, figurate numbers.

INTRODUCTION

Constructing mathematical proofs is said to be a major hurdle for many university freshmen. It still remains a challenge of tertiary education to impart knowledge about the notion of proof. Selden (2012) stresses: "Understanding and constructing such proofs entails a major transition for students but one that is often supported by relatively little explicit instruction" (Ibid., 392). To tackle this problem, the University of Paderborn offers the course "Introduction into the culture of mathematics" as an obligatory course for the first year secondary pre-service teachers (non grammar schools). This course has been developed and taught by the second author in collaboration with the first author. Its content was selected in order to help students to successfully get to know the way of mathematical proving that is prevalent at university. During this course, the students are to investigate mathematical problems (e.g., concerning figurate numbers) and to construct generic proofs and formal proofs. Refining and evaluating the course are a main focus of the first author's dissertation. In this context, students' perceptions of the different kinds of proofs were investigated.

THEORETICAL FRAMEWORK AND RELATED RESEARCH

In their article concerning generic examples, Mason and Pimm (1984) describe the basic feature of a generic proof: "The generic proof, although given in terms of a particular number, nowhere relies on any specific properties of that number" (Mason & Pimm, 1984, 284). This concept of a general verification in a concrete context has mainly been substantiated in Leron and Zaslavsky (2009) and Rowland (1998). But still there seems to be no overarching consensus regarding the notion of generic proofs as valid mathematical proofs. However, generic proofs are said to be especially useful in the learning of reasoning and proving in the field of number theory (e.g., Karunakaran et al., 2014; Rowland 2002; Stylianides, 2012). The advantages are mainly seen in the accessibility even for low-performing students because of the absence of algebraic variables. But as shown by Biehler and Kempen (2013), the concept and the construction of a generic proof remain problematic for many pre-service teachers.

It is very common to give examples of generic proofs with the use of arrays or patterns of dots. This is a valid mathematical approach, since these patterns of dots can be considered as a notation system (Dörfler, 2008). In a semiotic view, concrete numbers, or patterns of dots, with their different properties and rules for operations, can build the notation system to perform diagrammatic reasoning and to construct valid mathematical proofs (e.g., Stjernfelt, 2000).

In contrast to the recommended use of generic proofs, it seems surprising, that students' perception of generic proofs has not been investigated in detail yet. The research of Tabach and colleagues (2010) indicates that teachers often reject correct verbal justifications (including generic proofs), because of a claimed lack of generality and an assumed overemphasis of concrete examples. But as was shown by Malek and Movshovitz-Hadar (2011), students can benefit from being presented to generic proofs concerning proof comprehension and proof construction.

THE CONCEPT OF OUR BRIDGING COURSE

The course is meant to introduce students to the culture of the science mathematics, as it is practiced at university. We want to illustrate the procedural aspects and also give considerations to the ready-made knowledge of mathematics. Therefore, the students are to investigate assertions, build up hypotheses, test conjectures and form lines of arguments to finally achieve a mathematical proof. We also want to deal with the topics, which are known to be a barrier in the transition to tertiary level, so its content covers (1) discovery and proving in arithmetic, (2) figurate numbers, (3) proof by induction, (4) assertions, reasoning, types of proofs, (5) equations, and (6) functions.

The first chapter starts with the question "Someone claims: The sum of three consecutive natural numbers is always divisible by three. Is this correct?". Here, the students are engaged in testing concrete examples and in discussing their informative value. In this context of discovery and justification, we distinguish the significance of examples in a logical and in a psychological way: Logically, it is not important how many concrete examples one has tested, as the assumption is made for all natural numbers. Psychologically, the testing of several concrete examples can be seen positively to understand the assertion, to strengthen one's presumption on the validity of the assertion and maybe to get an idea why the statement is true (in all cases). Following these considerations, we introduce a generic proof of the statement as a possible student's answer (see below).

The concept of the generic proof is then exposed with an emphasis of its general argumentation. As a generic proof, we consider the combination of the following three parts: (1) there are operations on concrete examples that can be generalized, (2) one gives a (generic) argumentation, why the assumption is true in these specific cases and finally, (3) one has to point out, why this argumentation also fits all possible cases. In doing so, it becomes possible to highlight the difference between purely empirical verifications and general valid arguments. And in using generic proofs, the phase of examples-based exploration becomes an intuitive part of the proving process. Referring to the generic proof, we formulate a correspondent formal proof using algebraic variables (see below). Although this proof production seems to be an almost trivial task for a mathematician, our experience has shown, that our freshmen are not used to this kind of argumentation and are not familiar with this usage of algebraic variables.

We also construct the correspondent proofs in the notation system of figurate numbers (see below). Afterwards, the assertion with three consecutive numbers gets generalized: "Is the sum of four consecutive numbers always divisible by four" and so on. At the end of the chapter, we attain the statement that the sum of k consecutive natural numbers is divisible by k if and only if k is odd.

In this first chapter, arithmetic is the area for doing research and proving conjectures. Here, the notation system of figurate numbers is a tool for constructing alternative types of proofs (see below). But in the second chapter, the figurate numbers themselves become the object of investigation, where arithmetic and algebra can be treated as tools for proving. The field of figurate numbers (e.g., triangular numbers and square numbers) offers excellent possibilities for exploration, forming conjectures and proving. Here, it seems very natural to argue with the arrangement and the number of dots.

FOUR TYPES OF PROOFS

As we pointed out above, the generic proof is firstly presented in the context of the value of testing several examples. (See the following generic proof to the claim: The sum of three consecutive natural numbers is always divisible by three).

Generic proof with numbers:

$1 + 2 + 3 = (2 - 1) + 2 + (2 + 1) = 3 \times 2$

$4 + 5 + 6 = (5 - 1) + 5 + (5 + 1) = 3 \times 5$

You can always write the sum of three consecutive numbers as: ("number in the middle"-1) + "number in the middle" + ("number in the middle"+1). Since this sum equals three times the „number in the middle", the sum is always divisible by three.

It is the narrative reasoning that follows the generic examples, which makes a generic proof a valid general argument. So it gets possible to stress the differences between purely empirical examples and valid general arguments. In this way, we work against the misconception that examples on their own can form a valid proof. But the use of generic proofs is also meant to pick up a form of argumentation that is said to be used at school (e.g., Leiß & Blum, 2006). So our students could be somehow familiar with this type of proof and if not, they get equipped with this appropriate way of proving for their future work. In the following transition to the so-called formal proof (see below), it gets possible to introduce and promote the mathematical symbolic language: (1) to express generality, (2) to communicate general incidents, (3) to explore further a supposed relationship, (4) to fulfill arguing and proving and (5) to provide a complete verification of a given statement (as recommended by Malle (1993) and Mason and colleagues (2005)).

Formal proof:
For all $n \in \mathbb{N} \setminus \{1\}$: $(n - 1) + n + (n + 1) = n + n + n = 3 \times n$. *This sum is divisible by three, because* $n \in \mathbb{N} \setminus \{1\}$.

In the whole course we establish figurate numbers (geometrical representations and operations with arrays or patterns of dots or squares) as another notation system. So the students are also asked to construct generic proofs using figurate numbers (see below) and the proof with geometric variables (see below).

Generic proof in the context of figurate numbers:
In the example, one can see the sum 3 + 4 + 5 and 5 + 6 + 7. In every sum of three consecutive numbers, one obtains the same steps, independent from the starting number. After the transposition of the square at the far right, one always obtains three equal lines of squares. So, the sum is always divisible by three.

Proof with geometric variables:

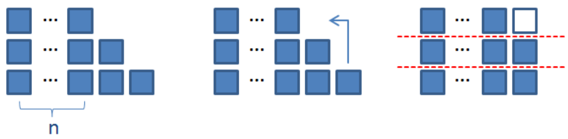

Table 2: A proof with "geometric variables" and figurate numbers

We defined the representation of an arbitrary number by inserting three little dots as a "geometrical variable" to have an analogy to the algebraic variables in the notation system of figurate numbers. This parallel treatment of arithmetic/algebra and geometric representation is said to be useful to ease the transition from arithmetic to algebra. Flores (2002) suggests a similar approach. Moreover, by using these alternative notation systems, it gets possible to stress the immanent quality of an argument, independent from its representation. While in the generic proof, the argument is given in a concrete context, which has to be generalized, the variables in the formal proof imply generality. So, it gets possible to emphasize the notion of variables in algebra and also in the geometrical context.

RESEARCH QUESTIONS

We will address the following research questions in this paper:

1) With which type of proof do the students start their proving process?
2) How can students' different perceptions of generic proofs with numbers be characterized?
3) How can the different perceptions of generic proofs with numbers be distinguished with regard to the logical and psychological aspects mentioned above?

The research presented in this paper is part of a wider research project, which comprises the following further research questions: Are the students able to construct the four different kinds of proofs? Are there common pitfalls in their proof productions and if so, what are these? How can students' different perceptions of proofs in the context of figural numbers be

Table 1: The sum of three consecutive numbers represented by figurate numbers

characterized? How can these perceptions be distinguished in regard to the logical and the psychological aspects? How do the students judge the different proofs in comparison to each other? By knowing our entire research interest, the following research design becomes coherent.

RESEARCH-DESIGN

Our study took place in the last week of the semester. We conducted sessions including proof construction and interviews with six different pairs of students, which were randomly selected from a group of volunteers. In the beginning of each session, the students were asked to proof a theorem (see "task analysis and expected solutions") and afterwards, to construct the remaining three types of proof that they had not used spontaneously. For every proof production, the students were given two sheets of papers, the "draft paper" and the "clean copy". The first sheet was meant to be used for their individual work, e.g., tests, explorations and proofs. After having finished the task individually, the two students were asked to develop a joint solution on the basis of their draft solutions and to write it correctly on the "clean copy". After having constructed all proofs, the students and the interviewer looked through the proofs, correcting gaps or inaccuracies. This phase was included in order to ensure the reference to correct proofs in the following interview phase. At the beginning of the interview, the students had to answer a questionnaire and to rate the four proofs with respect to their persuasiveness, their validity, their quality of explanation and their appropriateness for school mathematics on a six-level Likert scale. The last part of the session was an interview. Firstly, the students' were asked about the reasons for their spontaneously chosen type of proof at the beginning. Secondly, the interviewer asked questions based on the students' responses in the questionnaire to get to know their perceptions of the different types of proof. All sessions were recorded with two cameras, one in front, in order to capture gestures as well as motions in particular, and one in the back, filming students' writings.

TASK AND EXPECTED SOLUTIONS

At the beginning of each session, the following task was given to the students:

Prove or disprove: If one takes a natural number and adds its square, the result will always be divisible by 2.

Since we only discuss students' different perceptions of generic proofs with numbers in this paper, we will only give one possible solution for the generic proof with numbers:

Generic proof (with numbers):

$3 + 3^2 = 3 \times (1 + 3) = 3 \times 4 = 12$

$4 + 4^2 = 4 \times (1 + 4) = 4 \times 5 = 20$

The sum of a natural number and its square always equals the product of the initial number and its successor. One of two consecutive natural numbers is always even and the other one is odd. Since the product of an odd and an even number is always even, the sum is even, i.e. divisible by two.

DATA-ANALYSIS

We transcribed each session and analyzed the transcripts and students' proof productions. For this case study investigating students' perceptions of the generic proof with numbers, we followed the quasi-judicial procedure developed by Bromley (1986). We focused on common and characteristic patterns in students' comments to ultimately categorize them as cases of a certain type. The findings suggest three different types of students' perceptions of generic proofs with numbers.

RESULTS

Students' spontaneous choice of types of proof at the beginning of the session

Out of the 12 students participating in the study, nine started immediately to construct a formal proof. In one group, the two students started with testing the statement with two concrete examples. Afterwards, one student explained, referring to their examples ($3+9=12$ and $4+16=20$), that the sum must be even, because the square of an odd number is always odd. And if you add any two odd numbers, the sum is always an even number. So, she discovered a part of a general argument, she could use for a generic proof with numbers. But afterwards, both students started to construct a formal proof with algebraic variables to verify the statement.

All participants started to use algebraic variables when writing down the assertion. For their choice of the formal proof with algebraic variables, they named different reasons: their socialization in school and/or university, that the formal proof is easier, because one does not have to have an "idea", or they thought that the construction of the formal proof would be the intended task.

Only one student immediately wrote "generic proof" and started to investigate concrete examples. She gave the following reasons for her choice in the interview:

> *Yes, for me it is a support. [...] When I'm writing these things down, I recognise how it works. And afterwards, I insert variables. [...] I'm looking for regularity or something similar.*

Students' perceptions of generic proof with numbers

Analyzing the data, we could identify three different kinds of perceptions of generic proofs with numbers, which are described briefly and illustrated by examples from the transcripts. (The following transcripts were translated and linguistically smoothed.)

(1) Logical acceptance and psychological conviction

A student with this perception fully understands the concept of the generic proof and accepts the immanent general verification. The generic proof convinces the student without any doubt that the statement holds in any case. Moreover, he gets an insight, why the statement is true.

Michael reports his perception of generic proofs:

Michael: So, I marked "strongly agree" [for validity]. Because ... step by step, one can immediately follow the idea, e.g., you add this one and then you add the next one and so one. It is not the same as in a formal proof: It is just there and you have to prove it and that's it. This [the generic proof] is not [as] illustrative [as a proof] with pictures, but one can clearly see what happens. [...] That's what I like about a generic proof. If you see this, you can easily understand the way it has been done. There are always some examples given which are used for the following argumentation you can easily understand.

(2) General acceptance of the concept and psychological uncertainty

In this case a student understands the concept of the generic proof and is willing to accept the immanent general verification. In contrast to this conviction, a subjective, intuitive doubt remains, but this emotional uncertainty is considered as unnecessary. Sarah mentions her perception of generic proof with regard to the persuasiveness:

Sarah: I do understand its [the generic proof's] general validity and overall meaning. But with regard to the persuasiveness: if one submits a generic proof to me, I would say: "Can I also have a formal one?". For me, it is more convincing.

Christin describes her intuitive need to test the assumption for all natural numbers:

Christin: But this one [the formal proof] – for me – is somehow a more correct and coherent proof. For me, I would have to test it for all "n" - but it is nonsense, because one recognises the scheme, but...

(3) Inappropriate understanding of the concept

A student with this perception does not (fully) understand the concept of the generic proof. The student focuses on the concrete examples, without noticing the whole wider scheme and its general argument. The generic proof gets misinterpreted as a purely empirical verification.

We cite Paul and Amy as examples of perception (3). Paul quotes, that in a generic proof you are only testing specific examples:

Paul: It [the formal proof] is just – let me say – more correct.

Interviewer: What does it mean "more correct"?

Paul: Yes, correct in the sense that it shows its [the statement's] accuracy, so the validity, yes. And that the proposition is valid. We also show this in the generic proof, but this only applies to the numbers, we have tested.

Amy mentions her perception of generic proofs, which illustrates her misconception:

Amy: Yes. If it [the generic proof] is sufficient for me? I'm not sure. So I wouldn't say that there is 100%-validity. Since there has been a homework, where we had to refute or to prove a statement. And then we had to test examples. I found two examples that worked, but maybe, there is a third one that doesn't. So for me, it [the generic proof] is not sufficient for I have not proven it. I did only prove it for these two examples and not for all numbers. So there is no validity.

Considering all interviews, we only found one student holding perception (1), identified four participants with perception (2) and five with perception (3). In two cases we could not categorize students' answers, as they did not state clear positions.

DISCUSSION AND FINAL REMARKS

Nearly all students in our study started to work on the given task with formalisation and the construction of a formal proof using algebraic variables. Their socialization during their time in school and the reputation of advanced mathematics may be considered as reasons for this result. But one has to stress, that we explicitly did not try to convey an overemphasis of the formal proof in our course, but tried to highlight the validity of all four types of proofs. However, in this simple task the formal proof can be considered the easiest one. Another possible explanation could be that students think that "to provide a proof" implies the use of algebraic variables as we did not ask them to provide a "generic proof". Students may have misinterpreted this as a semiotic norm in the sense of Dimmel and Herbst (2014). Although this is incoherent to the semiotic norm the course has intended to establish.

Our findings concerning students' perceptions of generic proofs with numbers indicate that even after having passed our course, the notion of generic proof still remains problematic for a substantial proportion of our students. Only about half of the students in our study hold a perception, where the generic proof is a general and logical valid argument [perception (1) and (2)]. Five students did not realize the generic aspect of the investigated examples and still hold the view of generic proofs as purely empirical verifications [perception (3)]. One can identify an important pitfall in the usage of generic proofs: When students do not understand the important difference between testing several examples and generic examples combined with valid narrative reasoning, they might be confirmed in their understanding that checking several examples may constitute a proof. Here, the question "why is it true" in combination with the explanatory power of proofs seem to be a promising way to address this misconception. One has to point out, that perceptions (1) and (2) are desired effects of our course. While there are students, who are completely convinced by a generic proof, others accept its logic, but still feel an intuitive doubt. For the latter group, the meaning of variables and the usage of the mathematical language can be pointed out even clearer. While we argue, that our proposed use of generic proofs and formal proof gives a meaningful introduction into the process of proving and the mathematical language, it becomes clear, that generic proofs are not "generic" by themselves.

Disparate arguments in mathematics classrooms

Christine Knipping, Daniela Rott and David A Reid

University of Bremen, Bremen, Germany, knipping@math.uni-bremen.de

Understanding students' classroom argumentation requires the analysis at multiple levels and from multiple perspectives. Using analyses of students' arguments when solving the Problem of Points we illustrate three perspectives: a classroom interactional perspective, a Stoffdidaktik task analysis (at the individual level), and a sociological theoretical perspective (at the community level). Each of these perspectives offers insights into students' argumentation in mathematical contexts, but no single one is adequate to completely describe the nature of students' argumentations, their underlying influences, and ways to support their development. Multiple perspectives and levels of analysis are required when researching classroom argumentation in particular and mathematics learning in general.

Keywords: Argumentation, classroom interaction, task design, social context.

In this paper we argue that understanding students' classroom argumentation requires the analysis at multiple levels and from multiple perspectives. Levels of analysis touched on here include individual, small group, whole class, school and community, but more are possible. Perspectives considered here include a classroom interactional perspective, a *Stoffdidaktik* task analysis (at the individual level), and a sociological theoretical perspective (at the community level).

We begin with a short description of a task which was used in our research and a brief description of some of our results. We then compare these results to those of Goizueta (2014; Goizueta, Mariotti, & Planas 2014) and offer his framework for analysis as the first perspective considered: an interactional perspective at the classroom level. Goizueta proposed the task in Spanish and we proposed it in German, and we will consider changes to the task that may have occurred in translation, using a second perspective from the work of Schupp (1986): a *Stoffdidaktik* task analysis at the individual level. We will then describe additional results from our research that suggest that additional perspectives are needed. An interesting parallel between our results and those obtained by Holland (1981) suggests a third perspective that applies to our results: a sociological theoretical perspective at the community level. We close with some final comments on the need for multiple perspectives and levels of analysis in researching classroom argumentation in particular and mathematics learning in general.

THE PROBLEM OF POINTS

Rott (2014) asked 14/15-year-old students at Gymnasium (grammar school/college prep school) in Bremen (Germany) to solve the classic Problem of Points in the context of their regular classroom mathematics lessons.

> Silke and Acun take turns flipping a coin. Silke scores a point if the coin comes up heads. Acun scores a point if the coin comes up tails. At the beginning of the game Silke and Acun each bet 3€. The first to score 8 points receives the 6€. When the score is 7 to 5 in Silke's favour, they have to interrupt their game. How can they now divide the money? (Our translation from Rott, 2014, p. 25)

Rott classifies the students' answers into five types:

> Proportional A total of 12 rounds were played (7 + 5) and there is 6€ to be won. So each round played scores obtained 0.50€. Accordingly, Silke wins 7 · 0.50€ = 3.50€. Acun receives 2.50€.

> Point Difference Silke requires only one throw to win. The difference between Silke and Acun is 2 points. So Silke gets 2€ more than Acun.

> Mistaken Reasoning Silke receives 7/8 of the 6€, Acun 5/8. However, that totals too much: 5.25€ + 3.75€ = 9€. So Silke gets 3.75€ and Acun 6€ – 3.75€ = 2.25€.

> Point-Ratio The ratio of the scores so far is 7:5 = 1.4 So Silke gets 1.4 · 3€ = 4.20€. That leaves 1.80€ for Acun.
>
> Winner Silke has more points.
>
> (p. 40, our translation)

INTERACTION AT THE CLASSROOM LEVEL: RATIONAL BEHAVIOUR AND THE DIDACTIC CONTRACT

Some of these types of answers correspond to answers obtained by Goizueta (as reported in Goizueta, Mariotti, & Planas, 2014) and they can be accounted for by an analysis from the same theoretical perspective. Goizueta et al. analyse Goizueta's data using Habermas' construct of rational behaviour, in which accepting a validity claim amounts to accepting that certain conditions for validity have been fulfilled. This means that the criteria for validity have also been accepted. They describe three dimensions in students' argumentations:

> According to Habermas' construct of rational behavior and its adaptation by Boero et al. (2010), in the students' argumentative practices we can distinguish an epistemic dimension (inherent in the epistemologically constrained construction and control of propositions, justifications and validations), a teleological dimension (inherent in the strategic decision-making processes embedded in the goal-oriented classroom environment) and a communicative dimension (inherent in the selection of suitable registers and semiotic means to communicate within the given mathematical culture). (pp. 169–170)

They also make use of Brousseau's (1997) concept of the didactic contract, the implicit rules of acceptable classroom behaviour that govern teachers' and students' actions, and Douek's (2007) notion of a reference corpus, knowledge which is assumed to be unquestionable and shared and hence available as a basis for argumentation.

The five types of answers observed by Rott and listed above share a common characteristic which is of special interest to us here. They are all *mathematical*. Goizueta et al. account for this characteristic in the answers Goizueta recorded by reference to the didactic contract.

> When Vasi reminds the group of the need to resort to calculation, we recognize a constraint imposed by the didactic contract: any possible correct answer must be mathematics-related. (p. 172)

> According to the teleological and communicational dimensions, the didactic contract-related need to provide a mathematics-related answer, acting as a necessary normative validity condition, is what drives the students' efforts towards the construction of a first mathematical model. (pp. 174–175)

In short, from the perspective adopted by Goizueta et al. the students' choice to give mathematical answers to the question is accounted for by the didactic contract, which operates at the level of the classroom.

STOFFDIDAKTIK TASK ANALYSIS: LANGUAGE AT THE INDIVIDUAL LEVEL

The five types of answers listed above leave out one type that Rott observed: Money Back, of which an example is "The game was not completed. Both have a chance to win. The game was interrupted, without either reaching 8 points. The game is a tie." (2014, p. 40). This type of answer differs from the others in that it is not mathematical, instead making reference to everyday practices in game playing. Only two answers of this type were observed in the Gymnasium class, but its occurrence requires an explanation as it is not accounted for by Goizueta and colleagues' analysis.

The work of Schupp (1986) provides a different perspective that suggests a reason for the occurrence of such an answer. Schupp considers different wordings of the Problem of Points and suggests how students' answers might vary in relation to different wordings. He distinguishes three fundamentally different views of the problem: 1) situative; 2) quantitative; 3) stochastic and proposes different formulations of the problem to communicate these different views. The formulations all begin in the same way: "Two players are flipping a coin ... Unexpectedly, they are asked to interrupt the game when one of them has 7 points and the other 5. ..."

Situative view: What now?

One possibly ending to the task formulation is very open, asking “What now?” or “What happens next?” Schupp suggests that such a formulation invites a “situative view” of the problem resulting in answers drawing on everyday experiences of game playing. For example, students might answer: “Why not continue at another time?”, “Why not annul the game and give both players their money back?” “Toss the coin one more time to decide the winner.” All these answers seem plausible but they are not mathematical, as Schupp points out (p. 217).

Quantitative view: Fair division; how can this be accomplished?

Another possible ending is “The two players decide to split the money fairly. How can this be done?” (p. 218, our translation). Such a formulation invites a mathematical answer based on ratios. Interestingly, such answers were among the first given to the problem by mathematicians such as Pacioli. Many students in Goizueta’s and Rott’s research also seem to take this view.

Stochastic view: Dividing the pot according to probability

A third formulation considered by Schupp makes it clear that a “fair” division must take into account the players chances of winning when the game is interrupted, for example, by stating “Before dividing they agree that a ‘fair’ division must be done according to the probability each have at that moment of winning the game. How then must the pot be split?” (p. 218) This formulation of the problem motivates solutions like those given historically by Pascal and Fermat. In contrast to other approaches the focus is on the rounds that have not been played.

The tasks as given

How do the formulations of the task used by Goizueta and Rott fit into Schupp’s categories? Both Goizueta’s Spanish formulation and Rott’s German formulation, like Schupp’s, begin “Two players are flipping a coin … Unexpectedly, they are asked to interrupt the game when one of them has 7 points and the other 5.” It is in the way the final question is asked that they differ.

Goizueta’s formulation ends, “¿Cómo deben repartirse el dinero? Justifiquen su respuesta.” (Goizueta, personal communication). The phrase “¿Cómo deben repartirse el dinero?” (How should they split the money?) refers only to dividing the money, and not to the concepts of fairness and probability. However, the word “deben” (should) suggests that there is a single correct answer to this question. Also, the requirement to “Justifiquen su respuesta.” (Justify your answer) in the context of a mathematics class could suggest that mathematical methods of justification are expected. Hence, while this formulation is not as clearly promoting a quantitative view as Schupp’s example of invoking “fairness”, it is not surprising that a quantitative view was adopted by all the students in Goizueta’s study.

Rott’s formulation ends, “Wie können sie nun das Geld aufteilen? Begründe deine Antwort!” (Rott, 2014, p. 25). The phrase “Wie können sie nun das Geld aufteilen?” refers only to dividing the money, and not to the concepts of fairness and probability. And the word “können” (can) is more open than the alternative “sollen” (should). However, Rott’s formulation is not so open as Schupp’s examples of situational view formulations as there is an explicit mention of dividing: “aufteilen” and a requirement to justify the answer “Begründe deine Antwort!”. This places the formulation somewhere in between the situational and the quantitative which would account for answers of both kinds occurring in the Gymnasium class. The task formulation gave students the option of choosing between taking a situational or a quantitative view, and while most took a quantitative view some did not, perhaps reflecting personal preferences at the individual level.

A SOCIOLOGICAL PERSPECTIVE AT THE COMMUNITY LEVEL: RESULTS FROM THE OBERSCHULE

Rott did not only propose the Problem of Points in the Gymnasium class. She also proposed it in another class, in an Oberschule (comprehensive or mixed school). There the results were strikingly different. No students gave mathematical answers of the five types listed above. Most answered that Silke and Acun should get their money back. The only other type of answer Rott observed was a group that discussed extensively a variation on the Point-Difference argument, in which the difference of each players’ winnings from their original bet of 3€ should be equal to the point difference between the players. As one member of the group, Melanie, put it:

> If the score were six five, would then, they would then — ah, if it were six five, I would say that she gets two Euro, because that, he would get two Euro and she four Euro, but it is actually seven five. One point less. Then I would make it five Euro and one Euro. (Rott, 2014, p. 56, our translation)

If the score were 6:5 the point difference would be one, so Silke would win 1€ more than she bet, that is 4€, and Acun would win 1€ less than he bet, 2€. As the score is actually 7:5, the point difference is two, so Silke wins 2€ more than she bet, 5€, and Acun wins 2€ less than he bet, 1€. Melanie's group did not accept this argument, and at the very end of their work together, they almost persuaded her to accept the answer given by the standard Point-Difference argument, but she objected, and their final answer is a sort of compromise without any justification.

125 Melanie: Let's make it Silke four and Acun two.
126 Ines: [???]
127 Melanie: But then, look, just think, then Acun has two Euro, no? And she has, she has three
128 Euro, only one euro of Acun, although she has ||two|| points more.
129 Anne: ||let's make it|| one fifty for him and four-fifty for her. -
130 Ines: That's also an idea. Then both are somehow on the same wavelength, so then the two are
131 actually equal.
132 Melanie: Okay, do that. (p. 55)

Earlier Rott asked Melanie how she arrived at her answer of 5€ from Silke and 1€ for Acun.

92 D. Rott: How did you get that Silke gets five euros and Acun one Euro?
93 Melanie: (Points to the worksheet) So there it was, yes seven to five.
94 D. Rott: Yes.
95 Melanie: And if the score would be seven to six, Silke would get four and Acun
96 two, but it is actually seven to five, so Silke gets more and Acun one Euro.
97 D. Rott: And what did you calculate exactly, to get that?
98 Melanie: Nothing
99 D. Rott: Just by intuition?
100 Melanie: Yes. (p. 57)

Rott calls this groups argument "Intuition" in light of Melanie's comment about not calculating, and the group's quick conclusion to divide the money 4.50€ to 1.50€. While this group's arguments included mathematical elements, which is unusual for the Oberschule groups, their final answer does not have a mathematical basis.

Recall that the answers from the Gymnasium groups were mostly justified in mathematical ways, except for a few who said to give the money back. In the Oberschule, however, the situation is the opposite. Almost all the groups said to give the money back, with only one group providing an intuitive argument with some mathematical elements. We can be sure the formulation of the task was the same in the Gymnasium and the Oberschule as it was provided to the teachers by Rott. How then to account for the very different types of answers? To do so we will need further results from the two classes, as well as another perspective, at another level.

A second difference between the two classes is in the number of different answers students gave. In the Gymnasium it was expected and happened that students gave alternative answers, including that the players should get their money back. The seven groups offered a total of 11 answers, of six different types, while in the Oberschule the five groups gave one answer each, four answering that the players should get their money back. One could account for this by saying the didactic contract is different in the two classrooms. However, even when pushed to give alternative answers in the interview, the Oberschule students only gave answers based on everyday experience. The different preferences of the students, for mathematical answers in the Gymnasium and answers based on everyday experience in the Oberschule, combined with the ability of the Gymnasium students to give answers based on everyday experience as well as mathematical answers, is reminiscent of a study done by Holland (1981).

Holland gave 8 year old children the task of sorting photographs of familiar foods. She found that children from middle-class backgrounds tended to sort the photographs in terms of abstract properties (e.g., "animal/vegetable/dairy/cereal" or "from the sea/farm"). On the other hand, working-class children tended to sort the photographs in terms of their personal experiences (e.g., “things I eat for breakfast/lunch/supper”). Furthermore, when asked to re-sort the photographs, the children from middle class backgrounds could do so, sorting them in terms of their personal experiences, while the working class children could not offer additional sortings. As this result is very similar to the differences between the Gymnasium students and the Oberschule students, it is worth considering the theoretical framework used by Holland and looking at Rott’s results at a sociological level.

A sociological perspective

The neighbourhoods of Bremen are classified by the government into different types. The Oberschule is located in a Group A neighbourhood, in which the proportion of families with immigrant backgrounds as well as the proportion of people on social assistance is above average. Specifically in the neighbourhood around the school, the proportion of families with immigrant backgrounds is 65–86% and many parents have low levels of education (Die Senatorin für Bildung, Wissenschaft und Gesundheit, 2012a, p. 55). The Gymnasium, on the other hand, is a private religious school located in a Group B neighbourhood in which the proportion of families with immigrant backgrounds is below average (15–30%). This does not mean that all the students in the school come from upper-middle-class homes, but it does mean that the majority do.

This difference suggests that a sociological perspective might be useful in understanding the different answers given by students in the two schools to the Problem of Points.

Sociological approaches fall roughly into two groups. One approach collects data on very large groups of people and uses statistical techniques to draw conclusions about the relative weight of various social factors in determining, for example, success in school mathematics. Such an approach is clearly not suitable in this case. A second approach involves applying well developed sociological theories to describe and analyse the actions of smaller groups of people. We have chosen one such theory, the work of Bernstein, to analyse the data presented here.

Holland makes use of several concepts from Bernstein’s work: restricted and elaborated orientations to meaning, realisation and recognition rules, and re-contextualisation.

> For Bernstein an orientation to meaning is created by inter-actional practices which act selectively on what is to be meant, and what form the realization of meaning takes in which contexts. The inter-actional practices in the family and school transmit recognition rules which mark contexts as requiring a specific text, and realization rules which regulate what meanings are to be offered and how these are to be made public. Bernstein argues that families in different social class locations are typified by different inter-actional practices which regulate different recognition and realization rules and generate an elaborated or restricted code ... (Bernstein, 1977) or ... an orientation to context independent meanings or to context dependent meanings. For some children then the re-contextualizing principle of the school will entail recognition and realization rules very different from those acquired in the family. (Holland, 1981, p. 2)

Children learn at home how to *recognise* contexts that require certain ways of making meaning, and how to *realise* those ways of making meaning. School is a context in which meaning is context independent. Children’s experiences are re-contextualised in school into abstractions (Bernstein, 1977). The middle class children in Holland’s study had both the recognition rules to see Holland’s task as calling for abstract categories, as well as the realisation rules needed to use abstract categories in classifying. The working class children did not. Bernstein (1977) characterises an orientation to abstract, context independent meanings as an elaborated orientation, and an orientation to context dependent meanings as a restricted orientation. From this perspective we can account for the differences between the argumentations of the Gymnasium students and the Oberschule students by suggesting that the out of school experiences of the students led some to develop elaborated orientations to meaning, including both recognition and realisation rules related to using mathematical arguments in school contexts, while others developed restricted orientations to meaning, lacking either the recognition or the realisation rules needed to produce mathematical argumentations in school contexts.

Cooper and Dunne (2000) describe difficulty recognising the border between everyday and mathematical contexts as the "boundary problem". They researched sixth grade and ninth grade students' solutions to test items of two types: "realistic" items in which a mathematical task is embedded in an everyday context, and "esoteric" items in which the task was decontextualised. Working class students performed less well than middle class students, especially on realistic items. However, in an interview situation in which the students were explicitly told to disregard the context, they were successful on items they had incorrectly answered in the test situation. This suggests that their difficulty did not stem from an inability to act appropriately. Rather, they faced the boundary problem; they lacked the recognition rules to distinguish between everyday and mathematical contexts. If this was also the difficulty faced by the Oberschule students, then a formulation of the task that more clearly invokes a mathematical or stochastic view of the problem might help them to recognise the type of argument expected. In addition, a reframing of the didactic contract to more explicitly require multiple solutions and mathematical solutions might also help to overcome the boundary problem.

Knipping (2012) discusses the value of sociological approaches to research on argumentation, and identifies decontextualised language as a key issue. She cites the work of Hasan (2001), who studied the opportunities children have to engage in this kind of discourse in their homes before they begin schooling. In some homes the talk of adults to small children remains tied to the context, related directly to the activities and objects that are present to the senses. In others there is already at this early age a fluid shifting between decontextualised and contextualised language, which Hasan refers to as a "con/textual shift". There is reason to believe that the division Hasan found, between home situations in which con/textual shifts occur often and those where they occur rarely, is influenced by social class. This could provide a mechanism to account for the occurrence of the boundary problem among the Oberschule students.

CONCLUSIONS

In this paper we have offered three different perspectives at three levels that help us account for students' responses to the Problem of Points: a classroom interactional perspective, a *Stoffdidaktik* task analysis at the individual level, and a sociological theoretical perspective at the community level. We have made no effort to integrate these perspectives into a single all-encompassing model. This is likely to be impossible given the different fundamental assumptions of the theories involved. Moreover, as Reid (1996) points out, multiple perspectives offering different interpretations are valuable, even if contradictory, as no single perspective can capture the complexity of human learning in social contexts. And as we take a closer or wider view of phenomena of interest, different theories become applicable. Learning can be viewed at many different levels, from the neurological to the ecological. Different theories and methodologies are appropriate for these different levels. "Discourses concerned with different phenomena (such as radical or social constructivism—or neurology, ecology, or biological evolution) can be simultaneously incommensurate with one another and appropriate to their particular research foci." (Davis & Simmt, 2003, p. 143).

Researching classroom argumentation must involve theories at at least three levels. Argumentation is conducted by human beings, and influences the thinking of human beings, and so perspectives at the level of individual human cognition are needed. But argumentation is also a necessarily social phenomenon which takes place among groups of people using language. Perspectives that focus on communication, language, and interactions between people in small groups are therefore needed. People and communication develop in larger social and cultural contexts that shape them and are shaped by them. Argumentation in mathematics classrooms cannot be considered independently of argumentation in mathematics and people in mathematics classrooms cannot be considered independently of their social and cultural backgrounds. Multiple perspectives at every level are needed.

E-assessment of understanding of geometric proofs using interactive diagrams

Yael Luz and Michal Yerushalmy

University of Haifa, Faculty of Education, Haifa, Israel, yael.luz.halevi@gmail.com

The present study is part of a larger one examining the design principles of e-assessment of understanding of geometric proofs. The interactive assessment tasks are checked automatically and feedback is generated. We reviewed various proving task design studies, looking for a template that incorporates interactive sketching and that can be checked automatically. Our findings suggest that examples sketched in a dynamic geometry environment in order to complete the assessment task are a challenging target for e-assessment and are relevant for eliciting the students' understanding of geometric terms, geometric statements, and their validity.

Keywords: Assessment, DGE, examples, validity.

BACKGROUND

The present paper focuses on the challenge of automated assessment of knowledge of geometric proofs. Specifically, we propose to assess processes of conjecturing and argumentation. To this end, we study the roles of examples (designed to be checked automatically) demonstrating the logical validity of geometric statements.

Assessing understanding of geometric proofs

For decades an extensive efforts has been made to automate the process of checking proofs. But a deductive proof is a complex process, and most of the proofs produced by students are subject to their teachers' evaluation. We are interested in a facet that is not often checked in a school setting (neither by humans nor by machines), although it is an inherent part of mathematicians' work on proofs: conjectures and argumentation. In the process of conjecturing, mathematicians try to generate different examples, including extreme and boundary examples, in order to create a rich example space from which a pattern can emerge. When mathematicians investigate the validity of a new conjecture, they usually do not only look for the proof but try to construct counter-examples by means of quasi-empirical testing, because such testing can expose hidden contradictions, errors, or unstated assumptions (De Villiers, 1990). Proving often involves understanding how the proof relates to specific examples and how these examples can illustrate it. Being able to follow a sequence of inferences in a proof based on a specific example has been considered by mathematicians to be an indispensable tool for understanding a proof. Mejia-Ramos and colleagues (2012) constructed a model for assessing the comprehension of aspects of a proof. They discovered four main facets: summarizing the main idea of the proof, understanding the components or modules of the proof, applying the method of the proof in other contexts, and illustrating the proof with examples or diagrams. Kuzniak (2013) presented a new framework for the didactics of geometry work. The framework encapsulates instrumental processes. It transforms artefacts, such as dynamic geometry software, into tools in the construction process and into a discursive process of the proof that confers meaning on the properties used within the mathematical reasoning. The assessment template we designed follows Ramos's (2012) assessment model and is inspired by the framework suggested by Kuzniak (2013).

Buchbinder and Zaslavsky (2009) offered a mathematical framework for designing tasks that question the students' understanding of the role of examples in determining the validity of mathematical statements. This framework provides a basis for constructing tasks that assess and support students' understanding of the logical connections between examples and statements. Any mathematical statement can be reduced to two sets of mathematical objects: the "*if*" part of the statement, which is the domain, the set of all mathematical objects to which the statement refers (e.g., isosceles triangles), and the "*then*" part of the statement, the proposition that defines the set of all mathematical objects that exhibit a certain property (e.g., right angle triangles). In this context, the status of the example object can be defined as follows: a supporting example is an object in domain D that exhibits P (e.g., an isosceles triangle that is a right-angle triangle ). A counter-example is an object in domain D that does not exhibit P (e.g., an isosceles triangle that is not a right-angle triangle ).

Interactive diagrams

Herbst and Arbor (2004) found that building reasoned conjectures or using deductive reasoning to find out what could or should be true can be supported by tasks that engage students in generative interactions with diagrams. This study uses interactive diagrams as a tool to create examples that either support or refute conjectures. The interactive diagrams we use are designed to describe the domain and context of the task (an example of a geometric figure or drawing) and to support autonomous guided inquiry, by enabling direct manipulations of the example and by providing feedback that reflects the process of inquiry (Yerushalmy, 2005). Students interact with the diagram while exploring the conditions under which a version of the problem can be solved (Herbst & Arbor, 2004). By dragging a dynamic diagram students generate an example that demonstrates specific properties. The use of dragging allows students to experience kinematic dependence that can be interpreted as logical dependence within the dynamic environment, but also within the geometric context (Mariotti, 2006). According to Mariotti, the dragging interaction can be compared with formal arguments used in mathematical proofs (Mariotti, 2006).

e-Assessment

Whereas traditional assessment focused primarily on testing factual knowledge, new technologies gave rise to the need to assess new skills, such as problem solving, creativity, critical thinking, and risk-taking. To nurture and develop these skills, the assessment strategy should aim beyond testing factual knowledge and capture the less tangible themes that underlie these skills. Although technology offers a rich learning experience, studies show limitations when it comes to assessing solutions for complex mathematical problems. First-generation e-assessment was limited to multiple choice questions, subsequently enhanced by short verbal or numeric answers (Scalise & Gifford, 2006). Studies show that assessments based exclusively on questions of this sort lead to limited learning and incorrect inferences of purpose of the assessment, such as "there is only one right answer," " the right answer resides in the head of the teacher or test maker," and "the role of the student is to get the answer by guessing" (Bennett, 1993). To assess the complex processes involved in proofs we must understand the role that examples play in proofs and the links between these examples (in our case, dynamic figures) and logical argumentation.

THE STUDY

Objectives

The present paper presents results derived from a broader research study for which we developed a tool to assess students' skills in geometry proofs. The tool provides immediate multiple representation feedback and analysis at the level of the single student, group, or class, based on the teacher's choice. The challenge of the innovative development is to study strategies followed by students in investigating the validity of a geometric statement and in generating examples. We proposed to determine which aspects of the comprehension of a geometry proof are demonstrated by the automatically generated evaluation presented either as a personal solution or as a visually comparative collection of answers, and which aspects are demonstrated in the accumulated visual feedback.

Study setup

Sixty three middle school students participated in the study; 33 were in the 8th and 30 in 9th grade. The geometry classrooms featured mixed abilities, including gifted students and students with special needs. We use the terms "high-, medium-, and low-skill students" for students who showed high, medium, and low achievement in the subject of the examination before the experiment.

The experiment included a practice session, an examination session, and a whole-class discussion period. Before the examination, students had a practice session aimed at presenting the instructions and the technological interface (personal tablets) using a similar template task. The examination included three problem-solving tasks with a repeated five-item template [1]. In this paper we report the results of the work on two items of the template appearing in three tasks. We also report on the class discussion that took place a few days after the examination and on task-

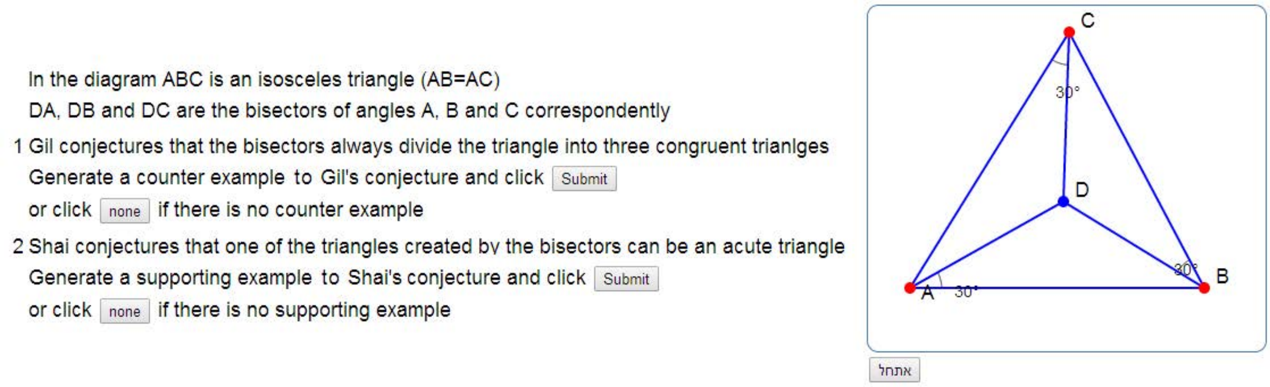

Figure 1: Page setup of paired items B1 and B2 (points A, B, C are draggable)

based interviews with three pairs of students (two high-skilled and one low-skilled) solving the same examination items a few weeks after the exam. The group feedback used in the whole-class discussion and the task-based interviews were conducted for the purpose of triangulation.

Design of the research tools

Task: The examination included three tasks that are instances of the same five-item template. Three items focused on the comprehension of terms and the reading of the proof. Here we discuss the other two items, which focused on assessing students' understanding of the validity of a geometric statement and generating supporting or counter-examples. The students were asked to provide a counter-example for the universal statement and a supporting example for the existential statement (Figure 1). The students could also choose "none," indicating that such an example does not exist. The domain of both items was identical in each task. The interactive diagram was a *figure*, therefore robustly in the class of objects described by the domain, and the properties defining the domain were invariant under dragging. The initial orientation of the *figure* does not represent the correct answer, and students must actively drag the diagram to generate the correct answer. The items of the three tasks are described in Table 1.

Objectives	Domain (if)	Proposition (then)	Diagram
A1. Counter- example	$AB = AC$ $BD = CE$	*AEFD* cannot be a square	A2. Supporting example		ΔFDB can be an isosceles triangle	
B1. Counter- example	$AB = AC$ *DA*, *DB* and *DC* are bisectors	The bisectors always divide the triangle into three congruent triangles	B2. Supporting example		One of the triangles created by the bisectors can be an acute triangle	
C1. Counter-example	$AB \perp CD$ $\angle A = \angle D$	$\Delta AMC \sim \Delta DMB$	C2. Supporting example		$\Delta AMC \cong \Delta DMB$	

Table 1: The logical structure of the three pairs items

In each diagram, some measures of lengths and angles were displayed. Other measures that were required for constructing the example were such that could be derived from the displayed measures and the properties of the domain (e.g., the measure of only one of the equal sides of an isosceles triangle is displayed). The use of measurements in interactive diagrams confronts students with the issue of the relationship between measurement and proof (Chazan, 1988).

Rubric: A rubric was developed for each task based on a literature review of relevant misconceptions and on pilot trials of the tasks conducted with students (mostly pre-service mathematics teachers).

Feedback: We designed two feedback sheets. A personal feedback sheet displayed the student's examination answers and personal evaluation feedback [2]. The feedback was not provided to the students immediately after completion of the examination in order to support an unbiased class discussion. The group feedback sheet (Figure 6) was designed to display the collective answers and results of all students for a single item.

Data sources and analysis

Data analysis included the personal and group feedback sheets, the class discussion videotape, and videotapes and transcripts of the interviews. We verified the automatic check by manually checking the results. Next, we used the group feedback to look for patterns of mistakes. Expected pre-configured misconceptions were captured by the automatic check, and other mistakes were identified manually. We conjectured about the source of the mistake and later verified our conjectures during the interviews.

FINDINGS AND RESULTS

The findings are classified into three categories: strategies, misinterpretation of terms, and understanding statement validity according to the three questions formulated in the objectives of the study. Each category includes the triangulation of the results obtained by analysis of the three research tools.

Strategies used to create examples

During the examination we found that highly skilled students demonstrated active and fearless engagement with the interactive diagrams, dragging points to the extreme and collapsing them to a single point.

This impression was verified during the interviews, when the two high-skill pairs intensively dragged the diagram from an initial state to extremes, constantly expanding the example space (Figure 2), whereas the low-skill pair showed hesitating and careful dragging, making small changes to the initial diagram (Figure 3).

Some students (mostly high-skill) submitted extreme examples even when standard examples were sufficient to provide a counter-example, as shown in Figure 4.

Another strategy was the use of symmetrical diagrams, with as regular as possible shapes. This strategy helped students to avoid common error such as matching non-corresponding sides, trying to create congruent triangles (see Figure 5) or examining isosceles triangle as a possible counter example to the statement "the median divides the triangle into two equal area triangles".

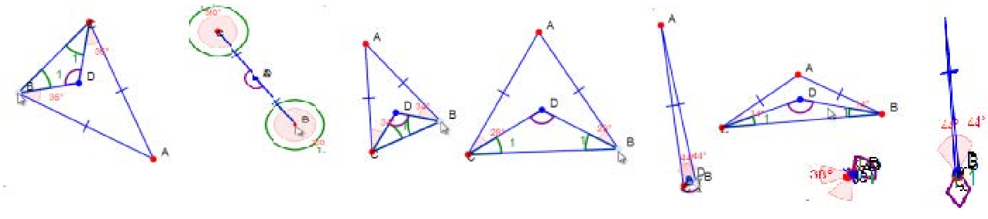

Figure 2: Example space of item B2 created by the high-skill pair

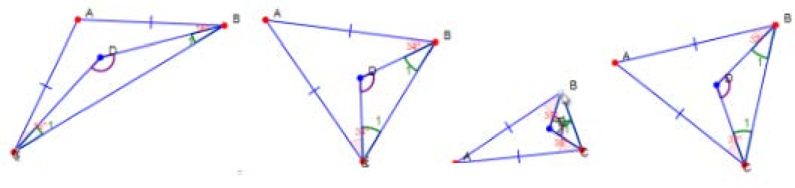

Figure 3: Example space of item B2 created by the low–skill pair

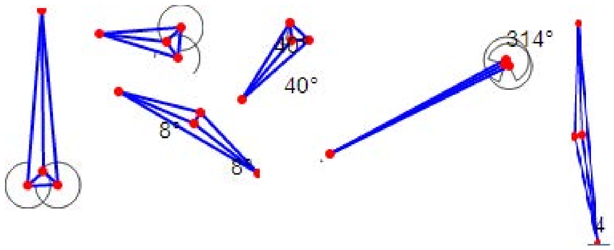

Figure 4: Counter-examples for item B1

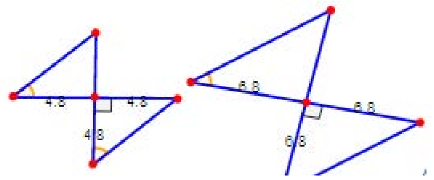

Figure 5: Examples of common strategy in item C2 (using isosceles triangles)

Analyzing terms in the given statement

The study uses the group feedback sheet to demonstrate the affordance of the assessment tool to inform the teacher in regard to students' interpretation of the terms in the given geometric statement. The examination feedback provided a view of the interpretation of terms and concepts in class. In the feedback sheet for the task "if AB ⊥ CD and ∠A = ∠D, and M is the intersection point of AB and CD, then ΔACM ≅ ΔDBM" (Figure 6), we were able to identify misinterpretations of the concept of "corresponding parts in congruent triangles." Although most students generated triangles with equal angles and one pair of equal sides, a substantial number of them (marked in orange) matched non-corresponding sides (AM = CM, instead of AM = DM).

Another common misinterpretation was found on the group feedback sheet of another task (B2), where students were asked to provide a supporting example for the incorrect existential statement: "the bisectors of an isosceles triangle create an acute triangle" (Figure 7). Although the example on the left is an extreme one and the closest to an acute triangle, the bisectors in the other two diagrams create clearly obtuse triangles. We conjectured that students misinterpreted the term "acute triangle." This assumption was verified in the class discussion following the ex-

	Counter-example		Supporting example	
	Validity	% Correct	Validity	% Correct
A	Invalid	84%	Valid	83%
B	Valid	79%	Invalid	59%
C	Valid	68%	Invalid	76%

Table 2: Correct reponses in regard to validity of statements

amination with students who defined an acute triangle as one that includes a single acute angle.

Determining the validity of the statement

In general, students were able to determine the validity of the statement, as can be seen in Table 2. The lower scores were in task B2, where the term “acute triangle” was misinterpreted by many.

Although most students correctly identified the validity of the statement, they did not necessarily provide a correct example figure (e.g. correspondence in congruent triangles). In a class discussion following the examination, students were asked to justify the “none” answers presented in the aggregated feedback sheet. All students based their justifications on empirical evidence, which means that they were not able to find any examples. This phenomenon was confirmed in the interviews. But during the interviews the high-skill pairs were able to produce a deductive explanation relatively quickly.

DISCUSSION

Based on the partial findings presented above we can draw several conclusions with regard to the objectives of the study: (a) we were able to learn what strategies students used, and take pedagogical action, such as encouraging low-skill students to use more active and fearless dragging in order to investigate extreme examples; (b) we were able to use the group feedback sheet as a tool to identify misinterpretations of terms; (c) the design of the items and the automatic checking provided immediate quantitative and personal data about the validity of the understanding of the geometric statement, but not about the presence of a justification when examples were not available; students simply based their answers on empirical evidence.

The visual feedback sheet helped us quickly identify central patterns of knowledge in class. In a discussion that took place in class after the examination, we displayed the group feedback sheet and found that it encouraged active discussion, as students were eager to participate in a conversation based on their generated examples. Successful brain-storming, involving many members of the class, was conducted about the existence of multiple correct answers, the importance of a large-scale example space and the use of active and fearless dragging strategy for expanding it, the role of extreme examples, and the need for students to justify their “no such example” answer. Future research on the role, use, and format of personal and group visual feedback should be a fruitful field for studying the use of the ample and immediate data produced by e-assessment.

Building stories in order to reason and prove in mathematics class in primary school

Marianne Moulin and Virginie Deloustal-Jorrand

University Claude Bernard Lyon 1, EA 4148 S2HEP, Villeurbanne, France,
marianne.moulin@ens-lyon.fr, virginie.deloustal-jorrand@univ-lyon1.fr

As a part of a multidisciplinary research lead by a team from the S2HEP Laboratory, the aim of our work is to explore the potential functions of stories in Scientifics and Mathematics learning. In this paper we focus on the potential connections between the mathematical space and rhetoric space during problem solving activity. We first characterized theoretically, and then tested experimentally, thanks to a didactical engineering, a didactical environment. We characterise a processes-transferring space between the narrative activity and the problem solving activity. Our results show that the narration act supports the student's mathematical reasoning.

Keywords: Problem solving, stories, narration act, processes-transferring space.

INTRODUCTION

This paper aims to study the contributions of the narrative act in the proving process. There is indeed a natural inclination of the Humans for stories (Bruner, 2003) with a valuable heuristic potential. Our research group has shown, for instance, how the stories' plot and possible worlds brought by fiction can lead children to question their knowledge and build new scientific knowledge (Bruguière & Triquet, 2012). This heuristic prospective leads us to imagine that a reasoning[1] can be built on narrative structures even in mathematics. The reasoning and the narrative acts are both structured process and thanks to Bruner's and Fayol's works, we can assume that the development of a reasoning can rely, from a structural point of view, on narrative structures. Six years old children, who are as able as adults to build complex narratives structures (Fayol, 1985), have to develop mathematical and logical structures. Maybe theses structures and the proof skills related can grow for a part on those already mastered abilities. Following this idea, we developed a model allowing us to anticipate and study connections between the reasoning and the narrative act (Moulin, 2013). In the first part of this paper, we share some theoretical elements about relations between problem solving and story writing activity. We focus on the processes involved and characterize a *processes-transferring space*. Then, we present a didactical environment shaped in order to allow a joint development between narrative and reasoning. We show on chosen examples how the narration-act provides structured guidelines and take part in the proving process.

THEORETICAL ELEMENTS: PROCESSES-TRANSFERING SPACE

The aim of this theoretical part is to define what we call a *processes-transferring space* between the reasoning act in problem solving activity and the narrative act in story building. We rest on Scardamalia & Beireiter's framework (1987) that postulates that during the drafting of a text, the interactions between the rhetoric space (inherent to the construction of the text) and the content's space (concerning disciplinary knowledge) lead to the application of high cognitive functions and to the transformation of the relevant knowledge in both fields (Figure 1).

Outlooks opened by this model lead us to the assumption that during problem solving activity, the commitment to a task related to story building can allow children to initiate, build, structure and/or prove their

1 In this paper, we call "reasoning" the cognitive process that consists in drawing conclusions from facts, evidence, etc. In school, a reasoning is expected form the children when solving a problem.

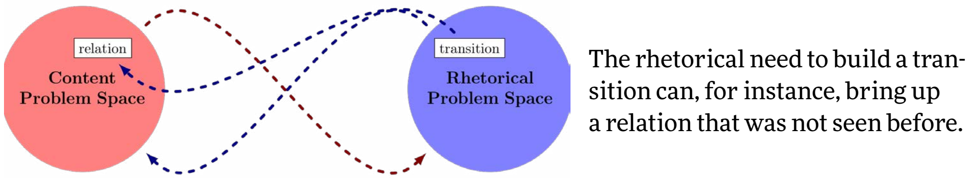

Figure 1: Problem spaces and interactions extract from *Knowledge Transforming Strategy* (Scardamalia & Beireiter, 1987)

reasoning. This assumption brings us to consider a double theoretical framework.

Characteristic elements of mathematical problems2 and solving process

This first point, about problem solving activity, settles down in the field of the didactics of mathematics. Most European curricula consider that the main objective of problem solving is to develop the reasoning and logic skills and to give meaning to mathematical objects. In our work, we study this activity by getting interested in the (cross-disciplinary) skills involvements linked to a heuristic activity (Polya, 1945). To study the processes involved in problem solving, we choose to consider as one object the problem and the solution in a three-block framework (Figure 2).

Determine the whole data's structure with structuring and modelling processes; or build valid conjectures about the nature and the value of the solution involving conception and reflexive processes; or calculate the value of the solution and prove the validity of the calculations using among other explanation and argumentative processes.

The proving process depends on each of theses cognitive processes, which are dependant of the quality of the problem environment. However, school problems are not always enough complex to impose to the pupil the construction of reasoning. Supported by various linguistic tools, we realized an analysis of school problem statement (French textbooks) as if they where stories. As a matter of fact, school problems are often

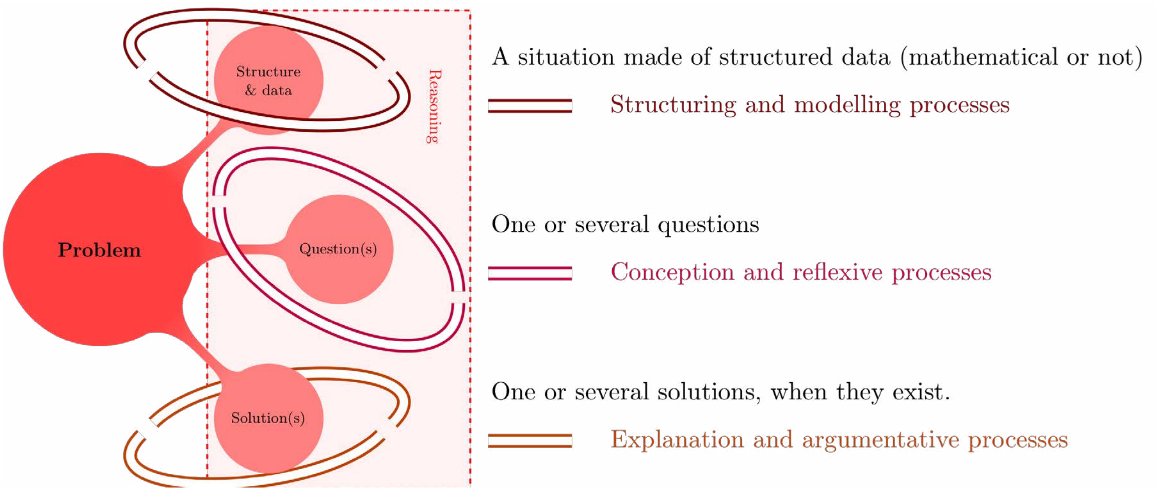

Figure 2: Mathematical problem's components and reasoning process

Problem solving is then a combination of processes developing the necessary actions to determine the solution(s) taking care of the mathematical object(s). Each one of the three problem's components must be handled. The complete processing of each component is equivalent to the problem's resolution. The problem can bee seen as solved when you have either:

(if not always) presented as little stories. But, none of them included neither problematic elements nor triggering factors as intended in the context of stories (Moulin et al., 2012). We could raise here the question of the relevance to present a problem in the form of a story if we remove the element from it that indeed "poses problem". But our main focus here is to grant a larger place to the story dimension already given in the problem's statements. The purpose of this approach is to supplement problem-solving process with *stories functions* that will be presented in the following point.

2 According to us, the name *mathematical problem* group together all the situations involving a mathematical object and asking one (or several) question(s) to which it is possible to answer only after the elaboration of a reasoning.

Characteristic functions of stories and narrative act process

We move our focus off didactics to the heuristic and structuring functions of stories linked to the narrative act. With this opening we want to highlight similarities in the cognitive activities and processes related to both activities (structuring, explanation, problematization, argumentation). When it comes to stories, one first thinks of a linguistic object, telling a story and showing some characteristics of singular shape. However, one can also approaches stories from the angle of their elaboration, as a mindset, with regard to the heuristic, and structuring functions put forward by several researchers such as Bruner and Ricœur. This is the way we chose.

To involve theses functions in the problem solving process, we have to consider in the same kind of way in one hand problems and stories and in the other hand reasoning and narrative act process. Stories have structural characteristics (Reuter, 2009) of their own organized around a plot. The plot may be considered as a question to which it is necessary to try to answer. From then on, the reception of a story, just like its production, involves cognitive processes of recognition and reproduction of this structuring. The solving of the plot therefore corresponds to a (more or less complex) sequence of movements of actions proposed by the story allowing to find a state of balance. Combining Genette's (1972) and Bruner's (2003) work, we came up with a three-block design for stories (Figure 3).

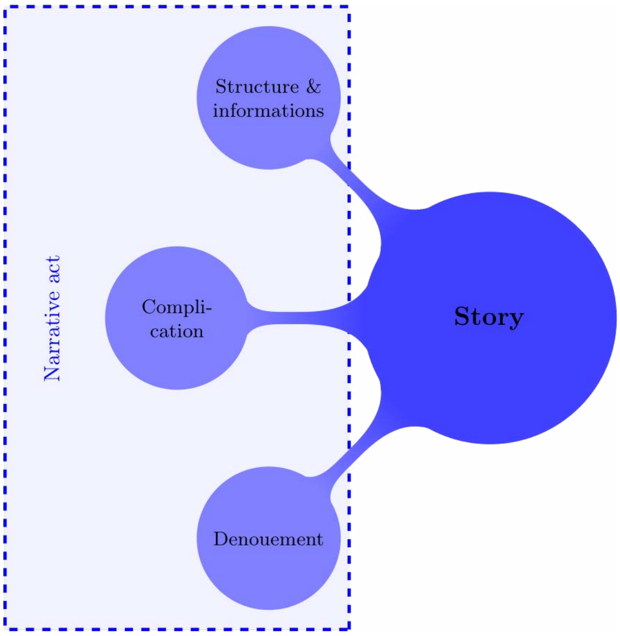

Figure 3: Stories' components and narrative act process

The characteristics of the story object express themselves in the processes of thought allowing to understand it, to build it and conversely. The solver/reader has to imagine from the information different explanatory possibilities. Fiction, as a characteristic of stories, brings a whole space to do it. For Ricœur (1983), the story has moreover this capacity to organize what is disparate into a coherent whole (*holos*). The reception, like the production of a story, therefore imposes to (re)build the temporal, spatial and causal relations of the presented events. These heuristic and structuring functions of stories are strongly connected to problematization and are submitted to an internal logic. So they play a part in similar processes to those that we have described for problem solving. There are three main functions considered in our work:

- The structuring function through situation, structure and information;
- The problematization function induces by the complication and the plot's study;
- The explanation function linked to the solving of the plot and the resolution.

Process transferring space in problem solving and story writing activity

We can now identify a potential *process transferring space* between the content problem space (including the mathematical problem) and the rhetorical problem space within with the story is build (Figure 4). Considering, as Scardamalia & Beireiter (1987) did, that a process is an answer to a local problem we can assume that each local problem (content or rhetoric) and the related process can be either realised in the content problem space or in the rhetoric one. In the context of a mathematic problem, we can make a "transfer hypothesis" assuming that *every processes related to the proving process (explanation, conjecturing, argumentation, etc.) can be handled with the help of tools available in the rhetoric space and vice versa.* In other words, as part of a problem solving activity, the narrative act and the narrative functions going with it can under certain conditions come in the solving and proving process.

In our work, we develop the story scope in integrating it as an essential component of the didactical environment (Brousseau, 1998). We position stories as an antagonistic object of the pupil in problem solving

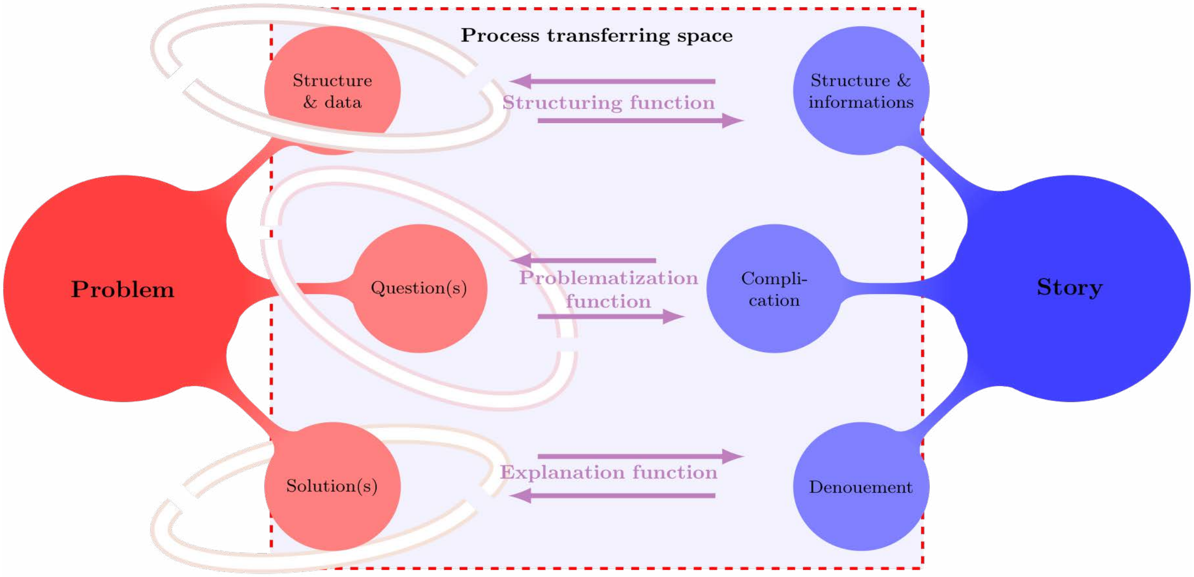

Figure 4: Process transferring space

activity. Indeed, with a structure and logic of its own, story complements the didactical environment. The story structures a space of thought in accordance with the situation at stake in the problem. According to us, this structured space allows the pupil to build and to validate his/her reasoning. We set up an experiment to test various aspects of the interactions between the story and mathematical reasoning. We present the original situation in the following point.

SITUATION AND DIDACTICAL ENVIRONMENT

With the aim of testing our transfer hypothesis, we shaped a didactical environment (Brousseau, 1998) with the objective of ensuring a joint development between narrative and reasoning. The situation of problem solving we offer is built around a game of spinning tops in which two players are in confrontation according to the rules given in Figure 5.

Due to its progress – a sequence of rounds bringing gains and losses of points – this game has a structure that is possible to determine completely through the application of mathematical rules. For instance, the score of the winner of a game is always between 7 and 9 and it is necessary to play a minimum of three rounds to end a game. These properties form, among others, the mathematical and logical structure fixing the possibilities and the impossibilities of the situation. It is on this structure, constituting a local axiom (Tarski, 1969), that we built our mathematical problems.

In a first time, we asked children to produce descriptive narratives based on games actually made. These descriptive stories were meant to be a support for the children to move from a material situation to a more objective one. At this point, the events of the game are the

The game is divided in rounds. To the signal, both players throw their spinning top in a stadium at the same time. It contains a play area and two areas of penalty. The round ends when: One of the spinning tops does not spin any more; One of the spinning tops is in the penalty area; One of the spinning tops is not any more in the stadium; A player touches the stadium. When the round is over, the points are distributed (the rules are applied in order, as soon as a point is given or removed, we move to the following round):
- 1 for the player who throws his spinning top outside the stadium;
- 3 for the player who touches the stadium during the round;
+3 for the player who sends the spinning top of his/her opponent outside the stadium;
+2 for the player who corners the spinning top of his/her opponent in the penalty area;
+ 1 for the player whose spinning top is the last one to stop.
The first player who gets 7 points (or more) wins the game.

Figure 5: Rules

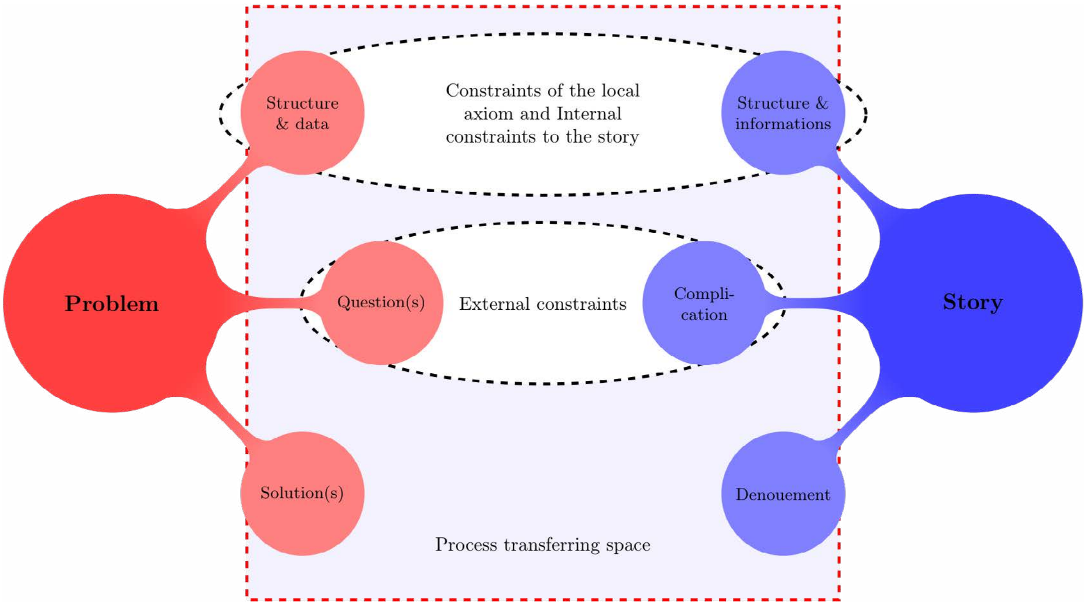

Figure 6: Constraints and didactical environment

events of the story; the scores are included in the story and the game's rules are automatically taking cared of.

Then, in a second time, we confronted them to various mathematical problems about the mathematical structure of the game and the properties presented above (about possible scores, number of rounds, etc.) To address these problematic situations, children could use anticipated-games narratives (based on imaginary games). At this point, the (imaginary) events of the game are still the events of the stories; however, points became mathematical objects and the game's rules are a mathematical structure. The problem's question reflects on the story's complication. There is a room for co-building between the reasoning and the story. In the built situation, the resolution of the problem and the proof process is subject to three types of constraints (Figure 6):

— *Constraints of the local axiom:* These are the constraints carried by the situation (Durand-Guerrier & Diaz, 2005). In our context, they define what can be done or not in the situation and are related to the structure and the data. For instance, the winner always ends the game with a 7, 8 or 9 points.

— *External constraints:* These are the constraints imposed by instructions. They are one or several additional constraint(s), which add up to those of the local axiom. They take place in the question. For example, to impose that the winner wins with 8 points instead of leaving the possibility that he ends up with 7 or 9.

— *Internal constraints to the story:* These are the constraints imposed by the style of the story. As the latter is a structured production, it has to respect an internal logic of time, characters and place.

The interaction between the two structures is the essence of our didactical environment. While solving various problems, children can rely on an environment that includes all the feasible games in accordance with the *local axiom*. We made the local hypothesis that children can produce their results through their stories and validate them thanks to the mathematical and logical rules that govern the situation. The construction through the interaction between the structure of the game and the production of the story constitutes the originality of our experiment. The outcomes presented in the following point are part of a larger research (Moulin, 2014).

RESULTS

We put ourselves in the methodological framework of *didactical engineering* (Artigue, 1988). This one allows us to confront the potentialities of our environment, by an analysis of the choices made determining the "possibilities of action, choice, decision, control and validation that [the pupil] has at his disposal" (p. 258), to the effective productions of the pupils. Therefore, we can validate, in an internal way, our hypothesis thanks to the confrontation between *a priori* and *a* *posteriori* analysis. We conducted our experiment in three primary schools (six class of 10–11 years old children, 138 children). We collected and analysed oral interactions in the class and children written productions. In this part of this article we present some chosen extracts to highlight two significant results regarding argumentation and proof.

Result 1: Children's natural tendency to stories in conjecturing and arguing

The first meaningful result we want to highlight is that, even in a mathematical context, children have a natural tendency to stories.

For instance, after playing and write some descriptive stories children were asked to establish to conjectures about the mathematical structure of the situation:

1. In your opinion, what is/are the score/s that can be obtain by the game's winner?
2. In your opinion, what is the minimum number of rounds needed to end a game.

The only constraint they had in some cases was to justify all of their answer (using the shape of a story or not). They indeed used stories to justify and/or prove. For the most part, 61 over 113, children use an explanatory possible story to justify their answer[3]. Only ten answers are based on mathematics using numbers and calculations. It seems easier for children to work in the narrative space than in the mathematical one (which concerns directly the game's rules). Moreover, the justifications build in the narrative space produce more correct conjectures than the one build on the mathematical space. 85% of the thirty-two complete conjectures came along narrative justification.

When we orally asked children to conjecture about the structure of the situation, they build and used stories in various ways:

— Anticipate potentially feasible games to put forward a conjecture;

— Propose an example (or a counter-example) to validate (or invalidate) a conjecture; the validation (or non-validation) is made by the confrontation between the stories, the mathematical structure of the situation and the constraints of the question.

While producing stories, students embrace the mathematical constraints of the situations and step back from the sensible world. No more restrained by material thinking, the students were more inclined to mathematical approach. Therefore, they develop or enhance their mathematical proving skills (example and counter-example arguments, mathematical conjectures and demonstrations, etc.). Some of them even produced mathematical proof of the impossibility to reach ten points.

Result 2: Children easily travel between the two spaces to solve problems

During our experiment, we asked children to solve various mathematical problems. For the most part, according to Vergnaud's typology for additive structures, they were problem with a composition of transformations (Vergnaud, 1986). The one we present now had this structure and the following wording:

> *Laura plays with spinning tops. During the beginning of the game, she wins 5 points. In total, she gains 3 points. What happened during the end of the game?*

With this formulation, we didn't constraint the children to use a narrative answer. We could have asked them to "tell" like we did in other exercises. However, a lot of them use narrative ways in order to solve this problem and the same type's other problems. We got a good rate of success comparing to the usual rate with this kind of problem4. But, most of all, we want to focus here on the effective practice use by the pupils to solve these problems. The oral correction sessions reveals that children easily travel between two problem spaces: the mathematical one and the rhetorical one. In this specific problem, the difficulty was to identify that you need two transformations (instead of one) to get the lost of two points. In the following example you can notice that the child goes from the narrative point of view, to the mathematical one, then again to the narrative one and finish with the mathematical one.

At the beginning, I though that it needed just one round, just that ... because it's said that she gain [loose]

3 The other answers were based on the games played during the previous session or on the game's rules. For instance, "you can have 8 points because when I played I won with 8 points" or "you can have 7 points because when you have 7 you won".

4 More than 50% against 25% according to Vergnaud (1986) in similar situations.

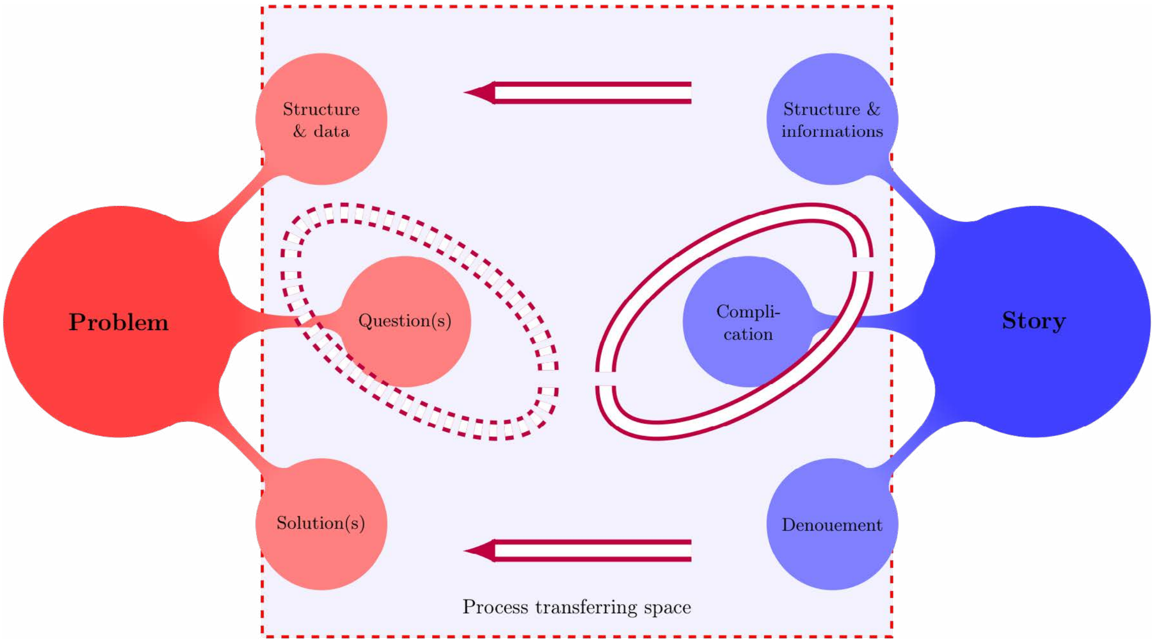

Figure 7: Problematization processes transfer

three points. She had five points in the beginning so she lost two points. And then, because there is no rules bringing the lost of two points, there is only minus one or minus three (...) so I said that I needed two rounds.

It seems that the combination of the narrative and the mathematical space offers a rich environment for children to work in. Instead of being considered only in the mathematical space, the problem can be part-treated in the story space (Figure 7).

The management of the problem in the narrative space brings children to improve their study of the situation. Because of that, their solving and proving are more accurate. Due to their heuristic and structural functions (Bruner, 2003), stories can play a part in problem solving. The act of narration supports the student's mathematical reasoning and justification. The story enriches, with the meaning of Hersant (2010), the didactical environment: there is more possibilities to explore the empirical part of the environment thanks to the fiction brings by stories; there is a need of proof brings by the structural aspects of stories. In accordance with our theoretical framework, story building together with a problem solving activity produces an environment allowing pupils to commit themselves, to structure and to justify the followed reasoning.

CONCLUSION

Our analysis of oral and written children productions reveals that stories are a powerful asset in problem solving activity. By integrating the story into the didactical environment, we offer children a structured space to reason and argue about problematic situations. Taking charge of an explanatory possible or impossible, via story building, allows them to argue and so to conjecture and to get into a proof approach. In a more general way, all the functions of the story can be mobilized as part of problem solving. Structuring, explanation, argumentation are inherent processes for both story writing and problem solving. The possibilities of interaction between these two activities let imagine a joint development, in the pupils, of the capacities needed in the proving process.

The genesis of proof in ancient Greece: The pedagogical implications of a Husserlian reading

Andreas Moutsios-Rentzos and Panagiotis Spyrou

University of Athens, Department of Mathematics, Athens, Greece, moutsiosrent@math.uoa.gr

In this essay, we present a reading of the genesis of proof in ancient Greece through the lenses of Husserl's transcendental phenomenology. We argue that the Husserlian perspective acts as the epistemological bedrock upon which a didactical framework that fosters the students' need for proof may be built. Importantly, we posit that this framework allows for the students' developing internal need for organising the corpus of mathematical knowledge within a deductively derived structure.

Keywords: Proof, geometry, Husserl, phenomenology.

THE STUDENTS' NEED FOR PROOF

The notion of proof is at the crux of modern mathematics, constituting the backbone of the axiomatic system implied by Euclid. Mathematics educators have investigated the phenomena related to proof, considering amongst others different protagonists (including students, teachers, mathematicians), their conceptions of proof and its functions, their cognitive and affective proving products and processes (Boero, 2007; Moutsios-Rentzos & Kalozoumi-Paizi, 2014; Reid & Knipping, 2010).

Though researchers have documented various functions of proof (including verification, explanation, systemisation; Hanna, 2000), the students seem not to share these conceptions. For example, high-school students appear to consider proof as means for establishing verification and to a lesser extent for explaining and communicating (Healy & Hoyles, 2000). Moreover, mathematics undergraduates would employ mathematical proof as an exam-appropriate answer, but they may choose a 'softer' argument (example, figure etc) to convince themselves (Moutsios-Rentzos & Simpson, 2011): they produce a proof to meet the externally-set requirements of a task, but their internal need for proof seems not to necessarily be in line with a fully-fledged conception of proof. The students need a reason to produce a proof (Balacheff, 1991), which may be externally or internally referenced (Moutsios-Rentzos & Simpson, 2011).

Zaslavsky, Nickerson, Stylianides, Kidron and Winicki-Landman (2012) discussed the mathematical and pedagogical aspects about the need for proof, differentiating internal needs amongst: *certainty* (verification of the truth of a statement), *causality* (why a statement is true), *computation* (quantification of definitions, properties or relationships through algebraic symbolism), *communication* (formulation and formalisation in conveying ideas), *structure* (logical re-organisation of knowledge).

Everyday activities utilising the notion of inquiry are suggested as possible means for fostering the students' developing these aspects of internal need for proof. Though existing didactical frameworks may be employed to help the students to develop internal need for proof, we argue that a Husserlian reading of the genesis of proof in ancient Greece may provide the epistemological backbone of a didactical framework that would foster the students' developing all aspects of internal need for proof, notably 'structure'. The realistic mathematics education research paradigm (Streefland, 1991) appears to be a suitable framework, since a problematic situation that is perceived as 'real' for the students is actively re-organised by the students with the teachers' guidance. The re-organisation of the situation results in the 're-invention' of the required mathematical tools that, constructed as a response to a 'real' need, are meaningful for the students. The process of mathematisation of the 'real' situation allows the incorporation of the constructed mathematical ideas within the existing mathematical world, but it does not explicitly address 'structure'. The new mathematical constructs need to derive from existing mathematical knowledge, but this necessarily implies (at best) only a local mathematical structure and certainly there is no 'real' need for attempting to re-organise the re-invented mathematical tools within a global mathematical structure (such as an axiomatic system). Additional requirements have to be activated for a student to develop the internal need for the logical re-organisation of the re-invented mathematical tools. From a different perspective, Radford (2003) emphasised the sociocultural aspects of mathematical thinking, suggesting a semiotic-cultural approach to highlight the subjective nature of the meaning constructed through semiotic activities. Meaning is constructed by subjects within specific sociocultural context and, thus, proof is meaningful for a student who experiences a specific sociocultural reality. Though we acknowledge the importance of the socio-semiotic dimension, Radford's research was not focused on the students' development of an internal need for proof.

Overall, in this essay we address the fundamental question: *What are the didactical principles constituting an epistemologically coherent framework that may foster the students' developing a fully-fledged need for proof?*

THE GENESIS OF PROOF IN ANCIENT GREECE

Katz (2009) notes that the notion of proof appeared in ancient Greece. Many of the mathematical results were already known, in the same way that something is known in the sensory-perceived world: as rules that held true for all the till then considered cases. With Greek mathematics things changed, including "objects whose existence cannot be visualised and which cannot be physically realised" (Grabiner, 2012, p. 152). Moreover, the mathematical ideas were re-organised to form a primitive proof-based version of an axiomatic system. A multiplicity of factors formed a complexity within which proof appeared to be 'natural'. But which were those factors?

The sociocultural context of the ancient Greek city (*polis*) appears to be the crucial factor that enabled the change of perspective about the issues that proof addresses in mathematics. Polis was the result of a transformation from monarchy to democracy. Employing the case of ancient Athens as an exemplar, we find that the legislation of Solon and crucially of Cleisthenes changed the social structure of Athens, resulting to a radically transformed lived social reality. The Athenians were administratively organised in ten geographical regions that purposefully did not correspond to the traditional *phyla* ('families'), in order to shuffle the traditional, blood-centred, immediate social circle of the individual. Thus, the new immediate social family was based not only on blood relations, but also on a *purposefully arbitrary* geographical proximity. Moreover, each of the ten new regions was the ruling region for a tenth of the solar year. This meant that each ruling month was not a lunar month. The time that a region was in power was *not* measured with reference to nature, but according to a *purposefully arbitrary* chosen fraction of the solar year. 'Arbitrary' is emphasised, because the number of the new regions could be anything that would ensure the *un-settlement* of the old structure. Furthermore, Solon's changes produced a hierarchy of citizens, according to specific analogies forming a harmony (2/1, 3/2, 4/3). Cleisthenes' reform reduced all these relationships to a single analogy, the simplest possible: 1/1. All the citizens were equal with respect to access and power within the polis, regardless of their profession, family name or wealth.

Within the polis all the important aspects of life assumed a public character. The 'significant' private obtains its 'significant' status by becoming object of the community. For example, murder was not a private matter to be resolved amongst individuals. It is a public matter open to the actions of the community which focus on the 'objective', verbally described characteristics of the *situation*, rather than on *who* was involved in the incident. In order for 'justice' to be reached, the community had to be convinced of what happened, to construct a shared logos. Note that *logos* in Greek has a multiplicity of meanings including oral speech, reasoning and ratio (and relationship in general). The common logos emerged as the ruling power of the city, forming a differentiated from ethics law; the ethically acceptable may or may not be lawful. Justice became a matter of a social, non-metaphysical, construction. The citizens of the polis were characterised as such by actively participating in the common matters. The Athenian *idiot* ('private') was the person who either lacked the reasoning skills or chose not to contribute in the public affairs. The citizen was a 'subject' to the logos, to the verbal communication and co-construction of the common, argued meaning. Language and the arguments employed were at the crux of this process. Through language the private meanings were communicated and through convergences and divergences the shared public meaning emerged.

Cleisthenes' changes towards the equality of the citizens within the public affairs allowed the transcendental notion of power to obtain an anthropological character: the numerical majority was right, true and responsible and the minority had to accept it. The ruling power was not divinely-given, nor inherited, but lied within the *countable community*. The shared logos, the thesis voted by the citizens was within the reach of every citizen-subject, as long as it was accepted as such by the majority. This conceptual lift from the subjectively described to the objectively defined by a simple number, by a numerical relationship, allowed for the city itself to obtain a transcendental aspect, to exist regardless of who were its citizens. Its infrastructure transcended the people who represented it. In this way, the polis achieved its supertemporal continuity. Thus, the subject was at the same time unique and the same, one and many, important and insignificant. Heraclitus stressed that "although *logos* is common to all, most people live as if they had a wisdom of their own" and that "having listened not to me but to the logos it is wise to agree that one is all". It should be clarified that Heraclitus wording for 'agree' is *homo-logo* (common logos), indicating that agreement is a result of a shared logos. Hence, common logos implies all private understandings and reasonings are in agreement with (*homo-logia*), in a relationship with, the public *logos*. Notice that the shared logos does not imply the disappearing of personal identity (Vernant, 1983), as the self becomes a multiplicity of higher mental internalised social relationships. Vygotsky (1978) notes that the external social processes are closely linked with the internal psychological processes so that in "their own private sphere, human beings retain the functions of social interaction" (p. 164). Thus, the argument became a dominant social instrument.

Within this sociocultural framework, the requirement of producing a proof for a mathematical statement seemed to naturally fit in. The mathematical community as part of the general community requires arguments that cannot be logically disputed. Such an argument could not be based on perception, which was philosophically treated at the time as false, changeable or unreliable. Nor could it be based on authority or affective linguistic tricks. The Sophists, the Eleates (notably Zeno) and the philosophy of Plato and Aristotle crucially determined Euclid's decision to organise old and new mathematical ideas in a deductive structure, within which each proposition derives from already proved or accepted as true ideas.

Moreover, within a social framework that the public is appreciated and the private is frowned upon, mathematical ideas had to be open to the community and not to be only for a certain social cast (the clergy or other). This required resorting to commonly lived experiences, which were inescapably bodily experiences masked as 'semi-abstract' ideas. This is reflected in the 'pseudo-axiomatic' character of Euclid's elements. The definitions, the common ideas, the axioms derived from the shared lived perceptual reality, which ensures the wider acceptance of the logos that draws upon such a structure, but clearly limits the breadth and depth of the mathematical structure. Nevertheless, Euclid's organisation enabled the synthesis of seemingly unrelated ideas, deriving from the same underlying ideas and reasoning (for example, the study of incommensurable magnitudes and the irrational numbers). Though Szabó (1978) claims that the notion of deductive proof did not meet any practical needs, we argue that it met the lived needs within the broader ancient Greek sociocultural context when transposed in the abstract-like Euclidean world. In this conceptual extension of the perceived reality, the logos and the argument are the only means for establishing the truth of a proposition.

Overall, we agree with Vernant (1975) who argued that the formation of the *polis* was the decisive event that allowed the shared logos to become the backbone of the social structure. We briefly discussed some of the factors that may have constituted this event: the *shared logos*; a *purposefully arbitrary administrative structure*; the *1/1 citizen relationship*; the *countable decisive power*; the *convincing the majority verbal argument*; the *reign of the public over the private*; the *quantification of power*; the *argument based on commonly experienced notions and ideas*; the inescapable *reign of the deductive over the inductive within an axiomatic-like system*. All these elements are some of the crucial events that posed the need for a deductive proof, rather than settling for an inductive or other argument.

ELEMENTS OF HUSSERL'S PHENOMENOLOGY

Husserl's phenomenology may be summarised in the phrase "back to 'the things themselves'" (Husserl, 2001, p. 168), implying the attempt to 'unearth' the sedimented relationships and the decisive factors, in order to mobilise the mental processes that constitute an ideality. Husserl's idealities crucially differ from the platonic ideas in that they are intentionally subjectively *constructed once within history*. Once objectified, they become atemporal, in the sense that every subsequent subjective knowing requires only the *reactivation* of this objectification. Language (oral or written) constitutes the means for the objectification of the subjective experiences, allowing their subsequent transcendental existence. The reactivation of objectification requires the subject to develop suitable intentionality, suitable "conscious relationship [...] to an object", (Sokolowski, 2000, p. 8). Such intentionality requires the suspension of the subjects' natural attitude, their "straightforward involvement of things and the world" (Audi, 1999, p. 405), implying that the objectification is not merely a psychological process, as it explicitly incorporates the relationship between the subject and the community.

Husserl contrasts the intersubjective experience of the communicated shared meaning with the transcendental subjectivity in which there is an awareness of a phenomenon that transcends the subjective perceptual experience: "a possible communicative subjectivity [...] through possible intersubjective acts of consciousness, it encloses together into a possible allness a multiplicity of individual transcendental subjects" (Husserl, 1974, p. 31). In order for such processes to be activated, Husserl's phenomenological reduction (*epoché*) is required. By bracketing out, suspending, natural attitude and by investigating the sedimented intentional history of the object, the phenomenological attitude is activated in order for the subject to "seek for its "constitutive origins" and its "intentional genesis" (Klein, 1940, p. 150). During epoché, the subjects' thinking is characterised by the subjects' intentionality and immanence to bring to the surface the sedimented already constructed and existing within the community knowledge.

TOWARDS A DIDACTICAL FRAMEWORK

In what way can the aforementioned genesis of proof be read through a Husserlian perspective in order to inform a didactical framework that fosters a fully-fledged need for proof? Though 'replicating' history in the classroom is clearly not possible, an ancient idea "through an adaptive didactic work, may probably be redesigned and made compatible with modern curricula in the context of the elaboration of teaching sequences" (Radford, 1997, p. 32). We shall argue that the Husserlian perspective may help in determining the principles of the 'adaptive' work required.

In order to identify the ways that Husserl's views may inform a didactical framework, we should first consider the following: What is the students' natural attitude towards mathematics and learning in general? What is the role of language? Of technology? What is the perceived by the students' natural form of argumentation in mathematics? In everyday life? We do not claim that there are universally applicable answers to these questions. Each country, city, school unit, class have their special characteristics constituting a unique system (Moutsios-Rentzos, Kalavasis, & Sofos, 2013). Nevertheless, we shall describe some elements that we think characterise the lived reality in Greece. With respect to the students' natural attitude to mathematics, it appears that many students' consider mathematics to be beyond their lived reality, to be hard, boring or unnecessary (Brown, Brown, & Bibby, 2008). Healy (1999) argues that the current technologies prevent the students' minds from developing deductive reasoning, while it has a negative effect on their "ability to remain actively focussed on a task" (p. 201). Though such claims may sound too strong, the current sociocultural context is fast, based on inductive arguments and decisions, while the virtual social networking sites produce a multiplicity of realities within which the students act and interact (Moutsios-Rentzos et al., 2013). The role of language in this complex context appears to have radically transformed. The need for fast, usually factual, communication developed shorter versions of words, sentences, meanings. Such abbreviated forms hardly suffice when discussing mathematical objects. Thus, the verbal, logically complete argument identified as the main vehicle for establishing the need for proof appears to be in stark contrast with the contemporary linguistic habits. A further consequence of the steep rate of change is that even a local 'logos' or connotations may suffice for the arguer to accomplish his/her purpose. The shared memory is short and the lived present is even shorter; there is no real need for immanence. This fragmented, disjunctive, sociotemporarily fragile common 'logos' and practices do not bear any resemblance to the common logos experienced in ancient Athens. Moreover, the contemporary way of living is characterised by connectedness, by the existence of non-linear networks. The seemingly simplistic linear, deductive argument makes sense to be considered by the students as incompatible or even useless in such a connected, seemingly non-hierarchical reality, favouring other forms of argumentation (including inductive or abductive). Consequently, the shared 'logos' of the contemporary sociocultural students' reality, their natural attitude, seems to be far from the phenomenological attitude that lead to the genesis of proof. Which pedagogies may facilitate the students' experiencing the reactivation of the need for proof? We argue that an appropriate *epoché* should be cultivated to suspend the students' 'natural attitude' (for example, not to prove something obvious), allowing for the students' phenomenological attitude to reactivate their need for proof.

Drawing upon these and upon the realistic mathematics research paradigm (the epistemological bedrock of which is close to a Husserlian perspective), we provide a sketch of a didactical framework (with examples deriving from Moutsios-Rentzos, Spyrou, & Peteinara, 2014). First, the students should be familiar with the practical, everyday uses of mathematical ideas. Mathematics should be 'real' for the students, it should be 'discerned' in the lived world, as it can be practical, useful. This may require the teachers' drawing the students' attention to everyday situations that incorporate sedimented mathematical ideas. For this purpose, the starting point may be a problematic 'real' situation for the students that requires the re-invention of mathematical tools to be resolved. For example, the construction of a table requires a perpendicularity identification physical tool and the construction of such a tool may facilitate the students' re-invention of a mathematical tool (e.g. the Pythagorean Theorem). It should be stressed that the materials employed in the students' investigations are at the crux of the proposed framework, since they constitute the physical shared reference of each communication (see Moutsios-Rentzos, in press).

In line with our reading of the genesis of proof, the mathematical ideas should derive from some common (at least in the beginning) to human principles. For this purpose, the common to the human body sensory experiences of the world may be the bedrock upon which the shared logos may be professed. Though perceptually born, those common principles can, by the necessity of obtaining a shared meaning, be potentially stripped of their subjective nature. For example, the human body is evolutionally designed to identify verticality, which enables us to survive in a perceived as perpendicular to verticality (horizontal) world. The sensory experience of perpendicularity –in order to be potentially infinitely communicated– is required to be linguistically described with appropriate signs. The aforementioned perpendicularity identification physical tool may be initially constructed with reference to an independent from human activity, naturally existing, perpendicularity (e.g., the angle between the surface of the liquid and the string of the 'plumb-bob').

Furthermore, appropriate interventions may facilitate the students' conceptual shift in the semiotic registries employed in their *communicating* their embodied experiences. For this purpose, it is crucial for the students to realise the need for employing more symbolic and abstract semiotic registries in order to successfully resolve the situation *and* to communicate (and to convince) their argument about the validity of their solution to their classmates, to their teacher, to whomever whenever may face such a situation. For example, the students may construct a wooden triangular frame that visually fits the natural perpendicularity, but the teacher's guidance towards revealing what are the properties that the frame has that renders such a fit feasible may foster the employment of mathematical symbolism. For this purpose, the students may be guided to realise the constraints of the physical material in conveying the 'general' (rule, case, etc.) to a large (potentially infinite) audience.

Mathematical symbolism may help in realising that the mathematical ideas logico-deductively derive (through mathematisation processes) from the communicated, shared experiences, but they no longer (need to) exist within the experience. They (may) have a pragmatic reference, but only ideal essence. For example, the triangle the lengths of the sides of which are 3, 4 and 5 *units* is right-angled regardless of the physical magnitude of the unit, since $5^2 = 3^2 + 4^2$ holds true under the usual algebra.

Establishing a common linguistic expression (homo-logia) of the shared sedimented axiomatic system of some common ideal, yet anthropological, principles is a crucial step in transforming this system to an object upon which mental processes may be acted. In the proposed didactical framework, the students realise that the backbone of the axiomatic system derives from the physical constraints of the human body and as such cannot be absolute or 'given'. Hence, once the axiomatic framework has been objectified, it can itself be subjected to metacognitive investigations. For example, "What if ... we perceptually experience the surface we walk as the surface of a sphere?". Or, "What if ... the $5^2 = 3^2 + 4^2$ is not true?". Our reading of Husserl's phenomenology allows the students' questioning the very fabric upon which the situation is perceived, because the central role of language and communication allows the learners to realise (re-reveal) that the mathematics they experience everyday are only an instance of the infinite potential mathematics the mind can create. Within this potential, the students may come to realise that the mind games with the constituting common principles can be played only with conceptual tools, with reason (for example, algebraic geometry). The need for proof in these strange (to perception) worlds appear to be natural, since proof is the only means for evaluating the validity of a statement. At the same time, the lack of a means for establishing some perceptually derived intuition of the new structure facilitates the students' developing the need for proof as the gatekeeper of the structure itself.

Overall, we argue that the Husserlian reading of the genesis of proof in ancient Greece helped in identifying pedagogical principles – *a 'real'; problematic situation, embodied experiences, pre-scientific materials, language (oral or written), communication (argumentation) to self and others through different semiotic registries* – that form an epistemologically coherent didactical framework. Within this framework, the "divergences of the different levels of communication and experience are constantly re-negotiated in order to converge to a shared logos of condensed meanings and experiences" (Moutsios-Rentzos, in press), thus fostering the students' developing a fully-fledged need for proof (including 'structure').

Discriminating proof abilities of secondary school students with different mathematical talent

Juan Antonio Moya, Angel Gutiérrez and Adela Jaime

Universidad de Valencia, Departamento de Didáctica de la Matemática, Valencia, Spain,
juan.moya@uv.es, angel.gutierrez@uv.es, adela.jaime@uv.es

A characteristic differentiating mathematically talented students from average students is their ability to solve problems, in particular proof problems. Many publications analyzed mathematically talented students' ways to solve problems, but there is a lack of data about the ways those students learn to make proofs. We present results from a study were we posed some geometry proof problems to secondary school students having different degrees of mathematical ability. We have classified their answers into categories of proofs. Our results suggest that the ability to make proofs of the mathematically talented secondary school students is better than that of the average students in their grade and also that mathematically talented students could be ready to begin learning to make deductive proofs even at secondary school grade 1.

Keywords: Mathematically talented and gifted students, learning proof, secondary school, geometry education.

INTRODUCTION

During last decades there is being an increasing number of publications informing on research on several components of teaching and learning proof (Hanna & de Villiers, 2012; Reid & Knipping, 2010; Harel & Sowder, 2007; Mariotti, 2006). Another important area of research in mathematics education is related to mathematically talented students (MT students hereafter), including, in particular, mathematically gifted students. The literature pays attention to their identification and to several aspects of those students' learning, reasoning, problem solving styles, behaviour, affectivity, etc. (Greenes, 1981; Leikin, 2010; Sriraman, 2008). A frequent methodology to identify MT students' characteristics is to compare the ways they and average students solve the same tasks (Heinze, 2005).

We are interested in the link between both research programs: The ways MT secondary school students learn to make mathematical proofs. There is a general agreement that MT students' learning processes are different from their age peers' ones (Sriraman, 2004). To better understand MT students and to design adequate ways to teach them proof, teachers and researchers work on identifying those differences. In particular, two research questions still needing an answer are:

Are secondary school MT students different from their classmates when solving geometry proof problems?

Are secondary school MT students in various school grades different when solving geometry proof problems?

To get information on these questions, we carried out a research experiment aimed to analyze proofs produced by secondary school students and to find possible differences among students with different levels of mathematical ability or in different school grades. We posed several geometry proof problems to a sample of 1st and 4th grade students and we classified their answers according to the categories of proofs in Marrades & Gutiérrez (2000). Due to the limited number of MT students in our experiment, we do not pretend to get general conclusions, but to bring data from this case study that might point at some differences.

LITERATURE REVIEW

Most of the literature on teaching and learning proof pays attention to whole class groups or, when they are based on case studies, to ordinary students. On the other side, many publications on MT or gifted students pay attention to their ways to solve problems, in particular proof problems, but they do not inform on characteristics of proofs produced by MT students nor on MT students' progress in learning to prove.

Leikin (2010) reflects on some aspects of classes for groups of MT students. She suggests that classes must be challenging for the students and a way to get it is by means of problem solving. Then, Leikin analyzes different types of challenging problem solving tasks, namely inquiry-based, multiple-solution, and proof tasks. The paper also presents an example of a lesson for 9th grade MT students, including examples of students solving proof problems, but Leikin's analysis does not enter into the characteristics of the proofs produced.

Koichu & Berman (2005) present a study based on MT students trained to solve olympiad-style problems. They analyze students' preferences for algebraic or geometric ways to solve geometry problems. Their conclusions show that MT students choose or value proofs taking into consideration effectiveness and elegance, and also that, when students are deciding how to solve problems, they may experience a conflict due to their preference for effectiveness or for elegance.

Housman & Porter (2003) analyzed the types of proof schemes (Harel & Sowder, 1998) produced by undergraduate mathematics majors who had received none, one or two proof-oriented courses, and had earned only A's and B's in their university mathematics subjects. The authors considered that these students were above-average mathematically talented. The students were presented 7 conjectures, and they were asked to state whether the conjectures are true or false and write the proof. Some conjectures are false, so one would expect empirical proofs (show a counter-example) for them. Housman and Porter's results demonstrate that we should expect a variety of types of proofs in any group of MT students, but they did not inform on students' processes to learn to prove nor included average students solving the same tasks.

Sriraman (2003) compared average and MT 9th grade students' solutions to non-routine combinatorial problems. His results show that the MT students were able to get generalized solutions, while the average students used particular cases. Although Sriraman's problems are not proof problems, the ability of his MT students to generalize is an indicator that they could give deductive answers to proof problems.

Sriraman (2004) analyzed the answers to a proof problem on triangles by 9th grade gifted students with no previous contact with proof. Students' processes of solution began with a checking of examples; they concluded that the conjecture is true only for equilateral triangles; then the students looked for counter-examples for non-equilateral triangles and, finally, they tried to prove the conjecture for the equilateral triangle. Sriraman did not give information about the types of proof produced by the students, but it seems that their proofs were empirical although near to deductive.

All the authors referenced in this section have used proof problems as part of their experiments, but none of them has analyzed students' processes of learning to make proofs. Only Housman & Porter (2003) paid attention to the types of proofs produced by MT students, although they did not compare MT and average students.

THEORETICAL FRAMEWORK

The literature shows a diversity of definitions of (mathematically) able, talented or gifted students, where some authors consider the terms as equivalent while others consider them as different (Leung, 1994; Sriraman, 2004), but entering into the analysis of different definitions is not our objective. For us, MT students are those who, when doing mathematics, show certain traits of mathematical ability higher or more developed than other students with the same age, experience, or school grade. Behaviour traits of MT students have been identified, among others, by Freiman (2006), Greenes (1981), Krutetskii (1976) and Miller (1990). In this context, we consider mathematically gifted students as an extreme case of MT students (that, in many countries, got more than 130 points in an IQ test).

In the context of secondary school mathematics, a mathematics education research line focuses on students' process of learning to prove, including both the ability to make a proof and the understanding of the characteristics of mathematical proofs. There is, among teachers and researchers, a diversity of positions respect to the concept of mathematical proof (Cabassut et al., 2012). For some of them, the term proof refers to the logic-formal proofs, and they use terms like justification, argument or explanation to refer to non-formal ways to warrant the truthfulness of a mathematical conjecture. Others define a proof as any mathematical argument created to convince somebody (oneself or an interlocutor) of the truthfulness of a conjecture. We agree with the later, since it has proved to be very fruitful to consider as proofs both authoritarian or ritual arguments, empirical arguments, informal deductive arguments, and logic-formal arguments (Harel & Sowder, 2007). In this framework, the process of learning to prove can be seen as a continuous progress, along the years, starting with authoritarian proofs and ending with logic-formal proofs.

Marrades & Gutiérrez (2000) presented a structure of categories of empirical and deductive proofs. We have used a variation of that structure (Figure 1) to organize the proofs made by our students. This consists of: i) Remove the "intellectual" category, since it really can only be matched to generic example proofs, so it is unnecessary. ii) Add the category of "informal deductive proofs" to discriminate deductive proofs lacking the formal style of language from formal proofs; those proofs are typical of students beginning to understand the need of deductive proofs (3rd Van Hiele level). We also add a "No answer" category, addressed to those outcomes that were either blank or providing no information at all about students' reasoning.

The categories cannot be linearly ordered according to their quality, but there is a perception that empirical categories are more elaborated from top (failed) to bottom (generic example). The same can be said for deductive categories of proofs.

METHODOLOGY

The research experiment took place in a secondary school in a big city in Spain. The students were a convenience sample consisting on several class groups of pupils of a mathematics teacher willing to collaborate. Table 1 shows the number of students in each group. We are reporting here results from students in grades 1 (aged 12–13) and 4 (aged 15–16). A part of the students participating in the experiment were in average class groups (without MT students), while the others were MT students attending a workshop devoted, mainly, to problem solving. The students participating in the experiment had not worked before on the stated problems nor on other similar ones.

To inform on the two questions stated in the introduction, we present data to compare the answers i) by grade 1 average and MT students and ii) by grade 1 and grade 4 MT students. We do not use here data from the grade 4 average students.

We selected several paper-and-pencil geometry proof problems to pose two problems to each group of students participating in the experiment. We did not use the term "prove" in the statements to avoid the possibility of a misunderstanding by some students that could not be habituated to it. To select the problems we had to take into account i) that the students should know the geometric contents necessary to solve them

	Grade 1	Grade 4
Average students	13	41
MT students	3	4

Table 1: Distribution of the students in the sample

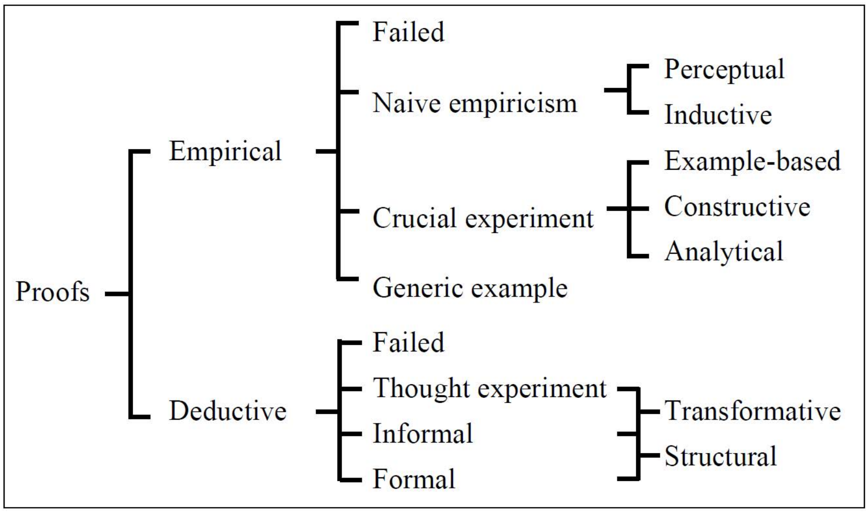

Figure 1: Structure of categories of mathematical proofs

but they had not solved the problems previously, and ii) that the topics of the problems should be related to the one being studied by the average groups at the time of the administration. The second condition to be fulfilled impeded us to pose the same problems to all students. Our aim is to identify the types of proofs produced by the students so data may suggest differences among average and MT students in the same grade or among MT students in different grades.

The problems were posed to each group of students in an ordinary class session of about 50 minutes. They worked alone and the teacher answered questions about the meaning of the statements but he did not give clues for the solution. Our data are the students' written answers.

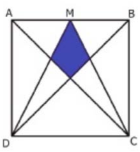
In grade 1, the two problems posed both to the average and the MT groups where:

1) How many diagonals does an n-sided polygon have? Justify your answer.

2) How much is the sum of the internal angles of an *n*-sided polygon? Justify your answer.

The two problems posed to the grade 4 MT group were problem 1 and:

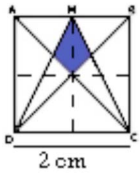
3) In square *ABCD* (figure on the right), *M* is the midpoint of side *AB*. We draw the two diagonals and segments *CM* and *DM*. Which fraction of the total area is the area of the shaded shape? Justify your answer.



To facilitate the answers to less able students and to students who did not come up with a way to solve a problem, each problem had two parts, labelled A and B. Part A was the statements given above. Part B included a clue aimed to help students to start solving the problem or to find a way to the answer. Problem 1B was:

1B) How many diagonals can be drawn from a vertex of a pentagon? How many diagonals can be drawn from a vertex of an *n*-sided polygon? How many diagonals does an *n*-sided polygon have? Justify your answer.

Problem 2B asked for the sum of the internal angles of a quadrilateral, a pentagon and an n-sided polygon. Problem 3B had the same statement as problem 3A but the figure was the one on the right.



To prevent the possibility that students could answer part A of a problem after having read the statement of part B, students were given part B of the problems only after they had completed part A and had given it back to the teacher.

RESULTS

We have classified students' answers according to the categories of proofs displayed in Figure 1. In the following paragraphs, we include information about

	No answer		Empir. failed		Naive empiricism				Crucial experiment						Generic ex.

the results of the experiment respect to the question stated in the introduction.

Do average and MT students in the same grade make different proofs?

Table 2 presents the types of proofs made by the grade 1 students in the sample.

All 12 possible MT students' answers (100%) were meaningful proofs. Respect to the categories of proofs produced, 5 out of 12 possible MT students' proofs (41,7% of the answers) were basic empirical proofs (naive empiricism perceptual) and 7 proofs (58,3%) were in the most elaborated types of empirical proofs and in the basic type of deductive proofs (2 crucial experiment analytic, 3 generic example, and 2 thought experiment structural proofs).

On the other hand, 20 out of 52 possible average students' answers (38,5%) were meaningful proofs. All these proofs were in the different empirical types, with more presence in the basic empirical categories (70% of the answers; 7 naive empiricism and 7 crucial experiment example-based proofs) than in the more elaborated categories (30%; 1 crucial experiment constructive, 1 crucial experiment analytic, and 4 generic example proofs). The average students did not produce any deductive proof.

Do MT students in grade 1 and grade 4 make different proofs?

Both MT students in grades 1 and 4 solved problem 1, so we can give an answer to this question based on their proofs in this problem. Table 3 presents the types of proofs made in problem 1 by the MT students in grades 1 and 4.

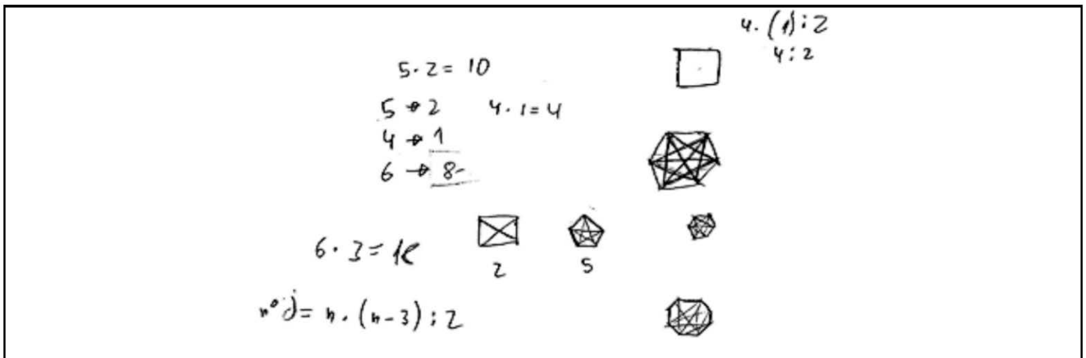
In problem 1A, all MT students in grade 1 (100%) and 3 MT students in grade 4 (75%) made empirical proofs. In problem 1B, 2 MT students in grade 1 (67%) and 2 MT students in grade 4 (50%) made empirical proofs. All but one deductive proofs made were the type thought experiment structural and one MT student in grade 4 made an informal structural proof for problem 1B. Figure 2 shows the answer of this student to problem 1A. He started by checking some specific polygons (4, 5, 6, 8 sides); this let him identify a relationship that he succeeded in expressing as a (correct) formula, although he was not able to prove its truthfulness. This incomplete proof has the characteristics of a thought experiment structural, since the student uses some examples to get an abstract relationship.

This student demonstrates the usefulness of parts A and B of the problems, since the help in problem 1B allowed him to write the deductive proof that he was not able to imagine when he was working in problem 1A.

This complete proof has the characteristics of a deductive informal structural proof, since the student does not use examples to write the deductive proof of the formula.

CONCLUSIONS

Related to the first research question (about differences in proof abilities among MT and average students in the same grade), our data show a clear difference in the ability to write mathematical proofs in favour of secondary school grade 1 MT students (100% of their answers) respect to their average peers (38,5% of their answers). Although the number of MT students does not allow a valid statistical comparison with the average students, the data from our experiment suggest a



You have to multiply the number of vertices by itself minus 3 *n·(n-3)* *because*

Figure 2: Answer by a grade 4 MT student to problem 1A

1. [From each vertex] *ever can be drawn 3* [diagonals] *less that the number* [of sides] *of the polygon because it is not possible to join* [a vertex] *with itself nor with the two* [vertices] *next to it.*
In the previous page I wrote the formula n·(n-3):2 because you multiply the number of vertices times the [the number of] *other non-consecutive vertices, and then you divide by* [2] *because there are repeated diagonals.*

Figure 3: Answer by the same grade 4 MT student to problem 1B

clear difference in the capabilities of MT and average students to produce mathematical proofs, in favour of the former.

It is not surprising that very few deductive proofs were produced by the 1st graders, nor that all of them were in the basic deductive category (thought experiment). The deductive proofs were made by one MT student in part B of the problems. This suggests that it would be worth study more in detail whether, as early as in grade 1, MT students could be introduced into deductive reasoning and, with some help from the teacher, some of them could write simple deductive proofs.

Related to the second research question (about differences in proof abilities among MT students in several grades), the data show that the empirical proofs made by the MT 4th graders were better than those made by the MT 1st graders, since 4th graders did not made naive empiricism proofs and most of their empirical proofs were in the types crucial experiment analytic and generic example.

MT 4th graders made more deductive proofs than MT 1st graders, and the proofs made by MT students in grade 4 were in the same type or better than those made by MT grade 1 students. These data suggest that secondary school MT students are able to advance in the learning of mathematical proof when they are allowed to gain experience in solving proof problems and they have guidance by their teachers. In our case, the ordinary classes provided such experience and, mainly, the workshop they were attending.

As a final summary, we can conclude that MT secondary school students seem to be more capable of producing mathematical proofs (either empirical or deductive) than the average students in the same grades, and also that MT students are able to begin learning mathematical proofs from grade 1, and they can learn to express their justifications in an organized way, progressing along the grades in their ability to make more elaborated proofs, even deductive proofs.

ACKNOWLEDGEMENT

The results reported are part of the research project *Analysis of learning processes by primary and middle school mathematically gifted students in contexts of rich mathematical activities*, funded by the R+D+i Program of the Spanish Ministry of Economy and Competitivity (EDU2012-37259).

Proof evaluation tasks as tools for teaching?

Kirsten Pfeiffer and Rachel Quinlan

National University of Ireland, Galway, Ireland, kirsten.pfeiffer@nuigalway.ie

This article reports on our experience, arising from an earlier research study, of incorporating proof evaluation tasks into a university mathematics curriculum. In particular, we discuss a task in which students were asked to evaluate and rank five different proposed proofs of a statement from elementary linear algebra. The students' responses to this task prompted rich learning opportunities on the nature and functions of mathematical proofs, as well as revealing some interesting features of their thinking. We argue that proof evaluation tasks can afford rich learning opportunities as well as enabling novice students to participate in authentic mathematical practice.

Keywords: Proof, proof evaluation, curriculum.

BACKGROUND

A CERME 7 article by Kirsten Pfeiffer (2011a) presents a conceptual schema that provides a frame of reference for consideration of what needs attention in a proof evaluation exercise. In accordance with Hemmi (2008), Pfeiffer regards proof and proofs as *artefacts* of mathematical practice. She adapts ideas of Hilpinen (2004) on evaluation of artefacts in general and specializes them to the case of mathematical proofs. In this context an *artefact* is a (physical or conceptual) object that is designed and made by an author (or authors) in order to fulfil a specific purpose (or purposes). Thus the quality of an artefact can only be judged in terms of its success at achieving its purpose(s). In the case of a proof of a mathematical statement, a primary and non-negotiable purpose is that the argument establishes the truth of the statement. Other purposes might include provision of a satisfying explanation, enhancing understanding of the concepts involved, and so on. Motivated by Hilpinen, Pfeiffer suggests that a proof can be evaluated in relating the three features of an artefact, its *intended character*, its *actual character*, and its *purposes*. Therefore evaluating a proposed proof might involve three considerations: that the author's intention or "proof design" is appropriately matched to the purpose of the proof, that the author's intention is appropriately realized in the actual written proof, and that the written proof appropriately achieves its purpose. The point of Pfeiffer's schema is to provide some context and terminology for discussion of what proof evaluation entails and for discussion of specific evaluations of particular proofs. It is intended not as a rigid framework but as a helpful theoretical construction.

The outcomes of Pfeiffer's research study (Pfeiffer, 2011b) included strong indications that proof evaluation tasks, including those involving more than one "proof" of the same statement, have the potential to prompt students to consider the mechanism and fitness-for-purpose of a proof in a serious way. Some students in the study even recognised a change in their own thinking stimulated by the task of comparing different proofs of the same statement. These observations encouraged us to include proof evaluation tasks in the curriculum alongside learning activities of other types.

Over the last decade several investigations into students' performances when validating or reading mathematical proofs have shown that students have difficulties in determining whether a proof is valid (Selden & Selden, 2003; Alcock & Weber 2005). Other studies describe the behaviour of experienced mathematicians when validating proofs (Weber & Mejia-Ramos, 2011) or the differences between novice and experienced readers (Inglis & Alcock, 2013). Techniques or teaching methods to improve students' proof comprehension have been suggested, for example *unpacking proofs* or *proof frameworks* (Selden & Selden, 1995), inclusion of instructional sequences in mathematics courses (Stylianides & Stylianides, 2008), *e-proofs* (Alcock & Wilkinson, 2011) or *self-explanation* (Hodds, Alcock, & Inglis, 2014). We consider *proof evaluation exercises* as another possible teaching practice to accomplish proof reading skills. In our experiences proof validation activities provide a rich teaching and learning tool provoking fruitful discussions and ultimately making a wide range of features and purposes of mathematical proof *visible* to learners. We aim to test the efficiency of proof evaluation exercises incorporated into a University level mathematics course and also to prepare resources for use by teachers.

In this paper we report on one particular proof evaluation exercise performed in a linear algebra course for first year students run by the second author of this article, who is a research mathematician and a lecturer in a university mathematics department. We will show that the students' responses to proposed proofs potentially stimulate a considerable variety of themes to discuss in a teaching/learning environment. As students have engaged with the relevant mathematical context and the suggested proofs in advance, and as they are encouraged to discuss their own feedback rather than experts' proofs and evaluations, students are inclined to participate actively and appreciate these discussions. We will also report on our experiences with the construction of suitable partly flawed 'proofs' and show how Pfeiffer's schema is useful to assure opportunities to highlight various aspects of proof.

EXAMPLE OF A PROOF EVALUATION EXERCISE

The task described below was included in the first written homework assignment in an introductory course on Linear Algebra for first year students. The students were familiar with the concept of a linear transformation of R^2 as a function that respects addition and multiplication by scalars, and they were familiar with the matrix representation of a linear transformation and with the procedure of using matrix-vector multiplication to evaluate a transformation at a particular point.

The proof evaluation task

Students were presented with the following text.

> Alison, Bob, Charlie, Deirdre and Ed are thinking about proving the following statement.
>
> *If the function T:$R^2 \rightarrow R^2$ is a linear transformation, then T fixes the origin, i.e. $T(0,0)=(0,0)$.*
>
> **Alison's Proof**
> Suppose that $T(1,1)=(a,b)$. Then

$T[(1,1)+(0,0)]=T(1+0,1+0)=T(1,1)=(a,b)$.

But on the other hand since T respects addition

$T[(1,1)+(0,0)]=T(1,1)+T(0,0)=(a,b)+T(0,0)=(a,b)$ from above.

So $T(0,0)=(a,b)-(a,b)=(0,0)$.

Bob's Proof
We know that for any element u of R^2 and for any real number k we have $T(ku)=kT(u)$.

Then applying T to $(0,0)$ and multiplying the result by any real number k must give the same result as multiplying $(0,0)$ by k first and then applying T. But multiplying $(0,0)$ by k always results in $(0,0)$ no matter what the value of k is. So it must be that the image under T of $(0,0)$ is a point in R^2 which does not change when it is multiplied by a scalar. The only such point is $(0,0)$. So it must be that $T(0,0)=(0,0)$.

Charlie's Proof
Think of T as the function that moves every point one unit to the right. So T moves the point $(0,0)$ to the point $(1,0)$. Then T is a linear transformation but T does not fix the origin. This example proves that the statement is *not* true.

Deirdre's Proof
Suppose that (a,b) is a point in R^2 for which $T(a,b)=(0,0)$. Then

$T[2(a,b)]=T(2a,2b)=2T(a,b)=2(0,0)=(0,0)$.

Thus $T(2a,2b)=T(a,b)$, so $(2a,2b)=(a,b)$, so $2a=a$ and $2b=b$. Thus $a=0$, $b=0$ and $T(0,0)=(0,0)$.

Ed's Proof
Since T is a linear transformation it can be represented by a matrix. Suppose that the matrix of T is

$$\begin{bmatrix} a & c \\ b & d \end{bmatrix}$$

Then the image of $(0,0)$ under T can be calculated as follows:

$$\begin{bmatrix} a & c \\ b & d \end{bmatrix} \begin{bmatrix} 0 \\ 0 \end{bmatrix} = \begin{bmatrix} a0+c0 \\ b0+d0 \end{bmatrix} = \begin{bmatrix} 0 \\ 0 \end{bmatrix}$$

So $T(0,0)=(0,0)$.

The students were asked the following questions about the text above.

(a) Does Alison's answer prove that the statement is true? If not, why not?

(b) Does Bob's answer prove that the statement is true? If not, why not?

(c) Does Charlie's answer prove that the statement is *not* true? If not, why not?

(d) Does Deirdre's answer prove that the statement is true? If not, why not?

(e) Does Ed's answer prove that the statement is true? If not, why not?

(f) Please rank the five answers in order of your preference (according to your own opinion). Include some comments to explain your ranking.

The five proposed proofs provide a sufficient variety of different approaches to provoke learning and discussion about the nature and features of mathematical proof and about the process of proof evaluation. Alison's proof is sufficient to prove the statement, it actually proves a more general statement. An evaluator might question the unexplained introduction of the point *(1,1)* and whether there is a reason for this choice. Bob's proof is written in text and also proves a wider statement than required. Charlie mistakenly proposes a counterexample to prove that the statement is incorrect. Deirdre's approach is written in a style which is familiar to students in the context of mathematical proof. However, her proof contains significant logical errors and does not establish the truth of the statement. Using Pfeiffer's terminology, the evaluator may find mismatches between the intended character and purpose of the proof, and between the actual and intended characters. Ed's proof establishes the truth the statement, but other purposes of proof such as enhancing understanding of the content and context of the statement are not met, i.e. the intended character of Ed's proof does not match these wider purposes.

DISCUSSION OF THE RESPONSES AND OPPORTUNITIES FOR DISCUSSION AND LEARNING

The 28 students whose responses are discussed here are those who fully answered all six parts of the question and included comments (many other students answered only some parts or gave "yes/no" answers without explanation). This account is intended to highlight some features of these students' thinking about proof and some opportunities for learning (for both the students and instructor) that arise. We followed the task with a lecture-based discussion session focussing on the themes mentioned below and prompted by the students' work. This session, though conducted with a large group, was notable for the students' interested attention and for an unusually high level of interaction. This may be due to the fact that many of the themes of the discussion arose directly from the students' written comments.

Alison's proof – responses and learning opportunities

Of the 28 respondents, 17 expressed the view that Alison proves that the statement is true. One was non-commital, and the other 10 stated that Alison's answer does not prove that the statement is true.

Five students objected to the introduction of the point *(1,1)*, apparently believing that focussing attention on this chosen point constituted a restriction of the statement to a particular example. Another accepted Alison's proof as correct, but commented:

Student: I would prefer if she used a point *(c,d)* in R^2 instead of *(1,1)*.

This last comment prompted a discussion about purposes of proofs. The student approves the proof but suggests altering it to avoid the choice of a particular vector. This alteration may make the argument more accessible for some readers, for example for the five of our students who were misled by the introduction of *(1,1)* to the extent that they rejected Alison's proof. On the other hand, some readers might see Alison's specification of a particular vector as simplifying the presentation and might prefer this to the alternative of cluttering the text with "general" notation that is not strictly necessary. The comment quoted above gave us the opportunity to highlight the fact that readers may have different mathematical tastes and that alternative presentations of essentially the same argument may appeal differently to different readers.

Bob's proof – responses and learning opportunities

21 students accepted Bob's proof as correct. One student described it as partially correct, and 6 considered it to be incorrect. It was the second most popular of all the proposed proofs, being ranked first (or joint first) by 8 students.

The six students who rejected Bob's proof stated two reasons for doing so. Two students objected to the assertion in Bob's proof that *(0,0)* is the only element of R^2 that "does not change when multiplied by a scalar" pointing out that (for example) "*(2,3)* does not change when multiplied by the scalar 1". This misinterpretation of Bob's intention highlights the importance of precision in mathematical proof.

The other four students who rejected Bob's proof (as well as three who accepted it) complained that it only used part of the definition of a linear transformation, namely the property of respecting scalar multiplication. All seven of these students criticized Alison's proof on the same grounds; the following is a representative comment.

> Student: Bob supplies the other half of Alison's proof, he proves the statement for scalar multiplication. He is also half right.

The students who reject or criticize Bob's and Alison's proofs on these grounds appear to recognize the strategy of reasoning from a definition towards a desired conclusion, but their verdict that the argument cannot be complete if it uses only part of the definition seems to be automatic. Their written comments do not indicate attempts to assess the significance to the argument of the "missing" part of the definition; their conclusions appear to be founded purely on an inspection of features of the proof without consideration of its logical structure.

No student cited as a reason to favour the proof of either Bob or Alison that both of these arguments prove a more general statement that they are directly concerned with. Alison's argument proves that every additive function fixes the origin, and Bob's proves that every function that respects scalar multiplication fixes the origin.

In the ensuing discussion, attention was drawn to the logical structure of Bob's proof and to the more general statement that it establishes. Students were reminded that a proof evaluator must consider the full content of what is achieved or omitted in a line of reasoning, and not hastily accept or dismiss an argument on the basis of superficial inspection. From the instructor's point of view, the student responses to Bob's proof highlight the important point that novice students are sometimes more attentive to the internal details of an argument than to its deductive quality.

Charlie's proof – responses and learning opportunities

Charlie's proof was considered incorrect by 25 students, and correct by three. It was ranked last by 21 students.

Of the 25 students who rejected Charlie's proof, only 11 did so on the grounds that the proposed counterexample is not or may not be a linear transformation.

Not all of the remaining 14 students who rejected Charlie's proof gave clear reasons. It is possible that the conflict between Charlie's conclusion and those of the other authors prompted some to object, but only two students cited this as a reason. Six students objected to the restriction of attention to a particular function. There is no sign in the work of these six students of acknowledgement that Charlie's goal is exceptional amongst the five, that he is trying to disprove the statement by exhibiting a counterexample. In the context of Pfeiffer's schema, their evaluations of Charlie's proof do not appear to include consideration of the relationship between the content of the proof and its main purpose.

A possibly surprising feature of the responses to Charlie's argument is that of the three students who considered it to be correct, each also accepted at least one of other four proofs. For example, one commented as follows on Charlie's proof:

> Student: As he notes, the linear transformation could possibly move every point one unit to the right. Therefore *T* does not fix the origin.

The same student accepted (for example) Bob's proof, and recognized the conflict between Bob's and

Charlie's positions, commenting on ranking Charlie's proof 3rd:

> Student: Even though Charlie disproves the statement, it's a very valid reason to disprove it.

The three students who approved Charlie's proof did not appear to be troubled by the inconsistency of their own positions, and apparently believed that the statement could simultaneously be validated by a correct proof and contradicted by a counterexample. The intriguing phenomenon of such beliefs is investigated and thoughtfully discussed by Stylianides and Al-Murani (2010).

Our in-class discussion of the responses to Charlie's proof focussed on the exceptional character of his argument among the five, on the roles of examples and counterexamples in mathematical reasoning, and on the inappropriateness of rejecting an argument solely on the grounds that it consists of a single example, without considering what it claims to establish. The opportunity arises also to discuss the question of whether a statement which has a valid proof can ever admit "exceptions", a question whose answer seems to be less clear to inexperienced students than to practising mathematicians.

Deirdre's proof – responses and learning opportunities

Deirdre's proof was considered correct by 19 students, and ranked 1st or 2nd by 11 of these. It was considered incorrect by 8 students, with one reporting no verdict.

Deirdre's argument begins with a linear transformation T and a hypothesized point (a,b) whose image under T is the origin. (There is no *a priori* guarantee that such a point exists.) From the fact that T respects multiplication by scalars, it is established that (a,b) and $(2a,2b)$ have the same image under T. It is then erroneously deduced that these two points must be the same and hence that $a=b=0$. This is a specific error in the line of reasoning documented in Deirdre's argument. The argument also suffers from a structural error in its logic: what it attempts to establish is not that $T(0,0)=(0,0)$ for every linear transformation T, but that if a point is mapped by a linear transformation to $(0,0)$, then that point must be $(0,0)$. In the context of the schema of Pfeiffer, this error corresponds to an opposition between the author's proof strategy (the *intended character* of her proof) and her purpose (establishing that $T(0,0)=(0,0)$ for a linear transformation T). The "internal" error in Deirdre's proof, (that $T(a,b)=(0,0)=T(2a,2b)$ means $(a,b)=(2a,2b)$) corresponds to a failure in the author's implementation of her strategy, a mismatch between the *intended character* and *actual character* of her proof. That such an error must exist is inevitable in this instance, since the author's intention is to prove an untrue statement.

Obviously notable is the fact that two-thirds of the students accepted an argument that has (at least) two serious flaws, one in its overall logical structure and one in its internal deductions. Many identified similarities between Deirdre's proof and Bob's, which may partly explain their readiness to accept this fundamentally flawed proof.

The 8 students who rejected Deirdre's proof did so for a variety of reasons. Two of them (as well as two who accepted the proof) criticized the use of the scalar 2 instead of a general k. Two of these students suggested that this specialization amounted to restriction to a special case and constituted a reason to reject the proof, the other two only that it compromised the quality of the argument (as opposed to its correctness).

Two students rejected Deirdre's proof on the basis of the erroneous deduction that $T(a,b)=T(2a,2b)$ means $(a,b)=(2a,2b)$. For example,

> Student: Her second line contains a mistake, when she states $T(2a,2b)=T(a,b)$ $(2a,2b)=(a,b)$. This is not necessarily true. She is incorrect.

For us, the most remarkable feature of the data on our students' responses to Deirdre's proof is that not one student noted its significant logical flaw. The only possible reference to the unexpected structure of Deirdre's argument is an oblique one from a student who accepted the proof and commented:

> Student: she works backwards to reach her conclusion.

From their comments it is not evident that any of the students gave careful critical attention to the question of "fitness-for-purpose" of Deirdre's strategy. In the context of Pfeiffer's schema, none of the students' written comments indicate consideration of the relationship between the intended or actual characters of this argument and its purpose. A key learning outcome for the instructor here is that the mathematician's practice of constantly testing the connection between the text of an argument and the statement that it purports to prove is not automatically adopted by students. Our discussion on Deirdre's proof focussed on this mental discipline and its essential role in mathematical practice and in the development and validation of mathematical knowledge. The validity of a mathematical argument cannot be assessed without analysis of the deductive process from the hypotheses to the conclusion. To conduct such analysis, a reader of proofs needs to have a measure of confidence in her ability to extract the logical thread from a passage of text, and to assess whether it does what it claims. As students progress through mathematical education at university, we expect their sense of their own reliable mathematical authority to evolve. Alertness to the possibility of logical failures in an argument is a habit of mind whose development may need explicit attention from both teachers and students. It is a key feature of mathematical practice, which might plausibly be encouraged by critical study of proofs, including some that are incorrect or inadequate in different ways.

Ed's proof – responses and learning opportunities

Ed's proof was accepted as correct by all 28 students, and was by far the most popular of the five proofs, being ranked 1st by 18 students and 2nd by 5 students.

Few students commented in detail on Ed's proof. Typical remarks included that it was clear, simple, short and easy to understand. Overall the group demonstrated a clear preference for Ed's translation of the problem into an easy matrix calculation over Alison and Bob's processes of reasoning from the defining properties of a linear transformation. The matrix representation of a linear transformation had been discussed in detail in lectures, and manipulations with matrices featured in several other tasks on the homework assignment that included this proof evaluation exercise.

Our discussion of Ed's proof and the responses to it focussed on the wider purposes of proof and on the reasons that a reader might have for preferring Alison or Bob's proof to Ed's, despite the fact that more effort is required to understand them. Students were invited to consider whether any of these proofs enhanced their appreciation of the significance of the defining properties of a linear transformation, or their understanding of *why* the statement is true.

CONSTRUCTION OF PROOF EVALUATION TASKS

Composing a suitable collection of "proofs" for a proof evaluation task can be an absorbing but time-consuming challenge for an instructor. It is not essential that such a task involves multiple proposed proofs, but our experience suggests that the invitation to compare different attempts to prove the same statement can stimulate meaningful learning opportunities. A first step in constructing a task of the type described here is to identify a statement is relevant to the disciplinary learning context, and admits different proofs that students have the requisite knowledge to understand. In the preparation of "proofs", there are at least two areas of potential scope for variability. One is the manner in which the proof is presented – whether it primarily consists of text or of algebraic formulation; whether it includes diagrams, either as a support or as the main content; whether the style of text content is formal and technical or more conversational. The presentation style can often be varied independently of considerations of the correctness of the proofs, and we have found it useful to give different styles of writing and presentation to our fictitious authors.

Another important dimension of variability is in the nature of errors or imperfections that appear in the range of proposed proofs. In this context the schema of Pfeiffer provides a useful framework for preparation of variously erroneous proof attempts. A task designer might decide to include one or more "proofs" in which the author's intention is mismatched to the stated aim, for example because of inappropriate logical structure (as in Deirdre's proof), inadvertent restriction to special cases, or unjustifiable deductions. A proof whose intended character is appropriate for the purpose but poorly conveyed in the actual character might also be included. Such a mismatch might be manifested through an insufficiently explained (but justifiable) line of reasoning, through the omission of some routine but necessary ingredient, or through imprecise or unclear statements. Proof evaluation tasks are flexible and adaptable and a number of degrees of freedom exist for their design. Instructors wishing to include such tasks in curricula will find opportunities to highlight essential points relating both to the nature and purposes of proofs and to relevant disciplinary knowledge.

A shared repository of adaptable proof evaluation tasks relating to different subject areas and levels would be a very useful resource.

CONCLUDING REMARKS

As anticipated by the research study of Pfeiffer (2011b), our incorporation of the activity of proof evaluation into a linear algebra course led to positive learning opportunities for our students as well as giving us some insights into their thinking about proof. We were surprised by the range of discussion opportunities that arose from students' responses to the task. Examples include the importance of precision, the role of counterexamples, and attention in proof-reading to overall structure as well as internal features. Proof evaluation activities with an advanced course in group theory have been similarly encouraging. All of these experiences motivate us to extend our resources for the use of proof evaluation tasks and to conduct comprehensive tests of their effectiveness for the development of proof-reading skills.

As a further argument for the incorporation of tasks of this nature in learning activities, we remark that a great deal of the professional activity of research mathematicians is concerned, directly or indirectly, with the validation and evaluation of proofs. However, in our experience it is rarely the subject of explicit attention in curricula. We propose that proof evaluation tasks, as well as providing meaningful opportunities in teaching and learning, also provide opportunities for students at all stages of expertise to participate in authentic mathematical practice.

Finally, we remark that our classroom experience with proof evaluation tasks demonstrates the potential of collaboration between researchers in mathematics education and academic mathematicians to deliver rich learning opportunities for students. Cooperation and mutual support of this nature is essential if insights arising from research in mathematics education are to have a significant impact on curricula and on the learning of mathematics at university level.

We discuss here the notion of mathematical fit, a concept that might relate to mathematical explanation and mathematical beauty. We specify two kinds of fit a proof can have, intrinsic and extrinsic, and provide characteristics that help distinguish different proofs of the same theorem.

Keywords: Proof, fit, explanation, beauty, aesthetics.

INTRODUCTION

Mathematics, as a subject, stands out from other fields in several ways. Even if proofs derive from axioms, there is a sense – which is grounded in the rigorous process of proving – that certain claims can be shown to be true or false. This is part of what makes mathematics satisfying. There are answers that can be shown to be, beyond a shadow of a doubt, true. Similar to the feeling one gets from establishing the truth of a claim, one can often experience a feeling in mathematics that a claim is right, that a certain proof fits a theorem, or that a particular argument is exactly the one needed. This is a stronger and somewhat more mysterious requirement than that a particular claim is true. There might be many arguments that establish the truth of a claim, but what is that makes us feel that some arguments are right? Is this just a subjective feeling or is there some objective grounding for this feeling? The purpose of this paper is to sketch some criteria for what it might mean for the (somewhat more limited and hence manageable) question of what it means for a proof to fit a theorem. While the criteria grew originally from empirical data (polling data and discussions with mathematicians) we present the paper as a theoretical one, with the idea of building, or at least starting to build, a framework that could be tested more broadly.

FIT IN THE LITERATURE

The notion of fit has been discussed in both science and mathematics communities. For instance, Wechsler (1978) compares the experience of "fit" to more aesthetic experiences often considered to be more artistic (and less scientific):

> Scientists talking about their own work and that of other scientists use the terms "beauty," "elegance," and "economy" with the euphoria of praise more characteristically applied to painting, music, and poetry. Or there is the exclamation of recognition — the "Aha" that accompanies the discovery of a connection or an unexpected but utterly right realization in art and science. These are epithets of the sense of "fit" — of finding the most appropriate, evocative and correspondent expression for a reality heretofore unarticulated and unperceived, but strongly sensed and actively probed.

Sinclair (2002) has discussed the role of fit in the process of mathematical discovery. She discusses several different kinds of fit. One kind of fit has to do with recognizing a particular theorem in a larger class of theorems (a case of a square was a specific case of the more general category of polygon.) Another kind of fit has to do with a corporeal sensation of physically putting together a vertex and an edge in a diagram to get a desired result. Sinclair connects these experiences of fit to a more general aesthetic sensibility. She quotes Beardsley who said that the first feature of aesthetic experience was "a feeling that things are working or have worked themselves out fittingly" (Sinclair, 2002, p. 288).

Fit, or the related notion of fitting (more on this distinction in the discussion), are natural, but somewhat vague terms to describe an aesthetic experience in mathematics, of something being appropriate or right, or something sharing some sort of family membership or having some kind of inner coherence. In this paper we try to clarify what some of the characteristics of fit might be (we do not claim that the list of characteristics is exhaustive, but it is at least a start). We illustrate our analysis with two contrasting proofs of the Pythagorean theorem.

THEORETICAL MODEL

Here we discuss two ways that a proof can be fitting in mathematics, which we will refer to as intrinsic and extrinsic fit. Proofs are not the only mathematical objects that can possess fit. Definitions, diagrams, even theories, might be fitting, but in this paper we will limit the discussion to proofs. In this section we list some criteria for determining if a proof has intrinsic or extrinsic fit.

Criteria for intrinsic fit

Intrinsic fit refers to the relationship between a theorem and the underlying ideas in a proof of the theorem. It is what gives one a sense of what is going on in a proof, and how accessible the underlying ideas are. There are (at least) three criteria for intrinsic fit.

> **I_1**: Economy. The underlying ideas are represented as concisely as possible. We say a proof is economic (or not economic).
>
> The number of words is not really what determines economy. Sometimes a proof can be too terse to see what is going on. The proof should be as short as possible, but a knowledgeable reader should still be able to follow it, filling in the missing details as appropriate.
>
> **I_2**: Transparency. The proof allows the underlying idea to be easily grasped. The structure of the argument is clear. We say a proof is transparent (or not transparent).
>
> This criterion deals with the question of how easy is it to see what is going on in a proof. This has two components: that the general logical structure of the proof is clearly presented, and that the underlying idea that makes the proof work is clearly stated.
>
> **I_3**: Coherence. The proof is stated in the same terms as the theorem. We say that a proof is coherent (or not).
>
> A proof that coheres has a clear underlying idea that is explicitly put to use in proving the theorem. The terms with which one would naturally state the proof idea (such as areas or graph cycles or eigenvalues of matrices) are the same terms which are stated in the theorem, allowing one to easily see why that particular idea is essential to the theorem.

Criteria for extrinsic fit

Extrinsic fit refers to the relationship between a particular proof and a family of proofs. The single case and the family might be related via an idea, but what stands out is not as much the idea as the family membership. When you realize that a proof is in the family you think, "Oh it is one of those!" There are (at least) three criteria for extrinsic fit:

> **E_1**: Generality. The idea of the proof generalizes to a larger class of theorems. We say that a proof is general (or not), though we often mean that the idea of the proof is general.
>
> This criterion deals with how well an underlying idea generalizes to prove a class of theorems. The proof at hand is seen as a specific instance of a more general claim. Generality is not the same as explanation. For instance in category theory, theorems might be perfectly general but not at all explanatory. See Steiner (1978) for other examples.
>
> **E_2**: Specificity. The proof requires a specific tool, or a particular technical approach, to make it tractable. We say that a proof is specific (or not).
>
> This criterion also deals with how well a proof fits into a class of theorems, but not through the idea, as with the criterion of generality above, but through the specific choice of technical tool that makes the proof work. Whereas with the criterion of generality the focus is on the family membership (This is one of those kinds of proofs!), here the focus is on the appropriateness of the specific technical tool for the job (We found a tool that works!). The tool itself is not as much of interest as is the fact that the proof is now within reach.
>
> **E_3**: Connectedness. The proof idea connects to proof ideas of other theorems. We say a proof is connected (or not).

We see this particular proof as one of family of proofs. This criterion is at the heart of what is meant by family membership. The idea in one proof is the same as the idea in a family of proofs, and the common idea is what makes the proofs hang together as a family.

AN EXAMPLE

We take as an example a classic, and much discussed theorem — the Pythagorean theorem. We will show two proofs of the theorem and use the model described above to discuss the extent to which each proof fits the theorem. The first proof comes from Euclid (300 B.C./2008, VI. 31) and has been discussed, for instance, in Polya (1954), as a particularly nice proof of the theorem. We suggest this proof is a clear example of a proof that really fits the theorem. It has been suggested that this proof captures exactly what the theorem is about (e.g., Steiner, 1978). The second proof, which uses a clever argument based on trigonometry, does not fit. Our model helps clarify why this is the case.

Theorem: In a right triangle with sides a and b and hypotenuse c, $a^2 + b^2 = c^2$.

Proof 1: We are given a triangle with sides a and b and hypotenuse c. Also line h ^ line c.

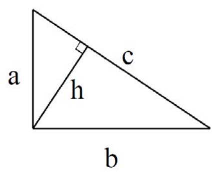

Figure 1

We can see that the sum of the areas of the smaller triangles is the same as area of the large triangle (by construction). We can also see (you can imagine folding out each of the three triangles over its longest side), that the sum of the areas of the triangles on sides a and b is equal the area of the triangle on side c. This relationship will hold for any similar figures on those sides, in particular squares, so $a^2 + b^2 = c^2$. QED

Why does this proof exhibit fit? Let us consider the criteria:

$\mathbf{I}_1$: Economy. The proof is economic. It gives relevant information simply and concisely. It could also be made more concise assuming more knowledge of the reader. (In this paper we have added some details for ease of reading.)

$\mathbf{I}_2$: Transparency. This proof is transparent. The proof consists of two main ideas, clearly presented, namely the dissection of the triangle into similar triangles, and that the equality of the areas carries over to arbitrary shapes.

$\mathbf{I}_3$: Coherence. The proof is coherent because the proof and the theorem are in the same terms, namely area. The theorem is a statement about the relationship of certain areas, and the proof directly relates these areas using properties of the triangles.

We also note that the idea of preserving areas is in line with the more famous proof in Euclid, where the areas of the squares constructed on either side are shown to be equal by area-preserving steps. A “Greek” proof that two areas are equal should ideally show that the one shape can be transformed into the other shape, using only area-preserving steps. The area-preserving step in the present proof is the reflection of either small triangle in the corresponding side of the large triangle. The scaling argument can also be traced to Euclid, and the present proof is also (less famously) given in Euclid.

$\mathbf{E}_1$: Generality. The proof is general. Steiner (1978) gives an account for this generality. This proof happens to be, according to Steiner, the proof that is most explanatory and most general. The generality comes from the fact that the proof works for arbitrary similar shapes constructed on the sides of the triangle.

$\mathbf{E}_2$: Specificity. The proof fulfils the criterion of specificity. The technical tool that works in this case is dividing the original triangle into similar triangles. Put more generally, this could be described as dissection. This division allows us to see the crucial relationship, namely that all three triangles are similar and their areas add up. The move to arbitrary similar figures, including squares, is a relatively small one.

$\mathbf{E}_3$: Connectedness. This criterion is not as easy to apply here as the other criteria, but we are inclined to say that this proof is connected. The class of proofs to which the proof can be seen to belong (other classes may be possible) might be taken to be proofs by area preservation, for instance the one referred to as "Greek" above.

Now consider the second proof, from Zimba (2009), which uses trigonometry.

Proof 2: Suppose we are given the subtraction formulas for sine and cosine:

$\cos(\alpha - \beta) = \cos(\alpha)\cos(\beta) + \sin(\alpha)\sin(\beta)$, and
$\sin(\alpha - \beta) = \sin(\alpha)\cos(\beta) - \cos(\alpha)\sin(\beta)$

Let α be the angle opposite to side a, and β be the angle opposite to side b, and without loss of generality, assume that $0 < \alpha \leq \beta < 90°$.

We now have:

$$\cos(\beta) = \cos(\alpha - (\alpha - \beta)) = \cos(\alpha)\cos(\alpha - \beta) + \\ + \sin(\alpha)\sin(\alpha - \beta) = \cos(\alpha)(\cos(\alpha)\cos(\beta) + \\ + \sin(\alpha)\sin(\beta)) + \sin(\alpha)(\sin(\alpha)\cos(\beta) - \\ - \cos(\alpha)\sin(\beta)) = (\cos^2(\alpha) + \sin^2(\alpha))\cos(\beta)$$

from which it follows that $\cos^2(\alpha) + \sin^2(\alpha) = 1$, since $\cos(\beta)$ is the ratio between one leg and the hypotenuse of a right triangle, and as such is never zero. The theorem now follows from the definitions of sine and cosine and scaling. QED

To what extent does this proof fulfill the criteria for intrinsic and extrinsic fit?

I_1: Economy. The proof is economic. It gives relevant information simply and concisely, and here some details are left out.

I_2: Transparency. This proof is not transparent. There is no clear sense of direction in the calculations performed. The structure of the proof is clear enough, and each step can easily be verified, but it seems that there is little in the way of a natural sequence of ideas, and the introduction of trigonometric quantities seems extraneous. Also, it is hard to see, for instance, why one would initially want to rewrite $\cos(\beta)$ as $\cos(\alpha - (\alpha - \beta))$.

I_3: Coherence. The proof is not coherent. The trigonometry used in this proof is not in the same terms as the theorem, which is about areas. The work of the proof, that is to say the algebra, takes place in the language of trigonometry. We translate in and out of that language to see that the trigonometric manipulations establish the theorem.

E_1: Generality. The proof as it stands is not general. It is true that once $\cos^2(\alpha) + \sin^2(\alpha) = 1$ is established, one can add the scaling argument to show that the result holds for arbitrary similar shapes, but the scaling argument is not an integral part of the proof.

E_2: Specificity. The proof exhibits specificity, in that the tool used (the subtraction formulas), surprisingly works out to be adequate for the conclusion to be drawn.

E_3: Connectedness. The proof is not connected. It is, as far as we know, the only trigonometric proof of the Pythagorean theorem, so there is no obvious family of proofs it would belong to.

Comparison

Here is how the two proofs compare in terms of fit, according to the six criteria. An X indicates that the proof satisfies the given criterion.

Criterion	I_1	I_2	I_3	E_1	E_2	E_3
Proof 1	X	X	X	X	X	X
Proof 2	X				X	

We conclude from this analysis that Proof 1 fits the Pythagorean theorem better than Proof 2 does. Notice that our notion of fit appears to be gradable. It seems natural to say that one proof fits better than another without all the criteria being fulfilled (or not fulfilled). What is less clear is how many criteria must be fulfilled to say that a proof exhibits fit at all. Further, the criteria are not equally weighted. It seems more central to the notion of fit to be coherent than to be economic.

DISCUSSION

We will now take up a few issues relating to fit that have a more general nature than those discussed above. First, we will discuss the relation between the terms 'fit' and 'fitting'. Next we will discuss the relation between fit and two other concepts, explanation and beauty. Finally we will discuss the applicability of the model given here.

Fit, Fitting, Fitness

There are several words related to fit which differ in meaning and use. With the examples above in mind of what it means for a proof to fit a theorem, or to fit into a class of theorems, we will explore the relation between these words. First, fit and fitting: Fit appears, commonly, to be a relation between two objects. A glove fits a hand. A model fits the data. The objects may be abstract, such as: The experience of going to Rome fits my expectations. The term can also be used metaphorically: Anna is a good fit for Roberto. In all of these cases, the objects that fit work like puzzle pieces. One set of objects has features that complement the features of the other object. When the match is found, we get a sense of satisfaction from having made and accomplished that match. However the fit might be more or less good, as in the case of a glove fitting a hand, or might be a perfect match, as in the case of a key fitting a lock.

Fitting, which has similar meaning to 'fit' has a slightly different connotation. Fitting often means 'appropriate', such as "that behavior was fitting for a man of his stature". Unlike fit, fitting often has a connotation of being socially appropriate. One would not say that a square is a fitting choice for this particular tessellation. 'Fit' refers more broadly to patterns found in nature, mathematics, etc. while 'fitting' is more restricted to the human sphere.

Fitness might not seem as obviously related to fit, but we mention it here to raise a question about whether the notion of 'fit' in mathematics might be at all related to the notion of 'fitness', say, in natural selection. One use of the term fitness has to do with physical aptitude. One trains to stay fit. When one is fit, one has achieved some level of fitness. In Darwinian terms, fitness is related to adaptability. The more adapted a species is for the environment the better it will fit. This reading of 'fit' or 'fitness' is not so different from what we call extrinsic fit above. The features that make a proof fit into a family of other proofs might be the ones that make it 'survive' in some sense, that it is more likely to be remembered, cited, and/or developed in mathematics. (This discussion bears resemblance to Gopnik (2000) who links understanding with sexual reproduction.)

Relation to explanation

Intrinsic fit and extrinsic fit have some parallels with contemporary treatments of mathematical explanation. We make no attempt here to summarize the literature in this area, and we do not try to spell out in detail any of the main models of mathematical explanation, but simply point to a few places in some of the more prominent theories where there are similarities with our account of mathematical fit.

Steiner (1978) provides an account of mathematical explanation in terms of 'characterizing property'. He described this as "a property unique to a given entity or structure within a family or domain of such entities or structures". This description of characterizing property has an obvious parallel with our notion of 'coherence'. Familial membership is central, both in identifying an entity as one that could explain, as well as in finding the grounds for the explanation. As Steiner continues, "an explanatory proof makes reference to a characterizing property of an entity or structure mentioned in the theorem, such that from the proof it is evident that the result depends on the property." Similar, but not identical, with our notion of coherence, the relationship between the entity or structure and the result is central for determining if a proof explains (or has fit). A proof that has the same terms as a theorem, which is how we have characterized coherence, seems similar to a proof that evidently gives rise to a particular result.

We will mention very briefly Steiner's notion of 'deformation' because it is essential to his view of explanation (though it has been criticized elsewhere, e.g., Hafner & Mancosu, 2005). To Steiner, a proof that explains can be modified for members of a particular family (e.g. the set of all polygons) while keeping the proof idea the same. An explanatory proof can be deformed to produce a new theorem [3]. While problematic, the idea behind 'deformation', that an explanatory proof contains an idea that is invariant to certain inter-family sorts of transformations, is not completely counter-intuitive. The focus on characterizing properties and deformation seems to build on an intuition similar to that which underlies our distinction between intrinsic and extrinsic fit. In both Steiner's account of explanation and our account of fit there is some aspect that is internal and related to proof idea (and its accessibility, in the case of fit), and there is some aspect that is external and related to situating a proof as a member of a larger family.

Contemporary philosophy of mathematics has reached no consensus on mathematical explanation, but we will consider two more theories, one of which is more aligned with our notion of connectedness, and the other with our notion of coherence. These two aspects of fit correlate most closely related with current accounts of explanation.

Kitcher (1989) offers a view of explanation that is considered to be a counter proposal to Steiner's view, based on the notion of unification. Kitcher says that explanation arises from the use of arguments that have the same form (see Lange (in press) for a summary of this view). These explanations can be found in what Kitcher calls "the explanatory store" and the main task of a theory of explanation is to "specify conditions on the explanatory store" (Kitcher, 1989, p. 80). While the details of what gives rise to an explanation differ greatly in Kitcher's and Steiner's account, one similarity seems to be the emphasis on familial membership, or what we would call connectedness. In Steiner's account the membership comes about via characterizing properties, and in Kitcher's account it comes about via the explanatory store. The fact that there is some kind of unification or some sort of family traits that naturally carry over to similar entities or structures seems central both in these two accounts of mathematical explanation and in our account of mathematical fit.

In contrast to Steiner and Kitcher, whose views of explanation seem to have some component similar to that of connectedness, Lange (in press) suggests a view with three components (unity, salience, and symmetry), the first of which seems to be related to coherence. To Lange, "A proof is unified when it exploits a property that all of the cases covered by the theorem have in common and treats all of those cases in the same way" (personal communication). Unlike Kitcher and Steiner, whose unification and characterizing property ideas involve family membership, Lange's notion of unity is one that is intrinsic to the proof. Lange's concept of salience might also overlap with our criteria for intrinsic fit. Salience is a feature that is "worthy of attention" (Lange, p. 27). Transparency includes a feature that makes a certain idea accessible. While not exactly the same concept, the idea that certain features of a proof make it more readily processed by the mind seem to be a commonality between our account of mathematical fit and Lange's account of mathematical explanation.

Relation to beauty

Less clear than the relation between fit and explanation is the relation between fit and beauty. The opening quote by Wechsler hints at a connection, as does the quote by Beardsley (that the aesthetic experience arises from things working themselves out *fittingly*). Could there be any motivation in mathematics for aesthetic experiences to arise from some sense of fit or fittingness?

We have gathered a small amount of pilot data related to this question. The proofs of the Pythagorean theorem, given above, were shown to a group of six mathematicians and three mathematics educators, along with several other proofs of the theorems. Participants were asked to rank the proofs according to which was most aesthetically pleasing. All of the mathematicians ranked the first proof higher than the second. The two math educators who chose the second proof stated that they did so because they felt they did not fully understand the first proof, but they could follow the steps of the second proof. The words given by the mathematicians to describe the first proof included "simple", "beautiful" and "conceptually correct". The words given for the second proof included "ugly", "clever" and "unnatural". Note that a proof can be clever without it being beautiful.

While far from conclusive, this data seems to suggest that there might be reasons to believe that fit has something to do with beauty. The criteria of economy and coherence seem to be similar what the mathematicians meant by simplicity and conceptual correctness.

Some applications of the model

The model proposed here for mathematical fit is only a sketch, but it may be a small step toward clarifying a few open questions related to the philosophy and aesthetics of mathematics. First, it helps identify some ways that current theories of explanation are at odds with each other. Steiner's account of explanation, which overlaps with our category of coherence, and Kitcher's account, which is more related to our category of connectedness, might be, like the parable of the blind men and the elephant, in which the men describe different parts of the beast, characterising different, but not necessarily contradictory, aspects of fit.

Second, our model takes a modest step towards clarifying what beauty in mathematics might have to do with explanation. If Wechsler is right that beauty involve some sort of fit, we have sketched two different kinds of fit that might play a role in our aesthetic judgments. This may also be a way to identify whether beauty is an objective quality.

ENDNOTES

1. Algebraic details: Let A, B, and C be the areas on the sides a, b, and c, respectively. Then $A/a^2 = B/b^2 = C/c^2$, which implies $A+B=a^2C/c^2+b^2C/c^2$. Since $A + B = C$, it follows that $(a^2+b^2)/c^2 = 1$ which implies $a^2+b^2= c^2$.

2. Note that for angles between 0 and 180 degrees, the subtraction formulas can be proven without recourse to the notion of distance, and are hence not dependent on the Pythagorean theorem. This proof is therefore not circular.

3. Counterexamples to this claim have been suggested, e.g. in Lange (in press).

Students of two-curriculum types Performance on a proof for congruent triangles

Ruthmae Sears[1] and Óscar Chávez[2]

1 University of South Florida, Tampa, USA, ruthmaesears@usf.edu

2 University of Texas at San Antonio, San Antonio, USA

This descriptive study examines students' performance on a proof task about corresponding parts of congruent triangles. We collected data from 1936 students, 59.8% used a subject-specific curriculum and 40.2 % used an integrated curriculum. Our findings indicate that, regardless of curriculum type, students experience difficulty with constructing the proof. Additionally, we observed that although students from the integrated curriculum were more likely to obtain partial credit when compared to their subject-specific counterparts, only 28 students in the sample (21 from subject-specific curriculum and 7 from the integrated curriculum) were able to obtain full marks.

Keywords: Proof, geometry, US textbooks, high school.

OVERVIEW

Although there is a consensus that students should have experiences with proof in all areas of mathematics (NCTM, 2000), proof has traditionally been part of only the geometry curriculum (Zaslavsky et al., 2012). Proof plays a central role in mathematics, and yet for many high school students it remains an alien concept, as suggested by weak performance of secondary students in proving (Harel & Sowder, 2007). For example, Senk (1985), studied 1520 students doing geometrical proofs and found that only 30% of students enrolled in a geometry course were able to demonstrate mastery of proof. Despite the low performance across the various proof tasks, Senk noted 47% of students were able to prove that a pair of congruent triangles was congruent. Similarly, Healy and Hoyles (1999) noted 19% of students were able to write a complete proof for familiar geometry statements, and 4.8% of students were able to write complete a proof for an unfamiliar geometry statements. Moore (1994) noted that students who are challenged to write proofs, may have difficulty with language and notation, may lack understanding of the concept, cannot state appropriate definitions, have difficulty structuring the proof, or may not know how to begin the proof.

Furthermore, large-scale assessments have documented that student performance in geometry is relatively poor. In the 1996 NAEP mathematics assessment, geometry was identified as a strand where student performance was low, particularly for 12th grade students (Martin & Strutchens, 2000). Moreover, extended constructed response items in the NAEP assessment had a much lower rate of satisfactory responses than multiple-choice items or short constructed responses for grades 8 and 12 (Silver, Alacaci, & Stylianou, 2000). Furthermore, in its report on evaluation of curriculum effectiveness, the National Research Council (2004) analyzed nine evaluation studies of NSF-supported curricula, and geometry was one of the strands where these curricula failed to show strong favorable results. On the other hand, two of four studies of commercial materials showed favorable results in geometry. Nevertheless, neither the analysis of NAEP data nor the NRC report specifically included results regarding proof in geometry.

Textbooks convey a mathematical progression for curriculum objectives and cognitive developmental structures for learners (Van Dormolen, 1986). The majority of secondary schools in U.S. follow a curriculum built around a sequence of three full-year courses, Algebra 1, Geometry, and Algebra 2 or Algebra 1, Algebra 2, and Geometry (Dossey, Halvorsen, & McCrone, 2008). Integrated curriculum materials developed since 1990 have been adopted in some high schools. These materials integrate algebra and geometry content, together with functions, data analysis, and discrete mathematics each year of the secondary mathematics curriculum (Hirsch, 2007).

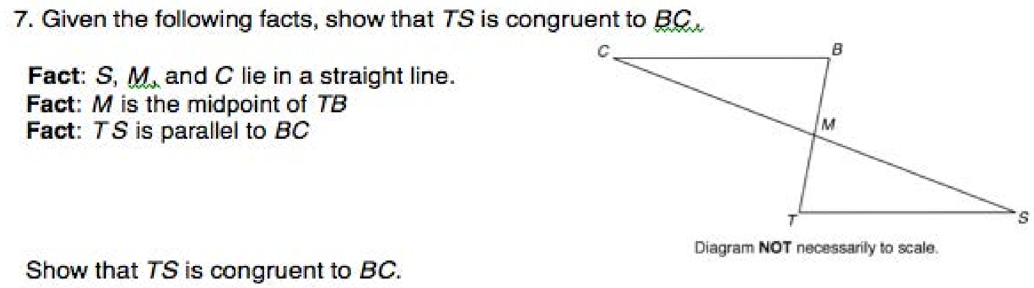

Figure 1: Proof task relative to corresponding parts of congruent triangles

Researchers have been interested in the different student outcomes that can be attributed to the use of these different types of textbooks. For example, at the fifth and sixth grade levels, Carroll (1998) found that students who used the UCSMP (an integrated curriculum that is designed to align with NCTM *Standards* (NCTM, 2000) outperformed on geometrical reasoning activities their counterparts that used a subject-specific curriculum, which are publisher-developed (Stein, Remillard, & Smith, 2007). Otten, Males, & Gilbertson (2014) documented that reasoning and proof tasks are visible in high school geometry subject-specific textbooks and integrated textbooks; however, few studies have documented high school students performance of proof in respect to the organizational structure of the curriculum used. Chávez and colleagues (2013) found that students using an integrated curriculum scored significantly higher than those using a subject-specific curriculum on a common objectives test. In this paper we examine students' performance on a geometrical proof task from this common objectives test with consideration to the curriculum type used. We investigated the following research questions:

— How successful are students on a proof about congruent parts of congruent triangles?

— What differences are there between curriculum types for students' performance on a geometrical proof task about congruent parts of congruent triangles?

METHOD

The mathematical task used and students' data were drawn from Test E in the Comparing Options in Secondary Mathematics: Investigating Curriculum (COSMIC) study. Test E is one of 5 tests developed for the COSMIC study (Chávez et al., 2011). This longitudinal study examined the impact of different content organizations on students' learning. The mathematics emphasized on Test E was *functions* and other topics that were common to both types of textbooks and were considered important, namely: symbolic algebra, Pythagorean Theorem and a proof for congruent triangles. Test E had 10 items: 1 multiple-choice item, 1 matching item, and the 8 remaining items were constructed response. For this paper, we will discuss students' performance on the proof task.

Mathematical task

In Test E, question 7 (Figure 1) required students to prove that two sides of two triangles were congruent. The given information was enough to prove that the triangles were congruent and therefore the corresponding sides were congruent. Figure 1 includes the task, as presented to students in the assessment instrument. The purpose of this task was to assess students' ability to write a proof for a very typical geometry problem. Our curriculum analysis had shown that tasks similar to this were found on both sets of textbooks.

This item was scored on a 9-point scale. The scoring rubric is shown in Figure 2. According to this rubric, the item was divided into four subitems, corresponding to the four expected components of a correct answer. Students were awarded points for identifying a pair of congruent triangles, pointing out at least two pairs of congruent angles, stating the correct theorem as to why the triangles were congruent, and for providing a concluding reasoning that the sides of congruent triangles were congruent. These four subitems are referred to as 7.1, 7.2, 7.3 and 7.4. As described elsewhere (Chávez et al., 2011), the rubric and the problem itself were submitted to external reviewers. The problem was also piloted before being use with the study participants. From these rounds of review, revision, piloting, and revision, we were confident that the problem was appropriate and that the scoring rubric was suitable. In particular, the scoring rubric enabled us to document student understanding, and also was

Student argues that one pair of sides is congruent:	
Student states that $\overline{TM} \cong \overline{MB}$ because M is the midpoint of $\overline{TB}$ (or equivalent statement)	2 points
Partial Credit — 1 point	
Student states that $\overline{TM} \cong \overline{MB}$ without a valid supporting reason	
Student argues that <u>two</u> of the three following pairs of angles are congruent:	
1. Student states that $\angle TMS \cong \angle BMC$ because they are vertical angles (or equivalent statement)	4 points
2. Student states that $\angle STM \cong \angle CBM$ because $\overline{TS} \parallel \overline{BC}$ or alternate interior angles	
3. Student states that $\angle TSM \cong \angle BCM$ because $\overline{TS} \parallel \overline{BC}$ or alternate interior angles	
Partial Credit — 3 points	
Student provides two of the above statements, but only one appropriate supporting reason	
Partial Credit — 2 points	
Student provides two of the above statements, but no valid supporting reasons	
OR	
Student provides one of the above statements, and one appropriate supporting reason	
Partial Credit — 1 point	
Student provides one of the above statements, and no valid supporting reasons	
Student argues that the two triangles are congruent:	
Student states that $\triangle TMS \cong \triangle BMC$ by ASA	2 points
OR	
Student states that $\triangle TMS \cong \triangle BMC$ by AAS	
Partial Credit — 1 point	
Student states that $\triangle TMS \cong \triangle BMC$ with no valid supporting reason	
Student argues that the required two sides are congruent:	
Student states that $\overline{TS} \cong \overline{BC}$ because $\triangle TMS \cong \triangle BMC$	1 point
OR	
Student states that $\overline{TS} \cong \overline{BC}$ because corresponding sides of congruent triangles are congruent (or equivalent statement)	
Total points	9 points

Figure 2: Rubric for proof task relative to corresponding parts of congruent triangles

sensible enough to allow us to measure variation in student's responses.

Participants

As described in previous papers (Grouws et al., 2013; Tarr et al., 2013), the schools in our study were high schools that offered both an integrated mathematics sequence (Course 1, Course 2, Course 3, Course 4) and a subject-specific sequence (Algebra 1, Geometry, Algebra 2, Pre-calculus); and that gave students the choice between these two alternatives without tracking them by ability. The students in the study ages ranged from 15–18 years old. Our sample included 10 high schools in six United States (US) school districts located in five geographically diverse states. *Core-Plus Course 3* (Coxford et al., 2003) was the textbook series used by all of the teachers teaching an integrated curriculum. Teachers of subject-specific curriculum used Algebra 2 textbooks produced by several different publishers.

The textbooks had similar content (Chávez, Papick, Ross, & Grouws, 2011; Chávez, Tarr, Grouws, & Soria, 2013). For example, in most subject-specific geometry textbooks Chapter 4 focuses on Congruent Triangles (Sears & Chávez, 2014). Teachers that used subject-specific geometry curriculum acknowledged that the chapter on congruent triangles is used to develop students' conceptions about proof (Sears & Chavez, 2014).

We collected data from 1936 students from these 10 high schools. Of these, 1157 students (59.8 %) used a subject-specific textbook; 779 (40.2 %) used an integrated textbook. The students in the study were in the third course for their respective curriculum sequence (Course 3 and Algebra 2, respectively). There is a slight variation among the subject-specific textbooks on their attention to proof (Sears & Chávez, 2014; Otten, Males, & Gilbertson, 2014). Given our focus on the impact of content organization on students learning, in this

The vast majority of students did not conclude that congruent sides of congruent triangles were congruent (Table 5).

Frequency by curriculum type

The following tables (Tables 6–10) show the scores by curriculum type. A larger percentage of students using subject-specific curriculum did not attempt to solve the problem. Among those students using subject-specific curriculum who did attempt the problem, a larger percentage received no points compared to those using integrated curriculum that attempted the problem. On the other hand, comparatively fewer students using the integrated curriculum received full credit for the problem. The mean score for question 7

was significantly different in these two groups, after controlling for prior achievement ($F = 6.355$, $p = 0.012$). Nevertheless, it is important to consider these differences in the context of the full test and taking into account all the relevant variables (Chávez et al., 2013). The results in these tables are simple summaries of the points scored by students in one assessment item.

DISCUSSION

Our results are consistent with others in showing that students, regardless of curriculum type, have difficulties writing proofs. There is evidence, however, that the organizational structure of curriculum can have implications on students' opportunities to prove. In particular, students in subject specific curricula were less likely to complete the proof task or to receive no points than students using integrated textbooks. Most students were not able to obtain full credit on the task. According to the results, only 1.8% of students in subject curricula, and 0.9% of students in integrated curricula were able to obtain full credit, which suggests that students continue to struggle with writing proofs. Otten et al (2014) noted that, although both subject-specific and integrated curriculum provides opportunities for students to differentiate between deductive and inductive reasoning, students were seldom required to construct complete proof arguments. This can be problematic, because it deprives students from viewing proofs in their entirety and can potentially contribute to students experiencing difficulty in starting proofs, as well as conceptualizing the structure of proofs (Moore, 1994).

Students should experience proofs more often. They should learn to expect that posing conjectures and proving statements is central to mathematics. Classroom observations for the COSMIC study indicated that teachers using integrated curriculum placed a greater focus on reasoning than teachers using subject-specific curriculum, "although it was not a strong focus for either group of teachers" (Grouws et al., 2013, p. 442). Complete proofs are seldom included in assessments, and more often they appear as fill-in-the-blank tasks. Emphasis on ritualistic aspects of proof may explain why students have difficulties writing proofs on their own.

CONCLUSION

Without a doubt, the results summarized here show that students in US high schools, regardless of the curriculum used in their schools, have difficulties writing proofs in geometry. Work done by Sharon Senk in the 1980s, among others, shows that this is an old problem. It was beyond the scope of the COSMIC study to conduct a fine-grained analysis of this specific topic. Nevertheless, it is clear that the evidence presented here points to grave deficiencies in how geometry is taught in schools. The case of proof is a particularly delicate one, because teachers attempt to teach proof as a topic that must be taught among other topics in the curriculum, rather than as a way to communicate mathematics. Therefore, these results may be interpreted as a lack of certain skills. It would be more appropriate, however, to consider them as an indication that when proof is taught as a set of rules that should be applied to specific problems in geometry rather than as a way of communicating mathematics, students learn neither. Hence, curriculum developers, and educators, must find ways to introduce experiences with proof in their materials and lessons, so that students develop sound habits of justification and proof.

A theoretical perspective for proof construction

Annie Selden and John Selden

New Mexico State University, Las Cruces, USA, aselden @math.nmsu.edu

This theoretical paper suggests a perspective for understanding university students' proof construction based on the ideas of conceptual and procedural knowledge, explicit and implicit learning, behavioral schemas, automaticity, working memory, consciousness, and System 1 and System 2 cognition. In particular, we will discuss proving actions, such as the construction of proof frameworks, that could be automated, thereby reducing the burden on working memory and enabling university students to devote more resources to the truly hard parts of proofs.

Keywords: University level, proving actions, behavioral schemas, System 1 and System 2 cognition, proof framework.

INTRODUCTION

This theoretical paper suggests a perspective for understanding university mathematics students' proof constructions and how the ability and skill to construct proofs might be learned and taught. We are interested both in how various types of knowledge (e.g., implicit, explicit, procedural, conceptual) are used during proof construction, and also in how such knowledge can be acquired. If that were better understood, then it might be possible to facilitate university students' learning through doing, that is, through proof construction experiences. Although one can learn some things from lectures, this is almost certainly not the most effective, or efficient, way to learn proof construction. Indeed, inquiry-based transition-to-proof courses seem more effective than lecture-based courses (e.g., Smith, 2006). Here we are referring just to inquiry into proof construction, not into theorem or definition generation. These ideas emerged from an ongoing sequence of design experiment courses meant to teach proof construction in a medium-sized U.S. PhD-granting university.

The Courses

There were two kinds of courses. One kind was for mid-level undergraduate mathematics students and was similar (in purpose) to transition-to-proof courses found in many U.S. university mathematics departments (Moore, 1994). In the U.S., such courses are often prerequisite for 3rd and 4th year courses in abstract algebra and real analysis. The other, somewhat unusual, kind of course was for beginning mathematics graduate students who felt that they needed help with writing proofs. The undergraduate course had from about 15 to about 30 students and the graduate course had between 4 and 10 students. Both kinds of course were taught from notes and devoted entirely to students attempting to construct proofs and to receiving feedback and advice on their work. Both courses included a little sets, functions, real analysis, and algebra. The graduate course also included some topology.

Psychological considerations

Much has been written in the psychological, neuropsychological, and neuroscience literature about ideas of conceptual and procedural knowledge, explicit and implicit learning, automaticity, working memory, consciousness, and System 1 (S1) and System 2 (S2) cognition (e.g., Bargh & Chartrand, 2000; Bargh & Morsella, 2008; Bor, 2012; Cleeremans, 1993; Hassin, Bargh, Engell, & McCulloch, 2009; Stanovich & West, 2000). In trying to relate these ideas to proof construction, we have discussed procedural knowledge, situation-action links, and behavioral schemas (Selden, McKee, & Selden, 2010; Selden & Selden, 2011). However, more remains to be done in order to weave these ideas into a coherent perspective. In doing this, two key ideas are working memory and the roles that S1 and S2 cognition can play in proof construction. Working memory includes the central executive and makes cognition possible. It is related to learning and attention and has a limited capacity which varies across individuals. When working memory capacity is exceeded, errors and oversights can occur. The idea behind S1 and S2 cognition is that there are two kinds of cognition that operate in parallel. S1 cognition is fast, unconscious, automatic, effortless, evolutionarily ancient, and places little burden on working memory. In contrast, S2 cognition is slow, conscious, effortful, evolutionarily recent, and puts considerable call on working memory (Stanovich & West, 2000). Of the several kinds of consciousness, we are referring to phenomenal consciousness—approximately, reportable experience. We turn now to the first of the two components of the proposed perspective.

THE PERSPECTIVE: MATHEMATICAL COMPONTENT

The genre of proofs

There are a number of characteristics that appear to commonly occur in published proofs. They tend to reduce unnecessary distractions to validation (reading for correctness) and raise the probability that any errors will be found, thereby increasing the reliability of the corresponding theorems. Proofs are not reports of the proving process, contain little redundancy, and contain minimal explanations of inferences. They contain only very short overviews or advance organizers and do not quote entire definitions that are available outside the proof. Symbols are generally introduced in one-to-one correspondence with objects. Finally, proofs are "logically concrete" in the sense that they avoid quantifiers, especially universal quantifiers, and their validity is independent of time, place, and author. (Selden & Selden, 2013).

Structure in proofs

A proof can be divided into a formal-rhetorical part and a problem-centered part. The *formal-rhetorical* part is the part of a proof that depends only on unpacking and using the logical structure of the statement of the theorem, associated definitions, and earlier results. In general, this part does not depend on a deep understanding of, or intuition about, the concepts involved or on genuine problem solving in the sense of Schoenfeld (1985, p. 74). Instead it depends on a kind of "technical skill". We call the remaining part of a proof the *problem-centered* part. It is the part that *does* depend on genuine problem solving, intuition, and a deeper understanding of the concepts involved (Selden & Selden, 2009, 2011).

A major feature of the formal-rhetorical part is what we have called a *proof framework*, of which there are several kinds, and in most cases, both a first-level and a second-level framework. For example, given a theorem of the form "For all real numbers x, if $P(x)$ then $Q(x)$", a proof framework would be "Let x be a real number. Suppose $P(x)$. ... Therefore $Q(x)$." A second-level framework would be obtained by "unpacking" the meaning of $Q(x)$ and putting the second-level framework for that between the beginning and end of the first-level framework. Thus, the proof would "grow" from both ends toward the middle, instead of being written from the top down. In case there are subproofs, these can be handled in a similar way. A more detailed explanation with examples can be found in (Selden, Benkhalti, & Selden, 2014).

THE PERSPECTIVE: PSYCHOLOGICAL COMPONTENT

In this second, psychological component of the perspective, we view the proof construction process as a sequence of actions which can be physical (e.g., writing a line of the proof or drawing a sketch) or mental (e.g., changing one's focus from the hypothesis to the conclusion or trying to recall a relevant theorem). The sequence of all of the actions that eventually lead to a proof is usually considerably longer than the final written proof itself. This fine-grained approach appears to facilitate noticing which actions should be taken to write various parts of a proof correctly and how to encourage such actions on the part of students.

Situations and actions

We mean by an (inner) situation in proving, a portion of a partly completed proof construction, perhaps including an interpretation, drawn from long-term memory, that can suggest a further action. The interpretation is likely to depend on recognition of the situation, which is easier than recall, perhaps because fewer brain areas are involved (Cabeza, et al., 1997). An inner situation is unobservable. However, a teacher can often infer an inner situation from the corresponding outer situation, that is, from the, usually written, portion of a student's partly completed proof.

Here we are using the term, action, broadly, as a response to a situation. We include not only physical actions (e.g., writing a line of a proof), but also mental actions. The latter can include trying to recall something or bringing up a feeling, such as a feeling of caution or of self-efficacy (Selden & Selden, 2014). We also include "meta-actions" meant to alter one's own thinking, such as focusing on another part of a developing proof construction.

Situation-action links and behavioral schemas

If, in several proof constructions in the past, similar situations have corresponded to similar actions, then, just as in traditional associative learning, a link may be learned between them, so that another similar situation yields the corresponding action in future proof constructions without the earlier need for deliberate cognition. Using *situation-action links* strengthens them and after sufficient practice/experience, they can become overlearned, and thus, automated. A person executing an automated action tends to (1) be unaware of any needed mental processes, (2) be unaware of intentionally initiating the action, (3) put little load on working memory, and (4) find it difficult to stop or alter the action. We call automated situation-action links *behavioral schemas*. Morsella (2009) has pointed out

> Regarding skill learning and automaticity, it is known that the neural correlates of novel actions are distinct from those of actions that are overlearned, such as driving or tying one's shoes. Regions [of the brain] primarily responsible for the control of movements during the early stages of skill acquisition are different from the regions that are activated by overlearned actions. In essence, when an action becomes automatized, there is a 'gradual shift from cortical to subcortical involvement ...' (p. 13).

Because cognition often involves inner speech, which in turn is connected with the physical control of speech production, the above information on the brain regions involved in physical skill acquisition is at least a hint that forming behavioral schemas not only converts S2 cognition into S1 cognition, but also suggests that different parts of the brain are involved in access and retrieval. Something very similar to the above ideas on automaticity in proof construction has been investigated by social psychologists examining everyday life (e.g., Bargh & Chartrand, 2000).

We see behavioral schemas as partly conceptual knowledge (recognizing the situation) and partly procedural knowledge (the action), and as related to Mason and Spence's (1999) idea of "knowing-to-act in the moment". We suggest that, in the use of a situation-action link or a behavioral schema, almost always both the situation and the action (or its result) will be at least partly conscious.

Here is an example of one such possible behavioral schema. One might be starting to prove a statement having a conclusion of the form p or q. This would be the situation at the beginning of the proof construction. If one had encountered this situation a number of times before, one might readily take an appropriate action, namely, in the written proof assume not p and prove q or vice versa. While this action can be warranted by logic (if not p then q, is equivalent to, p or q), there would no longer be a need to bring the warrant to mind.

It is our contention that large parts of proof construction skill can be automated, that is, that one can facilitate mid-level university students in turning parts of S2 cognition into S1 cognition, and that doing so would make more resources, such as working memory, available for the truly hard problems that need to be solved to complete many proofs.

The idea that much of the deductive reasoning that occurs during proof construction could become automated may be counterintuitive because many psychologists, and (given the terminology) probably many mathematicians, assume that deductive reasoning is largely S2.

Sequences of behavioral schemas

Behavioral schemas were once actions arising from situations through warrants, but that no longer need to be brought to mind. So one might reasonably ask, can several behavioral schemas be "chained together" outside of consciousness? For most persons, this seems not to be possible. If it were so, one would expect that a person familiar with solving linear equations could start with $3x + 5 = 14$, and *without bringing anything else to mind*, immediately say $x = 3$. We expect that very few (or no) people can do this, that is, consciousness is required.

Implicit learning of behavioral schemas

It appears that the entire process of learning a behavioral schema, as described above, can be implicit. That is, a person can acquire a behavioral schema without being aware that this is happening. Indeed, such unintentional, or implicit, learning happens frequently and has been studied by psychologists and neuroscientists (e.g., Cleeremans, 1993). In the case of proof construction, we suggest that with the experience of proving a considerable number of theorems in which similar situations occur, an individual might implicitly acquire a number of relevant behavioral schemas, and as a result, simply not have to think quite so deeply as before about certain portions of the proving process and might, as a consequence of having more working memory available, take fewer "wrong turns".

Something similar has been described in the psychology literature regarding the automated actions of everyday life. For example, an experienced driver can reliably stop at a traffic light while carrying on a conversation. But not all automated actions are positive. For example, a person can develop a prejudice without being aware of the acquisition process and can even be unaware of its triggering situations. This suggests that we should consider the possibility of mathematics students developing similarly unintended negative situation-action links, and behavioral schemas, implicitly during mathematics learning, and in particular, during proof construction.

Detrimental behavioral schemas

We begin with a simple and perhaps very familiar algebraic error. Many teachers can recall having a student write $\sqrt{(a^2 + b^2)} = a + b$, giving a counterexample to the student, and then having the student make the same error somewhat later. Rather than being a misconception (i.e., believing something that is false), this may well be the result of an implicitly learned detrimental behavioral schema. If so, the student would not be thinking very deeply about this calculation when writing it. Furthermore, having previously understood the counterexample would also have little effect in the moment. It seems that to weaken/remove this particular detrimental schema, the triggering situation of the form $\sqrt{(a^2 + b^2)}$ should occur a number of times when the student can be prevented from automatically writing "$= a + b$" in response. However, this might require working with the student individually on a number of examples, mixed with nonexamples.

For another example of an apparently implicitly learned detrimental behavioral schema, we turn to Sofia, a first-year graduate student in one of the above mentioned graduate courses. Sofia was a diligent student, but as the course progressed what we came to call an "unreflective guess" schema emerged (Selden, McKee, & Selden, 2010, pp. 211–212). After completing just the formal-rhetorical part of a proof (essentially a proof framework) and realizing there was more to do, Sofia often offered a suggestion that we could not see as being remotely helpful. At first we thought she might be panicking, but on reviewing the videos there was no evidence of that. A first unreflective guess tended to lead to another, and another, and after a while, the proof would not be completed.

In tutoring sessions, instead of trying to understand, and work with, Sofia's unreflective guesses, we tried to prevent them. At what appeared to be the appropriate time, we offered an alternative suggestion, such as looking up a definition or reviewing the notes. Such positive suggestions eventually stopped the unreflective guesses, and Sofia was observed to have considerably improved in her proving ability by the end of the course (Selden, McKee, & Selden, 2010, p. 212).

USING THIS PERSPECTIVE

Decomposing the proving process

In order to facilitate students' automation of certain parts of the proving process by developing helpful behavioral schemas, we have been decomposing the reasoning parts of the proving process, and focusing on those that occur frequently. Such decompositions of parts of the proving process can be mainly mathematical in nature or mainly psychological in nature. We find the psychological decompositions to be more surprising because they include things one might expect university students to be able to do without instruction. Some more mathematical possibilities are: (1) writing the first- and second-level proof frameworks which themselves can have parts (Selden, Benkhalti, & Selden, 2014; Selden & Selden, 1995); (2) noting when a conclusion is negatively phrased (e.g., a set is empty or a number is irrational) and early in the proving process attempting a proof by contradiction; and (3) noticing when the conclusion asserts the equivalence of two statements, "knowing" there are two implications to prove, and actually originating the two subproofs.

Here are some decompositions that may be more psychological in nature. One can change one's focus, for example by deciding to unpack the conclusion of a theorem, by finding or recalling a relevant definition, or by applying a definition. Such actions are sometimes part of constructing a second-level proof framework (Selden, Benkhalti, & Selden, 2014; Selden & Selden, 1995). Also developing a feeling of knowing or of self-efficacy can have a major effect (Selden & Selden, 2014). A student may develop and have for a time a feeling of not knowing what to do next, that is, the student might be at an impasse. Upon reaching such an impasse, the student might decide to do something else for a while, and coming back later, might hope to get a new idea. Many mathematicians have benefitted from this kind of "incubation". Nonemotional cognitive feelings (Selden, McKee, & Selden, 2010), such as those mentioned above can play a considerable role in proof construction, but we do not have space to elaborate on them here.

Proving activities that we have tried to help students automate include converting formal mathematical definitions into *operable interpretations*, which are similar to Bills and Tall's (1998) idea of operable definitions. For example, given $f: X \to Y$ and $A \subseteq Y$, we define $f^{-1}(A) = \{ x \in X \mid f(x) \in A\}$. An operable interpretation would say, "If you have $b \in f^{-1}(A)$, then you can write $f(b) \in A$ and vice versa". One might think that this sort of translation into an operable form would be easy, but we have found that for some students it is not, even when the definition can be consulted. We have also noted instances in which students have had available both a definition and an operable interpretation, but still did not act appropriately. Thus, *actually* implementing the action is separate from *knowing* that one *can* implement it. We are not sure whether, in implementing such actions, automaticity is difficult to achieve, but not acting appropriately can clearly prevent a student from proving a theorem.

Seeing similarities, searching, and exploring

How does one recognize situations as similar? Different people see situations as similar depending both upon their past experiences and upon what they choose to, or happen to, focus on. While similarities can sometimes be extracted implicitly, teachers may occasionally need to direct students' attention to relevant proving similarities. On the other hand, such direction should probably be as little as possible because the ability to *autonomously* see similarities can be learned.

For example, it would be good to have general suggestions for helping students to "see", without being told, that the situations of a set being empty (i.e., having no elements), of a number being irrational (i.e., not rational), and of the primes being infinite (i.e., not finite) are similar. That is, the three situations—empty, irrational, and infinite—may not seem similar until one rephrases them to expose the existence of a negatively worded definition. Unless students rephrase these situations, it seems unlikely that they would see this similarity and link these situations (when they occur as conclusions of theorems to prove) to the action of beginning a proof by contradiction.

In addition to automating small portions of the proving process, we would also like to enhance students' searching skills (i.e., their tendency to look for helpful previously proved results) and to enhance students' tendency to "explore" possibilities when they don't know what to do next. In a previous paper (Selden & Selden, 2014, p. 250), we discussed the kind of exploring entailed in proving the rather difficult (for students) *Theorem: If S is a commutative semigroup with no proper ideals, then S is a group.* Well before such a theorem appears in course notes, one can provide students with advice/experience showing the value of exploring what is not obviously useful (e.g., starting with $abba = e$ to show a semigroup with identity e, where for all $s \in S$, $s^2 = e$, is commutative, as discussed in Selden, Benkhalti, and Selden, 2014).

Understanding students' proof attempts

Here is a sample student's incorrect proof attempt of the *Theorem: Let S be a semigroup with identity e. If, for all s in S, ss = e, then S is commutative.* The student's accompanying scratchwork consisted of the definitions of identity and commutative. Here, the line numbers are for reference only.

1 Let S be a semigroup with an identity element, e.

2 Let $s \in S$ such that $ss = e$.

3 Because e is an identity element, $es = se = s$.

4 Now, $s = se = s(ss)$.

5 Since S is a semigroup, $(ss)s = es = s$.

6 Thus $es = se$.

7 Therefore, S is commutative. QED.

Line 2 only hypothesizes a single s and should have been, "Suppose for all $s \in S$, $ss = e$." With this change, Lines 1, 2, and 7 are the correct first-level framework.

There is no second-level framework between Lines 2 and 7. This was a beneficial action *not* taken and should have been: "Let $a \in S$ and $b \in S$. ... Then $ab = ba$." between Lines 2 and 7. Line 3 violates the genre of proof by including a definition easily available outside the proof. Lines 3, 4, 5, and 6 are not wrong, but do not move the proof forward. Writing these lines may have been detrimental actions that subconsciously primed the student's feeling that something useful had been accomplished, and thus, may have brought the proving process to a premature close.

TEACHING AND RESEARCH CONSIDERATIONS

The above considerations can lead to many possible teaching interventions. This then brings up the question of priorities. Which proving actions, of the kinds discussed above, are most useful for mid-level university mathematics students to automate, when they are learning how to construct proofs? Since such students are often asked to prove relatively easy theorems—ones that follow directly from definitions recently provided—it would seem that noting the kinds of structures that occur most often might be a place to start. Indeed, since every proof can be constructed using a proof framework, we consider constructing proof frameworks as a reasonable place to start.

Also, helping students interpret formal mathematical definitions so that these become operable might be another place to start. This would be helpful because one often needs to convert a definition into an operable form in order to use it to construct a second-level framework. However, eventually students should learn to make such interpretations themselves.

Finally, we believe this particular perspective on proving, using situation-action links and behavioral schemas, together with information from psychology and neuroscience, is mostly new to the field and is likely to lead to additional insights.

Textbook explanations: Modes of reasoning in 7th grade Israeli mathematics textbooks

Boaz Silverman and Ruhama Even

Weizmann Institute of Science, Rehovot, Israel, boaz.silverman@weizmann.ac.il

The goal of this study is to characterize the justifications and explanations offered in 7th grade Israeli textbooks for mathematical statements. The justifications and explanations offered in eight 7th grade Israeli textbooks for ten selected mathematical statements were analysed, using the modes of reasoning framework (Stacey & Vincent, 2009). The analysis revealed that the textbooks commonly used several modes of reasoning in explanations for each statement. Nearly every justification was deductive or empirical, yet different modes of reasoning were used for geometric and for algebraic statements. It was also found that empirical justifications were more prevalent in textbooks of limited scope, whereas deductive justifications were typically offered in textbooks of regular/ extended scope.

KEYWORDS: Modes of reasoning, textbook analysis, justifications, explanations, empirical and deductive justifications.

INTRODUCTION

Proving, justifying, and explaining are important components of doing and learning mathematics. However, the extensive research on students' conceptions of proof and ways of justifying mathematical claims reveals students' difficulties in understanding the need for justification and in distinguishing between deductive and other types of justification (e.g., Harel & Sowder, 1998). One factor that considerably influences classroom instruction and students' opportunities to learn mathematics is the textbook used in class (Eisenmann & Even, 2011; Haggarty & Pepin, 2002).

Studies of justification and proof in mathematics textbooks have examined various aspects, such as reasoning and proving activities (e.g., Davis, Smith, Roy, & Bilgic, 2014; Fujita & Jones, 2014), the nature of proof (e.g., Miyakawa, 2012), and the opportunities provided in the textbook for students to learn reasoning and proof (e.g., Dolev & Even, 2012; Stacey & Vincent, 2009). To better understand students' opportunities to develop the habit of justifying, and to learn how to justify in mathematics, this study examines the justifications and explanations to key mathematical statements offered in mathematics textbooks, specifically 7th grade Israeli textbooks.

BACKGROUND

Justifications of mathematical statements vary in their nature, from informal and intuitive explanations to rigorous deductive proofs (e.g., Blum & Kirsch, 1991; Harel & Sowder, 2007; Sierpinska, 1994). Research on the issue of justifications in school mathematics attends to a wide range of aspects. Some researchers focus on the formality of justifications (Blum & Kirsch, 1991); others consider the community addressed (Sierpinska, 1994); and yet others focus on the proof scheme of justifications (Harel & Sowder, 2007).

Studies of the opportunities for students to read justifications and explanations in textbooks show that textbooks justify mathematical statements in several ways, and that valid proofs are rare. Building on Harel and Sowder's (2007) framework, Stacey and Vincent (2009) developed the modes of reasoning framework and used it to analyse Australian textbook explanations. Stacey and Vincent identified seven modes of reasoning in textbook explanations:

— *Appeal to authority*: null explanation or reliance on an external source of authority.

— *Qualitative analogy*: reliance on a surface similarity to non-mathematical situations.

- *Experimental demonstration*: identifying a pattern after checking selected examples.
- *Concordance of a rule with a model*: comparing specific results of a rule and a model.
- *Deduction using a model*: a model that serves to illustrate a mathematical structure.
- *Deduction using a specific case*: an inference process conducted using a special case.
- *Deduction using a general case*: an inference process conducted using a general case.

These seven modes can be generally divided into three categories: External sources (*appeal to authority* and *qualitative analogy*); Empirical justifications (*experimental demonstration* and *concordance of a rule with a model*); and Deductive justifications (*deduction using a model*, *a specific case*, or *a general case*). Stacey and Vincent found that justifications offered in the analysed textbooks used several modes of reasoning, yet students were given no indication regarding which can be classified as deductive proofs and which can only serve as supportive empirical evidence at best.

Drawing on Stacey and Vincent's (2009) conceptual framework, Dolev (2011) analysed the modes of reasoning in justifications offered for three mathematical claims in six 7th grade Israeli textbooks (experimental version). She found that all the textbooks offered justifications for the sampled claims, at times using several modes of reasoning. Additionally, Dolev found a difference between the modes of reasoning used in algebra and in geometry – geometric claims were often justified by *deduction using a general case*, whereas algebraic claims were rarely justified that way. A similar pattern was noted in other studies – an abundance of proofs in geometry (e.g., Fujita & Jones, 2014; Hanna & de Bruyn, 1999), and a small number of formal proofs in algebra (e.g., Davis et al., 2014; Hanna & de Bruyn, 1999).

This study builds on these studies, and expands their scope. The research objective is to examine the justifications and explanations for key mathematical statements offered in mathematics textbooks, centring on 7th grade Israeli textbooks (approved version). We examine three aspects: (1) the modes of reasoning offered, (2) the nature of justifications of algebraic vs. geometric statements, and (3) the nature of justifications in textbooks of limited vs. regular/extended scope, designed for students with different achievement levels.

METHODOLOGY

Ten key mathematical statements were selected for analysis from the Israeli 7th grade mathematics national curriculum (Ministry of Education, 2009), across several curricular topics, similar to those in Stacey and Vincent's (2009) study on Australian textbooks. The selection criteria for each analysed statement were: (1) it contains a mathematical idea or concept that requires justification in the national mathematics curriculum, and (2) it is considered to be an important result in the curriculum and in mathematics education literature. The statements are listed in the following:

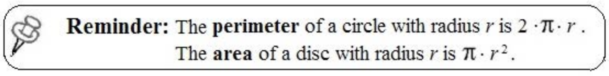
Algebra:

- The distributive property: $a \cdot (b + c) = ab + ac$ for every three numbers a, b, c.
- The product of two negative numbers is a positive number.
- Division by zero is undefined.
- Performing a basic operation on both sides of an equation maintains their balance.
- Two algebraic expressions are equivalent if for arbitrary values of the symbols in them the equality holds.

Geometry:

- Vertically opposite angles are congruent.
- The area formula for a trapezium with bases a, b and altitude h is $(a + b) \cdot h/2$.
- The area formula for a circle with radius r is πr^2.
- Angle sum of a triangle is 180^o.
- The corresponding angles between parallel lines are equal.

Analysis included all eight approved 7th grade textbooks for Hebrew speakers and their accompanying



Reminder: The **perimeter** of a circle with radius r is $2 \cdot \pi \cdot r$.
The **area** of a disc with radius r is $\pi \cdot r^2$.

Figure 1: A justification using an appeal to authority

teacher guides and supplementary materials. Six textbooks are of regular/extended scope, designed for the general student population (labelled A-F); two are of limited scope, designed for students with low achievements (labelled G-H). Data analysis included the textbook chapters introducing the statements – a total of 677 textbook pages; 57–110 pages (9–15%) from each textbook.

We analysed the explanations and justifications in the explanatory texts and those embedded in tasks and problems in the related task pools. Over 70% of the selected sections in the textbooks were analysed and discussed by 2–6 members of our research team until a consensus was achieved, and the remaining sections were analysed by the first author alone. First we identified distinct justifications of the statements in each section of the textbooks (i.e., explanatory texts and task pools). We then classified each justification for its mode of reasoning (following Stacey and Vincent, 2009) and compared frequencies relevant to the examined aspects: (1) the modes of reasoning offered; (2) algebra vs. geometry; and (3) limited vs. regular/extended scope.

FINDINGS

A total of 200 distinct justifications of statements were found in the textbooks. Comparison of the justifications by textbook section revealed that justifications were typically included in the explanatory texts, and seldom in tasks intended for student individual or small-group work, as shown in Table 1. This pattern was found in all textbooks (except textbook A) – regardless of the target student population, and in all statements – both in geometry and in algebra.

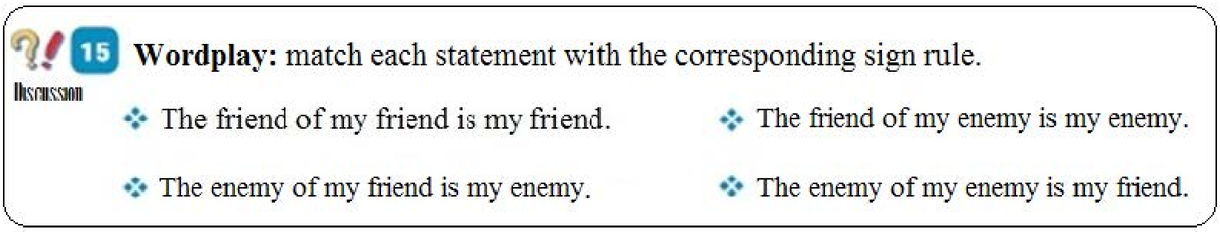
The modes of reasoning offered

Six of the seven modes of reasoning included in Stacey and Vincent's framework (2009) were identified in the Israeli textbook justifications, all but *concordance of a rule with a model*. Figures 1–6 exemplify justifications representing each of the identified modes of reasoning (translated from Hebrew).

Figure 1 illustrates a justification using an *appeal to authority* – a null explanation. The textbook merely presented a reminder for the area formula of a disc.

Figure 2 illustrates a justification using a *qualitative analogy*. The textbook included – among justifications using other modes of reasoning for the law of signs – an analogy that relies on a superficial similarity to the proverb "the enemy of my enemy is my friend". This justification does not reflect the mathematical structure of multiplication.

Figure 3 illustrates a justification using an *experimental demonstration*. The students were asked to tear paper triangles and rearrange the three angles, in order to convince themselves that the angle sum in a triangle is a straight angle.



15 **Wordplay:** match each statement with the corresponding sign rule.

Discussion

- The friend of my friend is my friend.
- The friend of my enemy is my enemy.
- The enemy of my friend is my enemy.
- The enemy of my enemy is my friend.

Figure 2: A justification using a qualitative analogy

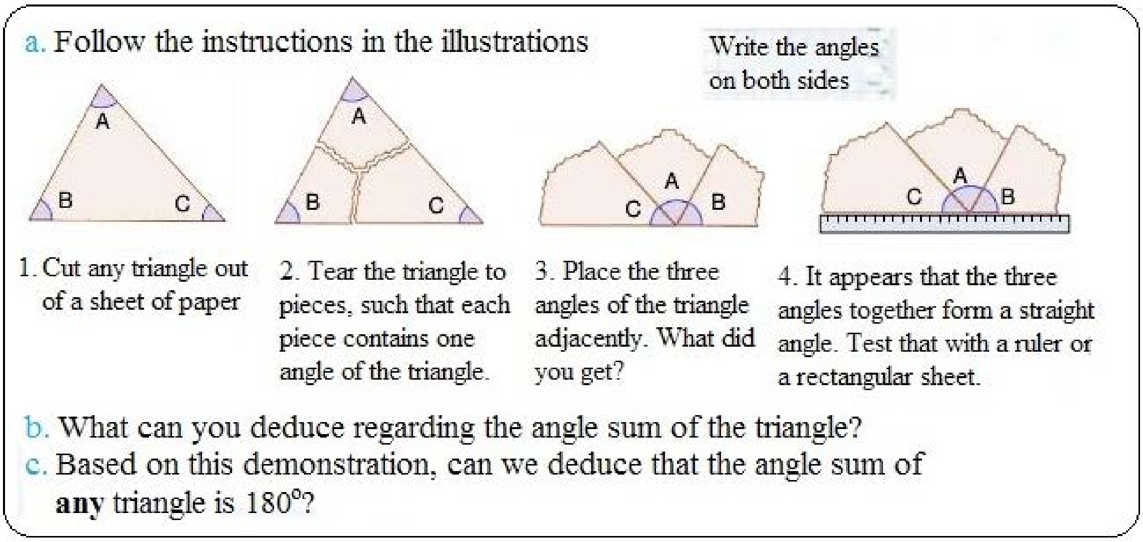
Table 1: Number of distinct justifications by textbook section for each textbook



a. Follow the instructions in the illustrations

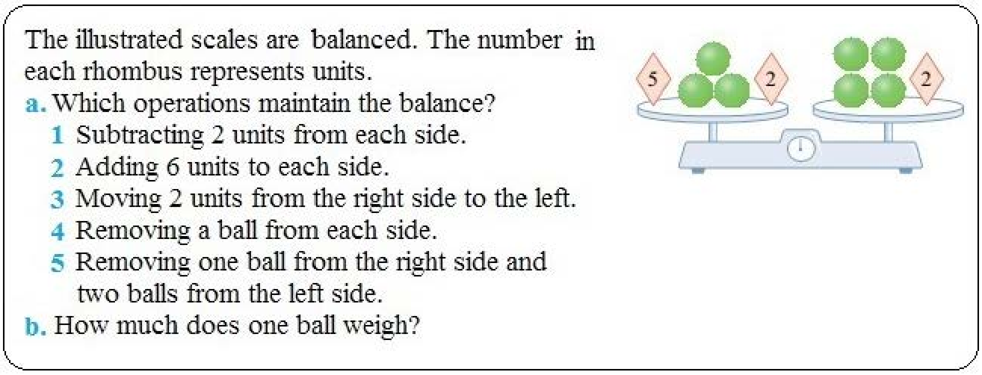
Write the angles on both sides

1. Cut any triangle out of a sheet of paper
2. Tear the triangle to pieces, such that each piece contains one angle of the triangle.
3. Place the three angles of the triangle adjacently. What did you get?
4. It appears that the three angles together form a straight angle. Test that with a ruler or a rectangular sheet.

b. What can you deduce regarding the angle sum of the triangle?

c. Based on this demonstration, can we deduce that the angle sum of **any** triangle is 180°?

Figure 3: A justification using an experimental demonstration



The illustrated scales are balanced. The number in each rhombus represents units.

a. Which operations maintain the balance?

1 Subtracting 2 units from each side.
2 Adding 6 units to each side.
3 Moving 2 units from the right side to the left.
4 Removing a ball from each side.
5 Removing one ball from the right side and two balls from the left side.

b. How much does one ball weigh?

Figure 4: A justification using a deduction using a model

Figure 4 illustrates a justification using a *deduction using a model*. The textbook relied on a structural similarity between the scales (the model) and balancing equations (the mathematics involved) to justify the statement.

Figure 5 illustrates a justification using a *deduction using a special case*. The textbook justified the area formula of a trapezium by splitting the area of a specific trapezium and forming a chain of reasoning, in which each step is logically deduced from previous steps. The given lengths are intended as a generic case (i.e., the specific values can be replaced without loss of generality).

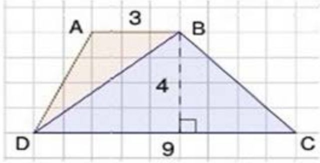
Figure 6 illustrates a justification using a *deduction using a general case*. The textbook justified the area formula of a trapezium by splitting the area of a general trapezium and forming a chain of reasoning, in which each step is logically deduced from previous steps. Pronumerals are used to note the lengths of the bases and of the altitude in the trapezium.

The textbooks provided justifications for all analysed statements (with one exception in Textbook E), commonly using several modes of reasoning in justifications for each statement, as shown in Table 2. Most of the justifications were of empirical (in blue) or deductive (in green, dark green, and olive green) modes, and only three instances of external sources (in red and dark red) were found. As Table 2 depicts, textbooks often justified a statement by using a certain mode of reasoning multiple times.

Algebra vs. geometry

Analysis of the modes of reasoning in the explanations offered in the textbooks revealed that different modes of reasoning were used for statements in algebra and in geometry. As Table 2 shows, algebraic statements (five top rows) were typically justified by deductive modes of reasoning, whereas geometric statements (five bottom rows) were usually justified by both deductive and empirical modes of reasoning. This analysis further shows that *deduction using a general case* appeared more in justifications of geometric

Draw the diagonal BD and split the area of the trapezium to two triangles: ΔABD and ΔDBC. The two triangles share an altitude (4 cm). The area of the trapezium ABCD is the sum of the areas of the two triangles:



$$S_{\Delta ABD} = \frac{3 \cdot 4}{2} \qquad S_{\Delta DBC} = \frac{9 \cdot 4}{2}$$

$$S_{ABCD} = S_{\Delta ADB} + S_{\Delta DBC} = \frac{3 \cdot 4 + 9 \cdot 4}{2} = \frac{(3+9) \cdot 4}{2} = 24 \text{ cm}^2$$

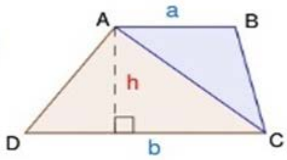
Let's observe the last step and identify the components of the formula. We see that we can find the area of a trapezium by finding the sum of lengths of the bases, times the length of the altitude, and dividing the product by 2.

$$S_{ABCD} = \frac{(\underset{\text{short base}}{3} + \underset{\text{long base}}{9}) \cdot \underset{\text{altitude}}{4}}{2}$$

Figure 5: A justification using a deduction using a specific case

Let's show that the area formula of a trapezium is true in all cases.
Fill in the missing steps in the proof.

- Draw the diagonal AC in the trapezium. It divides the trapezium ABCD into two triangles ΔABC and ΔADC.
- Therefore: $S_{ABCD} = S_{\Delta ABC} + S_{\Delta ADC}$
- The triangles ΔABC and ΔADC share an altitude h (why?)
- Let's write the area formula. Fill in the missing steps:



$$S_{ABCD} = S_{\Delta ABC} + S_{\Delta ADC} = \frac{a \cdot h}{2} + \frac{}{2} = \frac{ah +}{2} = \frac{(a+b) \cdot h}{2}$$

In other words: **The area of a trapezium is the sum of the lengths of the bases, times the length of the altitude, divided by 2.**

statements than in justifications of algebraic statements. Figure 7 presents the frequencies of modes of reasoning in textbook explanations in each textbook by content topic – algebra and geometry.

Limited scope vs. regular/extended Scope

Comparison of the explanations offered in textbooks of limited scope and of regular/extended scope was conducted on seven of the ten statements due to the textbooks' structure, a total of 136 distinct justifications. Figure 8 presents the distribution of the modes of reasoning in textbook explanations for these seven statements. A chi-square test of independence was used to test the association between textbook scope and empirical justifications. Textbooks of limited scope offered significantly more empirical justifi-

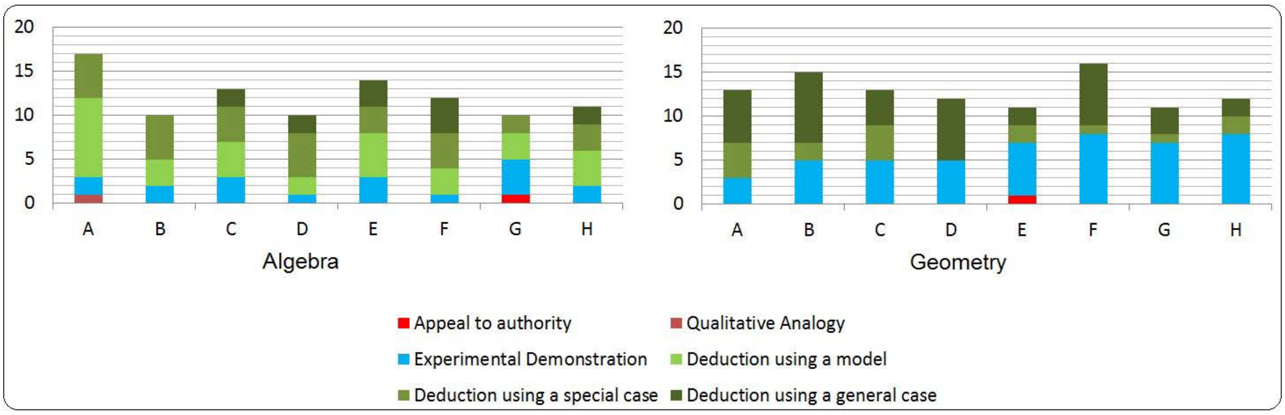

Figure 7: Frequencies of modes of reasoning by textbook and topic: algebra / geometry

cations than textbooks of regular/extended scope – roughly twice as much, $\chi^2_1 = 6.49$ (p = 0.01). An additional chi-square test was used to test the association between textbook scope and deductive justifications. Textbooks of regular/extended scope offered significantly more deductive justifications than textbooks of limited scope – roughly twice as much, $\chi^2_1 = 7.16$ ($p < 0.01$).

DISCUSSION

The findings reveal that Israeli 7th grade mathematics textbooks provide justifications for all the analysed key statements (but one statement in one textbook), commonly using several modes of reasoning in justifications for each statement. The inclusion of multiple modes of reasoning in textbooks might indicate an attentiveness of the textbook authors to the complexity of developing mathematical understanding, as the richness and diversity of textbook justifications might provide opportunities for students with different abilities, strengths, and backgrounds to learn and understand mathematics. Our results are in line with Stacey and Vincent's (2009) results on similar topics in Australian textbooks and with Dolev's (2011) results in Israeli textbooks (experimental version).

Our study shows that while most of the justifications for the analysed mathematical statements in 7th grade Israeli textbooks were included in the explanatory texts, some were embedded in the task pools intended for student individual or small-group work. However, our findings show that inclusion of the latter type of justifications in our analysis did not change the emerging patterns.

We found that 197 out of the 200 justifications analysed in the Israeli textbooks were deductive or empirical, implying that the textbooks typically explain each statement rather than present rules without reason. This finding does not comply with the findings reported in Stacey and Vincent's (2009) study, where 17% of the explanations for similar topics were neither deductive nor empirical.

Despite their emphasis on mathematical reasoning, our analysis shows that Israeli textbooks generally

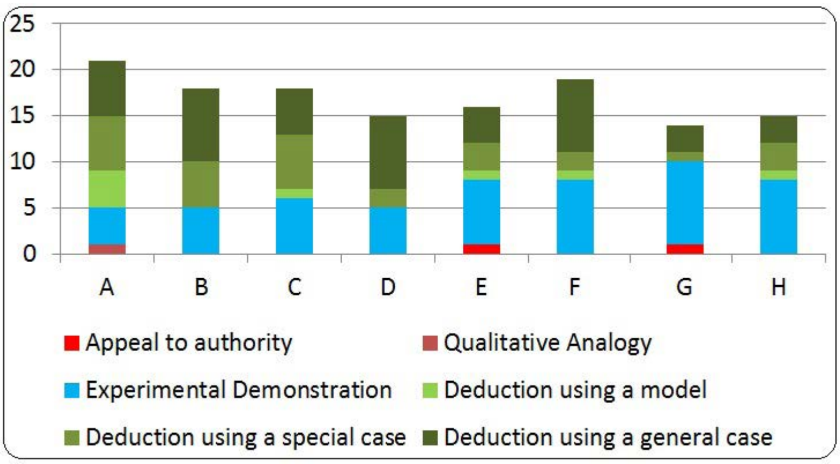

Figure 8: Frequency of modes of reasoning by textbook

give no indication regarding which justification can be considered a mathematically valid deductive proof and which serves only as a didactical tool to assist students' learning.

Comparison of the justifications for geometric statements and for algebraic statements in the Israeli textbooks showed that the textbooks typically use different modes of reasoning: deductive for algebraic statements, and both deductive and empirical for geometric statements. This finding is surprising at first glance due to the historic bias toward geometry as a subject suitable for teaching proof. However, careful analysis shows that the mode of reasoning closest to formal proof – *deduction using a general case* – appeared more in justifications of geometry statements than in justifications of algebra statements. Similar results were reported in Dolev (2011).

This study also shows that empirical justifications were more prevalent in textbooks of limited scope, whereas deductive justifications were predominant in textbooks of regular/extended scope. This pattern implies that student with different achievement levels are exposed to different types of justifications, and specifically that students with low achievements have fewer opportunities to deal with higher-order thinking and reasoning. These differences may have the potential to considerably limit the opportunities of students with low achievements to learn how to justify in mathematics, because teachers often follow teaching sequences suggested by textbooks (Eisenmann & Even, 2011; Haggarty & Pepin, 2002).

Our study focused on 7th grade textbooks. As Thompson (2014) notes, the similarities and differences we identified in this particular grade level – between textbook sections, between target student populations, and between curricular topics – might change over a textbook series. Additional research is needed to characterize the modes of reasoning in textbooks intended for higher grades.

The role of mode of representation in students' argument constructions

Andreas J. Stylianides

University of Cambridge, Faculty of Education, Cambridge, UK, as899@cam.ac.uk

Research into students' understanding of proof has generally considered few of the factors that can mediate the relation between students' argument constructions or their evaluations of given arguments and conclusions about students' understanding of proof. This raises concern about the validity of research findings and creates difficulties in comparing findings from different studies. I summarize some of these factors and explore the role played by another one: the mode of representation used in students' argument constructions. In particular, I report and discuss findings from a classroom-based design experiment suggesting that the use of an oral mode of representation may be more likely, compared to a written mode, to support the construction of an argument that approximates or meets the standard of proof.

Keywords: Proof, argument construction, oral representation, written representation.

INTRODUCTION

An assumption (often tacit) underpinning the findings of many studies on students' understanding of proof is that students' argument constructions or students' evaluations of given (researcher-generated) arguments are indicative of their understanding of proof. While this is a sensible assumption to make, there exist some factors, often uncontrolled for in relevant studies, that may mediate the relation between students' argument constructions or evaluations and researchers' conclusions about students' understanding of proof based on that work. For example, there is evidence to suggest the following: it is easier for students to evaluate given arguments than it is for them to construct their own arguments (Reiss, Hellmich, & Reiss, 2002); it is easier for students to identify invalid arguments as invalid than it is for them to identify valid arguments as valid (ibid); students' constructions can be poor indicators of their understanding of proof, as students can be well aware of limitations of their non-proof constructions (Stylianides & Stylianides, 2009); and students can evaluate given arguments in different ways based on different perspectives, such as what would satisfy them personally or what would satisfy their teachers (Healy & Hoyles, 2000).

Studies in this area considered at most one or two of these factors that may mediate the relation between students' argument constructions or evaluations and conclusions about students' understanding of proof. Thus a concern is raised about validity of research findings regarding students' understanding of proof. Take, for example, a study that draws conclusions about students' understanding of proof based on students' argument constructions in response to a number of proving tasks. This study is likely to report a poorer picture of students' understanding of proof than another study that considered also students' evaluations of their own constructions, for relevant research (Stylianides & Stylianides, 2009) suggests some students are fully aware of the reasons for which their non-proof constructions are not proofs. In addition to the issue of validity of research findings, there is also the difficulty in comparing findings from different studies; this creates in turn an obstacle to the development of a cumulative and coherent body of research knowledge in this area.

In this paper, I explore another factor that is worth attention by future research in this area. The factor relates to the *mode of representation* (Stylianides, 2007) used in students' argument constructions, that this, the forms of expression (written, oral, pictorial, etc.) with which an argument is communicated (ibid). I focus on two main modes of representation – written and oral – and I address the following research question: How does the mathematical sophistication of a student's arguments, for the same claim, compare when the bulk of each argument is communicated with a different mode of representation – written versus oral?[1]

There is some evidence to suggest that the verbal mode of representation may be associated with arguments of higher level of mathematical sophistication than the written mode (Schoenfeld, 1985). Schoenfeld described an episode where two students produced a lucid verbal argument, essentially a proof, for a geometrical construction problem, but then the students put down their ideas in writing by producing a contorted argument following the strictly prescribed 'two-column' presentational form (statement; reason). If further evidence was found that oral modes of representation were generally associated with mathematical arguments of higher level of mathematical sophistication than written modes, an important methodological implication would follow: An interview study that examined orally students' argument constructions would likely report a better picture of students' understanding of proof than a survey study that examined in writing the argument constructions of the same group of students and using the same proving tasks.

RESEARCH CONTEXT

The data for the paper are derived from a design experiment, which examined what may be involved in engineering classroom instruction to support secondary students to learn about proof. The design experiment was carried out in an English state school with 165 Year 10 students (14–15 year olds) who were set in seven classes according to their performance in a national assessment at the end of Year 9. All 61 students from the two highest attaining Year 10 classes, and the two mathematics teachers of these classes, participated in the research over a period of two years.

The focus of the study on high-attaining students was partly motivated by the findings of a prior large-scale longitudinal study in England (Küchemann & Hoyles, 2001–03) that showed (1) weak knowledge about proof amongst a national sample of high-attaining Year 8–10 students and (2) modest (if any) improvements in students' knowledge from Year 8 to Year 10. These findings raised concerns about English high-attaining secondary students' learning about proof, and suggested an even more pessimistic prospect for lower attaining or younger students.

The design experiment involved the development, implementation, and analysis of the effectiveness of six lesson sequences, each ranging from one to five 45-minute periods. Lesson sequences 1–4 were implemented when the students were in Year 10, while the rest in Year 11. At the beginning of the study I took the lead role in planning the lesson sequences, but over time the teachers felt more confident to take responsibility for planning the lesson sequences and this allowed me to assume more of a supportive role. All lessons were taught by the regular teacher of each class.

In this paper, I focus on lesson sequence 2, which lasted three 45-minute periods in one class and two in the other. It was implemented three months into Year 10 and capitalized on lesson sequence 1. Lesson sequence 1 lasted two 45-minute periods in each class, was implemented one month into Year 10, and had two main goals: (1) to help students begin to realize the limitations of empirical arguments as methods for validating mathematical generalizations and see a need to learn about more secure validation methods (i.e., proofs); and (2) to introduce students to the notion of proof in mathematics, including a list of criteria for deciding whether a mathematical argument met the standard of proof. The criteria were as follows.

> An argument that counts as *proof* [in our class] should satisfy the following criteria:
>
> 1. It can be used to convince not only myself or a friend but also a *sceptic*.
>
> — It should not require someone to make a leap of faith (e.g., "This is how it is" or "You need to believe me that this [pattern] will go on forever.")
>
> 2. It should help someone *understand why* a statement is true (e.g., why a pattern works the way it does).
>
> 3. It should use *ideas that our class knows already or is able to understand* (e.g., equations, pictures, diagrams).
>
> 4. It should contain *no errors* (e.g., in calculations).
>
> 5. It should be *clearly presented*. (PowerPoint slide used during Lesson Sequence 1)

The criteria were consistent with the following definition of proof, with care taken so that the phrasing of the criteria was suitable for secondary students.

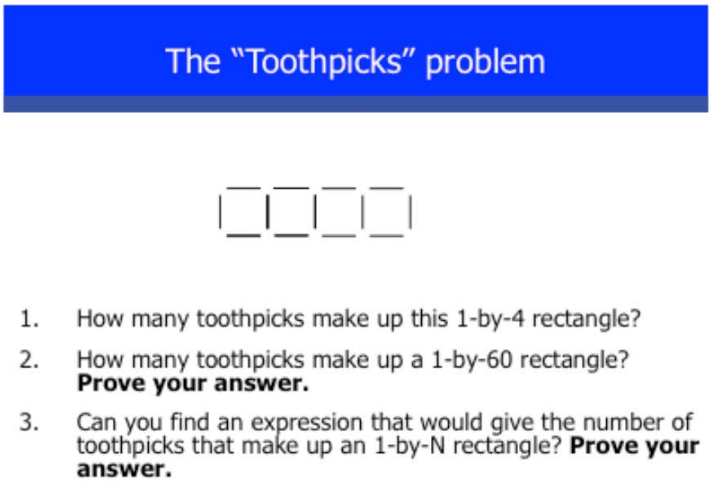

Figure 1: The first proving task

> *Proof* is a *mathematical argument*, a connected sequence of assertions for or against a mathematical claim, with the following characteristics:
>
> 1. It uses statements accepted by the classroom community (*set of accepted statements*) that are true and available without further justification;
>
> 2. It employs forms of reasoning (*modes of argumentation*) that are valid and known to, or within the conceptual reach of, the classroom community; and
>
> 3. It is communicated with forms of expression (*modes of argument representation*) that are appropriate and known to, or within the conceptual reach of, the classroom community. (Stylianides, 2007, p. 291)

Criteria 1 and 4 correspond to the requirement in the definition for valid modes of argumentation; criterion 5 to the requirement for appropriate modes of argument representation; and criterion 3 to the requirement that all components of a mathematical argument (set of accepted statements, modes of argumentation, and modes of argument representation) be readily accepted, known to, or within the conceptual reach of the class. Furthermore, criteria 1 and 2 reflect, respectively, two important functions that the development of arguments and proofs intended to serve in the two classes: to promote conviction at both the individual and social levels (e.g., Mason, 1982) and understanding (e.g., Hanna, 1995).

The goals of lesson sequence 2 were (1) to help students further understand the proof criteria and (2) to offer students opportunities to apply these criteria in three proving tasks. The tasks were mathematically similar though not necessarily of the same level of difficulty; they all involved making and proving a generalization by reference to an underlying structure. Lesson sequence 2 started with review of the proof criteria, and then the teacher introduced task 1 (Figure 1). There was individual or small group work on the task, during which the teacher asked the students to write down their 'best' arguments. The students were given ample time to do that and were free to work in pairs or larger groups. While students were instructed to write down individually their arguments, few of them wrote arguments in pairs. Finally, there was a whole class discussion during which several students presented individually or in pairs their arguments. Similar procedure was followed for tasks 2 and 3.

METHOD

Data

The data for the paper are the written arguments of, and transcripts of the subsequent oral presentations of these arguments by, 17 students in the two classes. These were all the students who, in response to an open call by the teachers, offered to present their arguments for any of the three proving tasks during whole class discussions. Thirteen of these students presented arguments for only one task while two students presented arguments for two tasks. The distribution of student-presenters across the three tasks was 10 students for the first task, 4 for the second, and 3 for the third.

Analysis

A research assistant and myself coded independently all written and oral (transcribed) arguments of the 17 students. First, we used the coding scheme developed by Stylianides and Stylianides (2009) to code each argument into one of the following five categories according to the argument's level of mathematical sophistication. The codes are presented in decreasing level of mathematical sophistication. We compared our codes and discussed disagreements to reach consensus.

- code M1: proof
- code M2: valid general argument but not a proof
- code M3: unsuccessful attempt for a valid general argument
- code M4: empirical argument
- code M5: non-genuine argument

All three tasks required proving the truth of a generalization. The definition of code M1 was consistent with Stylianides' (2007) definition of proof, which underpinned in turn the criteria for proof used in the two classes. Specifically, code M1 was defined to be an argument that was *general* (i.e., it referred to all cases in the domain of the generalization), used *valid* modes of argumentation (i.e., it offered conclusive evidence for the truth of the generalization), and was accessible to the students in the class (i.e., it used statements that were readily acceptable by the class as well as modes of argumentation and modes of argument representation that were known to the students or within their conceptual reach at the particular time). Code M2 was used for arguments that approximated but not quite met the standard of proof, because, for example, of missing or inadequate justification of an assertion that could not be considered readily acceptable by the class. Code M3 was used for arguments that reflected an attempt to justify the generalization for all cases in its domain, but were either incomplete or used *invalid* modes of argumentation (i.e., they included a logical flaw). Code M4 was used for arguments that verified the truth of the generalization only in a proper subset of the cases in its domain but concluded it was true for all cases. Finally, code M5 was used for responses to the proving tasks that showed minimal engagement, were irrelevant to what was being asked, or were potentially relevant but the relevance was not made evident to the coder.

In addition to the above, for each argument we coded the following:

- Who wrote or orally presented the argument: an *individual student* or a *pair of students*;
- The kind of input from the teacher or the rest of the class during the oral presentation of the argument: *no input*, *some but not substantial input* (i.e., input that simply reiterated or briefly clarified a point mentioned by the student without influencing the presented argument), or *substantial input* (i.e., input that influenced the presented argument and possibly altered its level of mathematical sophistication).

Furthermore, we examined whether there was any evidence to suggest that preceding oral presentations of arguments for a proving task influenced subsequent presentations for the same task. We found no evidence of such influence: students' oral presentations were rather distinct from one another; students' orally presented arguments matched closely their written arguments (e.g., oral presentations tended to be based on the same figures or drawings as in students' written work); and students looked at or referred to their written work during their oral presentations.

Yet, the temporal sequencing of students' arguments (first written, then oral) was a factor we could not account for. It is possible that a student's original efforts to write an argument for a proving task helped the student build familiarity with the task and underlying concepts, thus placing the student in a position to orally present later on an argument of higher level of mathematical sophistication. Another factor we could not account for was whether the teacher offered any substantial input during students' written work in small groups. According to the plan that I had agreed with the teachers prior to the lessons, the teachers would ask students probing questions, but they would not directly influence students' argument constructions. There was no concrete evidence that the teachers deviated from the agreed plan. But even if they had done that, the result would have been better written arguments and, presumably, better oral presentations of those arguments, too. Thus there would likely be limited if any impact on the *comparison* between the levels of mathematical sophistication of the written and oral arguments, which is the issue examined in this article.

RESULTS

The results are summarized in Figures 2–4, which show the relationship between the level of mathematical sophistication of the written arguments produced

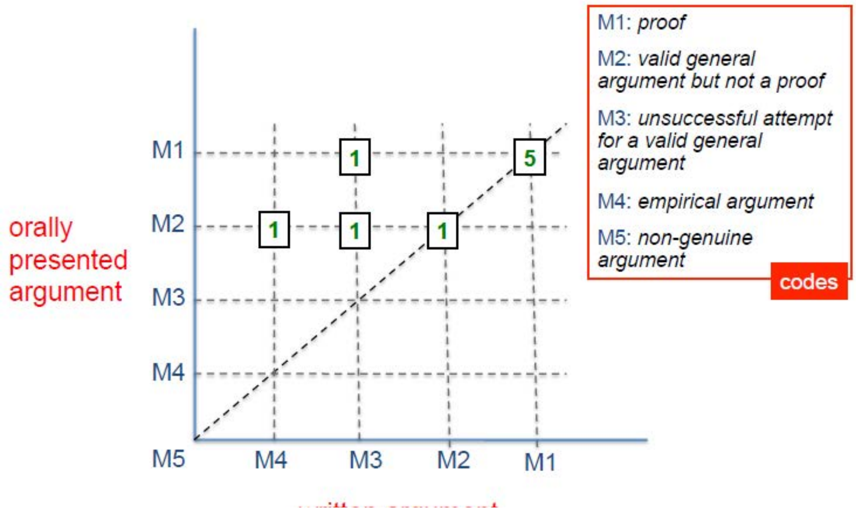

Figure 2: Students who wrote and presented their arguments individually, with no input (N=9)

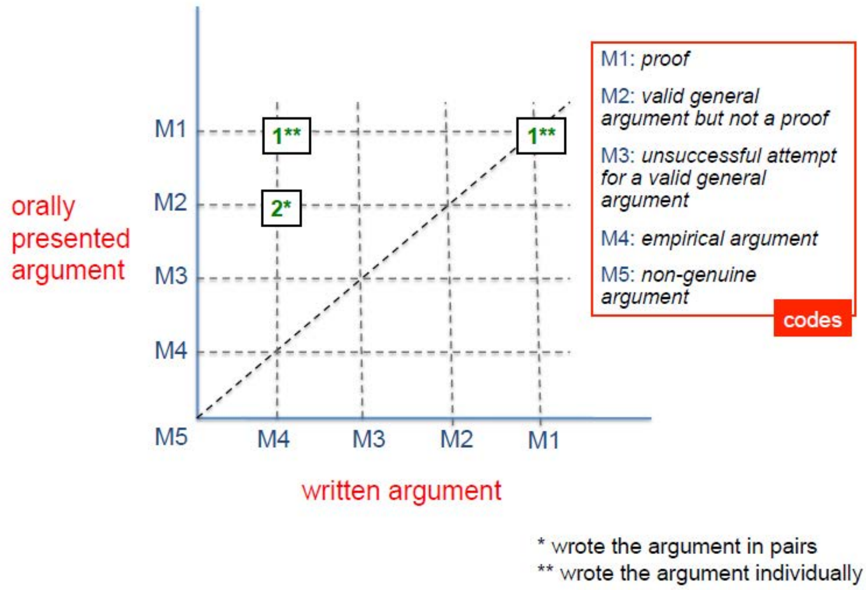

Figure 3: Students who presented their arguments in pairs, with no input (N=4)

by certain groups of students and the corresponding level of orally presented arguments by the same groups. The numbers in the figures represent frequencies of students.

Nine of the 17 students wrote and presented their arguments individually, with no input from the teacher or the rest of the class during those presentations (Figure 2). Five of these students wrote and presented proofs (M1), one wrote and presented a valid general argument but not a proof (M2), and the other three presented more mathematically sophisticated arguments than they had written earlier: two wrote arguments that reflected an unsuccessful attempt for a valid general argument (M3) but presented M1 and M2 arguments respectively, while one wrote an empirical argument (M4) but presented an M2 argument.

Four other students presented their arguments in pairs and received no input from the teacher or the test of the class during those presentations (Figure 3). The students in one of the pairs wrote together an M4 argument but presented (again together) an M2 argument. The students in the other pair wrote different arguments but made a joint presentation, which was coded as M1; one student had written an M1 argument while the other had written an M4 argument.

The remaining four students wrote and presented their arguments individually, but during their presentations they received input from the teacher (Figure 4).

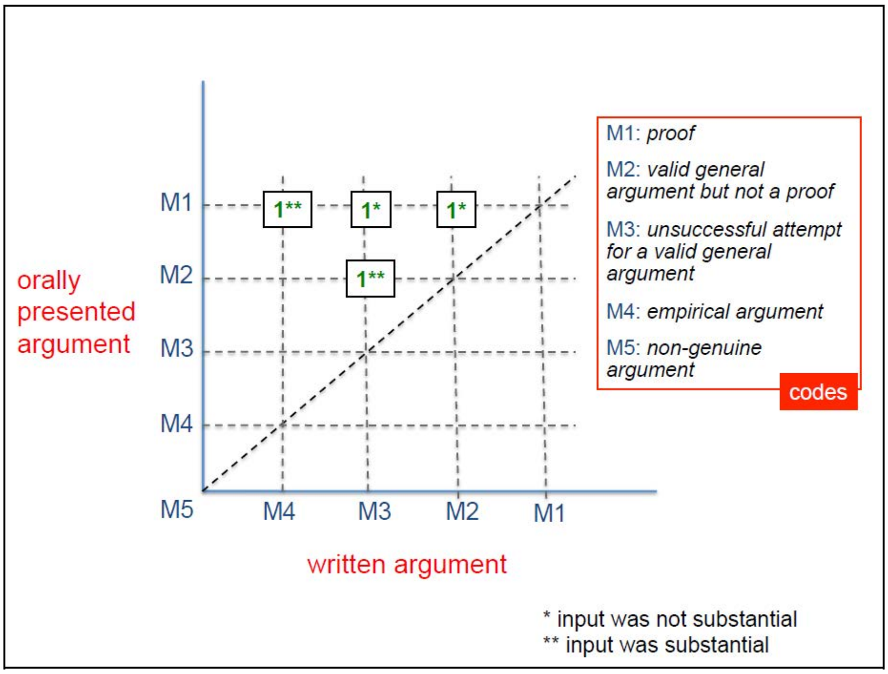

Figure 4: Students who wrote and presented their arguments individually, with input (N=4)

Yet, in two of the cases the input was not substantial: the teacher simply reiterated or clarified briefly a point mentioned by the students during their presentations, without influencing the presented argument. One student wrote an M3 argument and presented an M1 argument, and the other wrote an M2 argument and presented an M1 argument. In the remaining two cases the input from the teacher was substantial. For example, in one of the cases the teacher made a comment at a point during the student's oral presentation when the student paused and seemed to have difficulty articulating the general case; this comment might have helped the student articulate an argument of a higher level of mathematical sophistication than she would have presented otherwise. In both cases the presented arguments were of higher level of mathematical sophistication than the arguments the students had written in their papers: one was M4 and became M1, while the other was M3 and became M2.

To sum up, the proportion of arguments for which the teacher's input was substantial was small (2 out of 17), while in all of the cases the orally presented arguments were of the same or of higher level of mathematical sophistication compared to the corresponding written arguments. All orally presented arguments were either proofs (M1) or valid general arguments but not proofs (M2). Eight of the written arguments were already at the M1 or M2 levels, but the remaining nine were either empirical (M4) or unsuccessful attempts for a valid general argument (M3) and yet, during the oral presentations, all of these arguments were elevated to the M1 or M2 levels.

DISCUSSION

The findings offer support to the hypothesis that the level of mathematical sophistication of students' arguments for the same claims may depend on the mode of representation (oral vs. written) students use to communicate these arguments. The students whose arguments I examined in this study tended to omit few essential steps or explanations in their written work, but they addressed most of these omissions during their oral presentations. All orally presented arguments were of the same or higher level of mathematical sophistication than their written counterparts. A methodological issue stands out from these findings: If a study had analyzed students' oral arguments only, it would have reported a better picture of students' ability to construct arguments than another study that analyzed students' written arguments only. Yet, limitations of the research design, notably the lack of control over the temporal sequencing of students' arguments (first written, then oral), do not warrant any definite statement that the oral mode of representation is generally advantageous over the written mode in the construction of arguments that approximate or meet the standard of proof.

Below I present four other possible and not necessarily competing reasons for which students' oral arguments tended to rank higher than their written arguments.[2] Reasons 1 and 2 reinforce, while reasons 3 and 4 weaken, the presumed role played by the mode of representation in the observed differences between students' written and oral arguments, thus highlighting the need for more research in this area.

1. *Relative difficulty of written versus oral arguments.* Writing mathematical arguments may be genuinely more difficult than presenting orally mathematical arguments, especially for students who were recently introduced to the concept of proof as were the students in this study.

2. *Relative preference for oral versus written expression.* Students may tend to prefer oral over written expression of their mathematical ideas, and so students in the study might have responded in a minimalistic way to the teacher's expectation to produce written arguments for the three tasks (indeed, a didactical contract regarding proof work was not yet established in the class).

3. *Possible role of the specific nature of proving tasks.* The three proving tasks all belonged to a special family of tasks and involved making and proving a generalization by reference to an underlying structure. High linguistic demands are imposed on solvers as they try to express a general argument by reference to a specific diagram that nevertheless exemplifies the underlying mathematical structure; students may be better able to cope with these demands when they express their ideas orally rather than in writing.

4. *Possible influence of the broader social context on students' oral presentations.* Even though almost all of the oral presentations were carried out with no verbal input from others in the class, extra-linguistic forms of expression, notably gestures, might have given to presenters some non-verbal cues (cf. Roth, 2001) that encouraged them to also evaluate or elaborate more on their arguments, thus addressing some of their limitations and elevating their status (cf. Stylianides & Stylianides, 2009).

To conclude, in this paper I have called, and reinforced the need, for more research into factors mediating the relation between students' argument constructions or evaluations and conclusions about students' understanding of proof. Do we, as a field, document an accurate picture of students' understanding of proof? Are findings from different studies in this area comparable with each other?

ACKNOWLEDGEMENT

The research reported in this paper was supported by a grant from the Economic and Social Research Council in England (RES-000-22-2536). The opinions are those of the author and do not necessarily reflect the position or policy of the Council.

ENDNOTES

1. While a written or an oral mode of representation may be used to communicate the bulk of a student's

argument, other modes of representation can also be used alongside this mode. For example, a student who presents orally an argument in front of a class can draw on the board a picture, or write on the board an algebraic expression, in order to supplement the verbal expression of the argument.

2. I do not mention time as a possible reason, for students were given ample time to produce their written arguments. Yet, one cannot completely exclude the possibility that few students recorded in writing their 'exploratory' work and then, during whole class discussion, shifted to a more 'deductive' form of presentation of their finished products.

Considerations on teaching methods to deepen student argumentation through problem solving activities

Tsutomu Ishii

Bunkyo University, Faculty of Education, Koshigaya, Japan, benishii@koshigaya.bunkyo.ac.jp

In this research project we evaluate the Toulmin model to analyse students' mathematical arguments (Toulmin, 2003). We use this method to analyse a teaching episode in which the sum of the interior angles in a five-cornered polygon was discussed. This episode took part in a mathematics lesson in junior high school, Japan. The analysis highlights students' difficulties to understand ideas of their peers, and how these led to an improved level of discussion.

Keywords: Argument, problem solving, Toulmin's model, argumentation, 180(n-2).

THE AIM OF RESEARCH

Teachers promote problem solving in a mathematical lesson. In the beginning of the lesson the teacher introduced the topic to initiate a discussion. In order to achieve the purpose of the lesson, it is necessary for the teacher to evaluate students' arguments correctly. However, it can be difficult to understand students' arguments. The purpose of this research is to examine if the Toulmin model (Toulmin, 2003) helps to gain a better understanding of students' mathematical arguments.

THE METHOD OF RESEARCH

I chose the Toulmin Model as a tool to analyse students' arguments. Toulmin claims that arguments typically consist of six parts: claim(C), data (D), warrants (W), qualifiers (Q), rebuttals (R), and backing (B) (Hitchcock & Verheij, 2006). A typical Toulim diagram to describe an argument may look as follows:

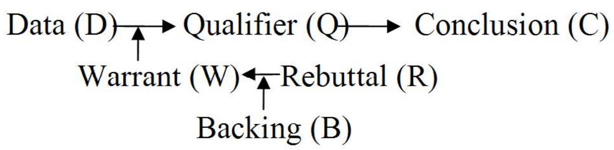

Figure 1: The Toulmin Model

EPISODE

The episode which I describe here took part in a mathematics lesson in the second grade of junior high school in Japan. The topic of this lesson was the sum of the interior angles of a polygon. The teacher's aim was for students to develop the fact that the sum of the inside of an n-cornered polygon is *180(n-2)*.

Individual solutions and preparation of the argumentation are summarized in the following diagrams or comments from students D-G (Figure 2).

D E F

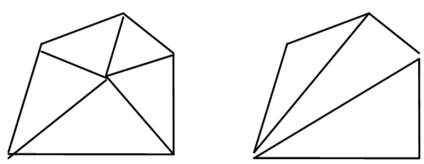

Figure	Triangle	quadrangle	equal form
The sum of angle	180	360	540

G If the number of angles is set to $\chi 180(\chi - 2)$

Figure 2

The discussion leading to this result began with an explanation given by student H. Then student G explained his view which is opposed to H's. His argument showed that H was wrong. From this result the following points can be deduced why the mistake occurred and how correct evidence can be concluded. Student D's figure illustrates a misconception caused by the fact that an additional angle has been constructed in the centre of the pentagon. As student E's figure shows, all the angles are included in the polygon. Therefore this figure illustrates the general formula.

THE CONCLUSION OF RESEARCH

We use the Toulmin Model to describe the arguments of students H and G, as illustrated in Fig 3 and Fig 4 below.

(D) D,E,F,G → (Q) D is right → (C) E is wrong
(W) F and G had the same ideas as E ← (R) 180(x-2)
(B) 360 about 180(x-2) at the time of x=4

Figure 3: Student H's argument described by the Toulmin Model

(D) E is wrong → (Q) E is right → (C) H is a wrong
(W) 180x-360=180(x-2) ← (R) 180-360
(B) 360=180×2

Figure 3: Student G's argument described by the Toulmin Model

H was not able to understand the solution of D correctly. The difficulty to understand the other students' ideas was emphasized in our analysis. And since H misunderstood, G felt excited. Although feeling controlled the understanding to become a new driving force was decided in the restorative. As a result, the quality of arguments improved remarkably.

Unpack and repack mathematical activity with pre-service teachers: A research project

Simon Modeste[1] and Francisco Rojas[2]

1 Université de Montpellier, Montpellier, France

2 Pontificia Universidad Católica de Chile, Santiago, Chile

We present a research project that aims to build a model of mathematical activity that can be used in primary teacher education. This model must be useful both for teacher training and be able to support teachers' practices. We propose the idea of Unpacking and Repacking mathematical activity to achieve this goal.

Keywords: Unpacking, repacking, teacher training, mathematical activity.

CONTEXT, HYPOTHESIS AND RESEARCH QUESTIONS

Assuming that experiencing mathematical activity (MA) is important in learning mathematics, a corollary for mathematics teacher education is that teachers have to be confronted with an authentic MA in order to learn mathematics, to be conscious of its nature and to be able to deal with it at school. By authentic, we mean an activity that is *open* in the meaning that in it, the didactical contract leaves more mathematical responsibilities to the students than classical tasks in the classroom and is closer to the experts' practice of mathematics (mathematicians).

In order to make effective and efficient the opportunities to experience and think about MA in primary teacher training, conceptual and didactical tools are needed. We aim at building such tools, by tackling the following questions: Can a model of MA and a way to experience and think about it can be proposed in primary teacher education? How primary teacher education can include opportunities using this model in order to develop knowledge of the activity? Do such a model and opportunities make primary teachers use MA in their classrooms and help them to deal with it? Does it impact teachers' conceptions about MA or their conceptions about teaching mathematics?

THEORETICAL APPROACHES

Genres

MA involves different genres of activity, that is to say a set of prototypical practices which configure this activity. Research in mathematics education often distinguish mathematizing and modelling; defining; specifying, generalizing and extending; proving (reasoning, demonstrating), among others. Particularly, the MTSK model (Carrillo et al., 2013) develop the knowledge about mathematics as a dimension that is considered as a part of the mathematics teacher specialized knowledge. This dimension includes knowledge of ways of knowing and creating or producing in Mathematics, aspects of mathematical communication, reasoning and testing, knowing how to define and use definitions, establishing relations, correspondences and equivalences, selecting representations, arguing, generalizing and exploring.

Unpacking and repacking

The model we want to develop must be designed to be used by teachers and teacher educators to think about MA when they solve problems or give opportunities to their student do it. We consider as important to deal with deep epistemological aspects of the MA, in the sense that it is fundamental to understand, through a reflexive MA, what are the objects, the objectives, the ways of validating, etc., in mathematics.

This is why we propose, inspired by Martin (2013), the concept of unpacking the MA, which is the work of separating and analysing each part of the mathematical practice and its role and place in the global process of problem solving. Genres would be a first level of unpacking. Besides, repacking is the part of the work that permits to underline the links between the different parts and levels unpacked and understand how they interplay.

We claim that a teacher who can unpack and repack his/her (and others') mathematical work would be better equipped to deal with MA in the classroom.

METHODOLOGICAL PLAN

In order to tackle the research questions, we plan to:

— Build a model of MA and its genres, based on specialized research results on each genre, but also on literature on problem solving, advanced mathematical thinking, Theory of Didactical Situations, or other theories dealing with MA;

— Propose problems that permit primary teachers to experience a MA that can be unpacked and repacked, involving different genres – here, using Research Situations for Classroom (Gravier & Ouvrier-Buffet, 2009) may be pertinent;

— Experiment with mathematicians, mathematics educators, and then with primary teachers to analyse the potential for unpacking and repacking;

— Propose a model of unpacking and repacking and experiment it in primary teacher education with selected and well-tried problems;

— Evaluate the impact on teachers' conceptions about mathematics and its teaching, how they feel prepared and how they manage with MA in school.

How is proving constituted in Cypriot classroom?

Maria Pericleous

University of London, UCL Institute of Education, London, UK, mariapericleous19@gmail.com

This report focuses on a research study the aim of which is to investigate the activity of proving as constituted in a Cypriot classroom for 12 year old students. By drawing on Activity Theory, this study explores the way the teacher is working with the students to foreground mathematical argumentation. Analysis from classroom discussions points toward a teacher-directed mathematical argumentation as an approach to establish justification as a socio-mathematical norm in the classroom

Keywords: Activity theory, proving, socio-mathematical norms.

BACKGROUND OF THE STUDY

In recent years, it has been established that proof and proving should be integrated across all levels of schooling (Hanna, 2000; Stylianides, 2007). In this context, explanation, justification and argumentation are aspects of proof that provide a foundation for further work on developing deductive reasoning and the transition to a more formal mathematical study. In the social environment of the classroom, where hypothesising, explaining and justifying geometric conjectures is encouraged, the tools and tasks used, the rules of the classroom, the way the students work together, the way the teacher negotiates meanings and other external factors all interact, interrelate and influence each other in forming classroom activity. The purpose of the present study is to explore the way the structural resources of the classroom setting shape students' argumentation. Research has responded to the need to conceptualise proof and proving in such a way that is can be applied not only to older students but also to those in elementary school (Stylianides, 2007). The question remains however to understand how proof is constituted in such classrooms.

METHOD

Cultural Historical Activity Theory (CHAT) provides this study with a theoretical basis to steer the identification of forces that interact to shape pre-proving activity in a complex environment. That is, CHAT is used both as a framework for conceptualising the research and formulating the research design. This study was conducted in a year 6 classroom in a public primary school in Cyprus. The content of the curriculum covered during the classroom observations was the area of triangles, and the circumference and area of circles. The overall process of analysis of the collected data was one of progressive focusing. The systematisation of the data led to the evolution of two activities: (i) activity of exploration which is concerned with the degree of exploring mathematics in the classroom. It includes the exploration of mathematical situations and exploration for supporting mathematical connections and (ii) activity of explanation which is concerned with instances of classroom discussion that are related with explaining the purpose of which is to clarify aspects of one's mathematical thinking that might not be apparent to others and, explaining why, that is justification the aim of which is to establish for somebody else the validity of a statement.

FINDINGS AND DISCUSSION

Analysis of the classroom episodes show the teacher frequently using the word 'play'. Two contrasting values have emerged through the teacher's ambiguous use of the term 'play'; play/learn. When providing opportunities for exploration and investigation, the teacher was presenting the exploration constructively as 'play.' The word 'play' had a negative value when the exploration was interpreted as 'play' instead of learning. Closing down a task clashed with the object of the activity of exploration. The use of play highlights a tension between the two activities of exploration and explanation. Exploration was understood by the teacher as worthwhile in order for the students to seek out explanation but at the same time exploration in her eyes might have led to loss of focus, which might have resulted in different activity from explaining. By closing down the investigation, the students did not have the opportunity either to initiate a solution, or to test the hypothesis made, thus limiting their explaining and justifying. The 'play' contradiction relates to the notion of the play paradox (Hoyles & Noss, 1992) and the notion of the planning paradox (Ainley, Pratt, & Hansen, 2006). While a play-like exploration can facilitate learning, it is not automatically clear that it is the teacher who decides what counts as meaningful. Thus, the teacher may find it difficult to take advantage of such opportunities. The teacher had concerns about focus and discipline, which seemed to lead to such closing down. The intention therefore in leading the discussion around justification to establish this as a socio-mathematical norm is comfortably in line with maintaining focus. We might therefore conjecture that the students will have few opportunities in the near future to engage with proving related activity in a more independent way.

Four steps on the way to create argumentation competence supported by technology

Evelyn Süss-Stepancik[1] *and Stefan Götz*[2]

1 University College of Teacher Education Lower Austria, Baden, Austria, evelyn.stepancik@ph-noe.ac.at

2 University of Vienna, Vienna, Austria

Extending the spiral curriculum which is originally focused on content matter areas dealing with typical mathematical activities we create a competence-based four step model to develop arguing. According to the four levels, the use of technology has different purposes: from exploring at the beginning to explaining at the end of the search for mathematical reasons. This cannot only prove but also enlighten certain problem areas.

Keywords: Argumentation competence, use of technology, reasoning, proof.

ARGUMENTATION AND PROOF

The Austrian educational standards for Mathematics at grade 8 define competences such as "*cognitive abilities which are available for a longer time (and the readiness to make use of them)*". Moreover, they define standards descriptors within four content areas and four types of mathematical activities/processes that students should make use of when making use of their content related competence (IDM, 2007). One of these activities is, as with many other mathematical standards *Reasoning and Proof*. To be able to reason and prove requires continuing development. For that we propose to extend the spiral curriculum with its main ideas (revisiting topics, increasing complexity) to typical mathematical activities. Accounting this we generated a four level model to develop arguing on mathematical topics from grade 5 to grade 12.

A competence based four level model for arguing

Based on the forgoing our model includes several levels. All levels can occur in a specific field of arguing. Each level should be dealt with in one particular grade or even across grades.

Level 1 (Disposition): Disposition to engage in mathematical tasks that demand (simple) reasoning.

Level 2 (Comprehension): Ability to understand, comprehend and explain prescribed reasons. An important aspect in this context is to identify the frame of reference.

Level 3 (Communication): Ability to explain and argue completed mathematical proof in communication situations.

Level 4 (Autonomy): Finding a reason for a (mathematical) statement/conjecture, including the choice of the frame of reference, autonomously.

The four levels in a specific field

The Pythagorean Theorem is an example for a broad field for reasoning and proof with various possibilities to use a paper and pencil approach as well as technology. Applets like the one shown in Figure 1 (left) can engage students in reasoning tasks (Level 1) as well as explaining and arguing a proof (Level 3). Figure 1 (right) addresses Level 2.

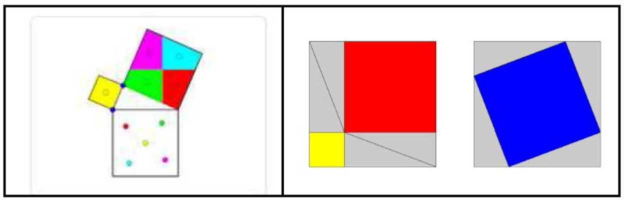

Figure 1: http://tube.geogebra.org/student/b615817#; Proof by Zhou bi suan jing

Here technology fosters the exploration and generation of conjectures.

The four levels across several grades

In grade 6 students explore triangles and construct particular points of a triangle. These points have in-

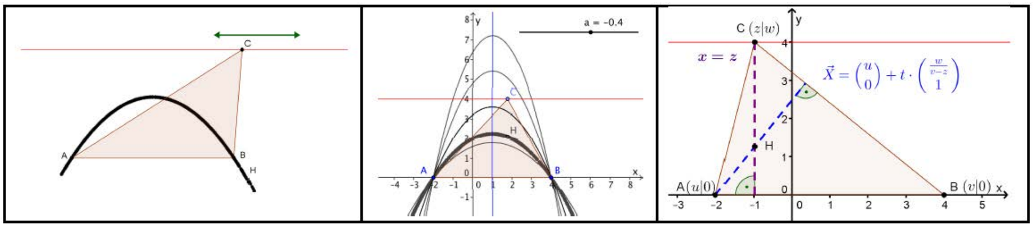

Figure 2: The trace of the orthocentre ***H*** and the embedded triangle ***ABC***

teresting traces under certain conditions. The exploration of the shapes of these traces leads from Level 1 to Level 4 if one starts with the following task (Figure 2): Assume vertex C of triangle ABC moves on a line parallel to AB and observe the trace of the orthocentre H (Figure 2, left). In grade 6 on Level 1 students should explain why the trace of H always intersects the vertices A and B. Here technology helps to explore the phenomenon. In grade 9 and on Level 3 students should find a quadratic function that describes the trace of the orthocentre H, a parabola. Here a slider helps to find the fitting parameter of the function (Figure 2, middle). Also in grade 9 on Level 2 students should understand the analytic description of the trace of the orthocentre H. For that purpose the triangle is embedded in a coordinate system. Here technology helps to see that the movement of C is just a numerical variation of the coordinate z (Figure 2, right). After finishing these levels it is possible to reach Level 4. At this level students should find an analogous result for the circumcenter (low requirement) or the incircle (high requirement).

An example of Proof-Based Teaching: 3rd graders constructing knowledge by proving

Estela Vallejo Vargas and Candy Ordoñez Montañez

Pontificia Universidad Católica del Perú, Lima, e.vallejo@pucp.pe

This study provides an example of what proof-based teaching is and how students of elementary school level can construct their own knowledge about division and divisibility of natural numbers by following this approach.

Keywords: Proof-based teaching, constructing mathematical knowledge, elementary school level mathematics.

BACKGROUND

In the last decades research on the teaching and learning of mathematical proof has substantially increased (Blanton et al., 2011; Reid & Knipping, 2010; among others). In addition to this, there is worldwide a growing tendency to include mathematical proofs in school programs, including at the elementary level, as exemplified by the Principles and Standards for School Mathematics from the National Council of Teachers of Mathematics (NCTM, 2000).

Despite all of this interest, most of the time it is still quite common to find researches focused on mathematical proof as a subject of study and not as a means to contribute to constructing mathematical knowledge. On that subject, Reid (2011) has proposed that proving could be the vehicle for learning new mathematics through what he calls “proof-based teaching”. He tells us:

> We must ensure that we see proof as fundamental to mathematics as a way to develop understanding of mathematical concepts, and as a way to discover new and significant mathematical knowledge. Proof cannot be limited to the format of proofs, and to the role of verification of knowledge (for which there is probably good empirical or other evidence already). (p. 28)

THE EXAMPLE

The work of Ordoñez (2014) was developed with students around 7–8 years old who did not have prior knowledge about division when this research began. This study provides a clear example of what Reid (2011) calls proof-based teaching. In this work, for which Estela Vallejo was the supervisor, Ordoñez shows how third graders are capable of constructing their own knowledge of division and divisibility of natural numbers from the key notion of equitable and maximum distribution, which is understood by students in a natural way. The knowledge construction becomes evident when students are capable of answering problems that demand justifications of their answers. In the process of knowledge construction, it can be seen that students not only participate actively, but are also encouraged to correct their classmates’ or their own answers, refine ideas, suggest conjectures, etc. All of this shows us that it is possible to develop a classroom environment rich in knowledge construction, in which the students experience similar processes to those experienced by professional mathematicians, including especially the process of proving to discover and establish new knowledge.

In this research study two important elements of proof-based teaching are combined: establishing a framework of established knowledge from which to prove, and establishing an expectation that answers should be justified within this framework.

This transcript from the class shows these two elements:

Tutor: Can we have 3 marbles left after a distribution of certain number of marbles among 3 people?

Student 1: No, because you have to distribute the maximum number of marbles.

Tutor: So, does it mean I have not distributed the maximum number of marbles?

Student 2: We can still distribute these 3 marbles! One more for each person!

The tutor's question could be answered with a 'yes' or 'no', but the student provides a justification as well, in keeping with the expectation that answers should be justified. It refers explicitly to the basic notion of maximum distribution, which is part of the framework of established knowledge. The tutor questions whether this basic notion applies in this case, and the second student provides an additional justification, a backing for the use of the basic notion in this case. This way of constructing division knowledge helped these students to realize why they cannot have 3, or a number greater than 3, as a remainder when they are dividing by 3.

TWG02
Arithmetic and number systems

Introduction to the papers of TWG02: Arithmetic and number systems

Sebastian Rezat[1], Lisser Rye Ejersbo[2], Darina Jirotkova[3] and Elisabeth Rathgeb-Schnierer[4]

1 University of Paderborn, Institute for Mathematics, Paderborn, Germany, srezat@math.upb.de

2 Aarhus University, Department of Education, Aarhus, Denmark

3 Charles University in Prague, Faculty of Education, Prague, Czech Republic

4 University of Education Weingarten, Weingarten, Germany

THE FOCUS AND SCOPE OF TWG02

Thematic Working Group 2 focused on six questions related to teaching and learning of arithmetic and number systems from grades 1 to 12:

1) What is the interplay between conceptual understanding and procedural skills for number operations, and how should these two aspects be balanced in the design of learning environments?

2) What does it mean to operate flexibly with numbers, and what knowledge and skills are required therefore?

3) What are the roles of models in teaching and learning of arithmetic and number systems, and how do they support flexibility and conceptual understanding?

4) What are effective approaches for teaching and learning of arithmetic and number systems in inclusive education? How can this content area be taught for students with special needs?

5) What aspects of number theory (including specific reasoning) are supposed to be taught in primary and secondary school, and how can this be done?

6) How is it possible to support and analyze long-term learning processes from grade 1 to grade 12? How can different transitions that come with a long-term learning process be taken into account, especially the primary-secondary transition, but also the secondary-tertiary transition.

NUMBER SENSE, CONCEPTUAL UNDERSTANDING AND FLEXIBILITY

Although it is not mentioned explicitly in the focus of TWG02, the notion of number sense included in most of these questions.

In their paper, Sayers and Andrews remind us that there are very different definitions of number sense. Not only different notions of number sense are used in different domains, but in fact, there are no two researchers who use the same definition of number sense. Sayers and Andrews distinguish three distinct perspectives on number sense, which they label *preverbal, applied* and *foundational*. In their paper, they aim to offer a concise conceptualisation of what they call foundational number sense in a way that would support a range of activities, including developments in curriculum, teacher education or assessment, as well as cross-cultural classroom analyses.

An important issue related to the first question is the role of counting strategies in the development of conceptual understanding of number and operations with numbers. Counting strategies are usually regarded as an intermediate stage in the development of conceptual understanding of number. On the one hand, it is assumed that counting strategies are necessary, but on the other hand, they need to be substituted by other strategies that rely on knowledge about number facts and relationships between numbers. At a certain point counting strategies are even regarded as an indication for mathematics disabilities.

Gaidoschik, Fellmann and Guggenbichler challenge the view that counting strategies are actually a necessary intermediate stage in the development. They investigate how teaching of derivation strategies affects strategy use by first graders. They are able to provide empirical support for the claim that counting-on is not a necessary strategy in the development of conceptual understanding of number and operations with numbers.

Häsel-Weide is also interested in possible ways of substituting counting strategies. Her study focuses on the role of peer interaction in cooperative learning situations that encourage children to pay attention and use number relations as well as relations between tasks and problems. She concludes that it is rewarding for both children in heterogeneous pairs to work together. Additionally, she observed that children rather focus on number relations than on relations between tasks and problems.

The first question also addresses the design of learning environments as an important issue. Nührenbörger and Schwarzkopf tackle this issue related to the conceptual understanding of equations. They investigate the development of a rich learning environment that enable students to access the algebraic meaning of equalities and the equal sign. Furthermore, they argue that a rich learning environment itself does not suffice, and highlight the importance of argumentation in order to foster the learning process.

Veldhuis and van den Heuvel-Panhuizen also emphasize the fact that it is not only the design of learning environments and related activities that foster students' learning of mathematics, but also a matter of classroom assessment. In a large-scale experimental study they are able to provide evidence that teachers' use of classroom assessment techniques in mathematics has a positive effect on students' achievement.

The notion of flexibility in terms of operating flexibly and adaptively with numbers is taken up in the second question. Explicitly or implicitly flexibility is seen as an indicator of what Sayers and Andrews call applied number sense. The papers in this TWG focus mainly on two aspects of flexibility:

— conceptualizing flexibility and adaptivity in mental calculation,

— promoting flexibility in mental calculation.

Rathgeb-Schnierer and Green target to identify degrees of flexibility in students' mental arithmetic by revealing the cognitive elements that sustain the solution process (learned procedures or problem characteristics, number patterns, and relationships). They are able to identify three forms of reasoning: flexible (multiple reasons predominantly referring to characteristics), rigid (one reason referring to a solution procedure) and mixed (multiple reasons when referring to characteristics, one reason when referring to a solution procedure). Furthermore, the results show the tendency that students who refer to problem characteristics in their reasoning seem to be more cognitively flexible.

Serrazina and Rodrigues are also concerned with the notion of flexibility in terms of adaptive thinking. However, their approach is different since they do not regard strategies as the unit of analysis, but quantitative reasoning. They argue that quantitative reasoning underlies the development of flexible calculation because it focuses on the description and modeling of situations and the involved comparative relationships. In a qualitative approach they attempt to understand how children establish a network of connections through their reasoning about different representations of the numbers, and about relationships between numbers and quantities.

Given the importance of the fundamental arithmetic properties for flexible mental calculations on the one hand, and for algebraic thinking on the other hand, Larson aims to better understand how students make sense of arithmetical properties in particular of the distributive property in multiplicative calculations. She analyses students' arguments when they have to evaluate the validity of (wrong) strategies to carry out a multiplication of two two-digit numbers. Finally, she makes inferences from students' arguments to students' understanding of the distributive property.

Besides developing a better theoretical understanding of the notion of flexibility, the issue of fostering the development of flexibility is another important issue related to the second question. Rechtsteiner-Merz and Rathgeb-Schnierer pay attention to the development of flexible mental calculation in less advanced students. In this regard, they investigate the contribution of a specific approach (called "Zahlenblickschulung") to foster the recognition of problem characteristics, number patterns and numerical relationships.

Within a qualitative design they identify different types based on three dimensions: (1) the amount of correct solutions, (2) solution procedures, and (3) related reasoning. They conclude that knowledge of basic facts and strategies seem to be insufficient for the development of a deep understanding of calculation that goes beyond counting. Therefore, the focus on numerical relationships and structures is essential in order to develop flexibility in mental calculation. Their approach of "Zahlenblickschulung" seems to be promising in this regard.

Lübke tackles the issue of estimation as another aspect related to number sense. She investigates fourth graders' conceptual understanding of computational estimation using indirect estimation questions. She argues that the interrelation between an estimate and the exact calculation is not only a very important aspect of understanding computational estimation, but also proved to be a useful tool to analyse students' concept of computational estimation. Her findings indicate that even students who are able to carry out estimations do not necessarily understand the concept of estimation.

Carvalho and da Ponte as well as Almeida and Bruno address aspects of number sense in the domain of rational numbers. Carvalho and da Ponte analyze mental computation strategies and errors of 6th grade students particularly focusing on how they use relational thinking. Based on the theory of mental models they are able to better understand the relation between mental representations and mental calculation strategies and errors respectively.

Almeida and Bruno analyze the effects of an intervention on three abilities of grade 8 students related to number sense in the domain of fractions: the use of benchmarks, the use of graphical representations of numbers and operations, and the recognition of the reasonableness of a result.

THE ROLE OF MODELS

The third question relates to the role of models in teaching and learning arithmetic. The notion of model consciously has been left open. The papers in the TWG mainly address four different kinds of models: models in the sense of manipulatives, models in the sense of visual representations, models in the sense of mental models, and finally, models in the sense of role models.

Hejný, Jirotková and Slezáková offer a theoretical approach to the role of models in the learning process. A process that they call "desemantization" lies at the heart of their Theory of generic models. It describes stages of learning processes in mathematics in terms of two different kinds of mental models, which differ in their semantic embedding: isolated models denote the set of pupils' experiences related to a certain mathematical concept, relationship, or situation, and generic models refer to generalizations of this previous experience. Through an abstraction process the generic model is transferred into abstract knowledge, which does not include the semantic embedding. The ability of pupils to work with models is thus an indicator of their level of understanding of mathematical phenomena.

Finesilver analyzes strategies and errors of S.E.N. students when asked to determine the number of cubes in cuboid blocks made up of multilink cubes. It was intended to evoke the use of different multiplicative strategies by highlighting different structures using different colors. The tasks proved to be a useful tool to understand students' multiplicative thinking in terms of structuring, enumeration and errors.

Hattermann and vom Hofe analyze the effects of a game in the domain of negative numbers on students' performance in tasks with addition and subtraction of negative numbers and students' argumentation schemes. The intention of the game is to foster metaphorical reasoning, which is regarded as crucial for the understanding of negative numbers and the construction of mental models by the authors. First results that are based on a small number of students indicate positive effects on both, performance and metaphorical reasoning.

Pöhler, Prediger and Weinert investigate the influence of different representations (numerical, visual, verbal) in percent problems on students' performance in relation to their language proficiency. Their findings indicate that the difficulties with verbal test items cannot be explained by students' restricted reading proficiency, but rather seem to be a consequence of their lack in conceptual understanding of percentages.

Papadopoulos focuses on the teacher as a role model. He analyses the influence of a teacher's persistent misconceptions on students' performance. The results highlight once more the importance of content knowledge in pre- and in-service teacher education.

SUBJECT-MATTER ANALYSIS

Three papers take the subject-matter and related content knowledge as their starting point. Real and Figueras present a framework of notions, concepts and processes for fractions and rational numbers, which was developed based on Freudenthal's Didactical Phenomenology. The framework is organized according to five classes of phenomena / processes related to fractions: describing, comparing, dividing, distributing, and measuring. It has proved to be a useful analytical tool.

Nicolaou and Pitta-Pantazi evaluate the impact of an intervention, which was based on a framework comprising seven abilities that are supposed to be important for conceptual understanding of fractions in elementary school. They conclude that the intervention had a positive impact on students' understanding of fractions.

Gómez and García carry out a rational analysis of problems with unequal ratios. In the first step, their analysis aims to work out critical components of the problems in order to evaluate them empirically in the second step. Their findings indicate that students do not apply different strategies flexibly when solving the problems, but rather stick to a standard strategy.

OPEN QUESTIONS AND FUTURE DIRECTIONS

Many of the papers in TWG relate to the notion of number sense. Consequently, number sense can be regarded as one of the focal concepts of this TWG. The papers in this TWG have contributed significantly to improve the understanding and applicability of this concept. However, many questions are still open.

First of all, very different conceptualizations of number sense are used in different domains. Whereas number sense in cognitive psychology refers to the innate arithmetic of the human brain, in mathematics didactics it relates to the ability to perceive number relations and to make use of them when solving problems. It seems promising to relate these different perspectives and strive for a comprehensive definition of number sense. Main questions in this context are:

- How is number sense in the didactical meaning related to the innate number sense of the brain?
- How can insights into the innate number sense contribute to the development of number sense in the didactical meaning of the term?

Secondly, the relation between number sense on the one hand and flexibility and adaptivity on the other hand needs to be further clarified. Is number sense conceptualized via flexibility and adaptivity or is it a prerequisite for flexibility and adaptivity?

Finally, it is tempting to use the term number sense related to other number domains than the natural numbers – and some papers in this TWG actually do so. However, it is not clear yet, what number sense means related to these number domains and how it relates to the number sense in the domain of natural numbers.

Important questions related to number sense in every number domain are:

- What influences the development of number sense?
- What is the role of metaphors, manipulatives, models, and mental models in the development of (didactical) number sense?
- What is the role of reasoning and argumentation in the development of (didactical) number sense?
- What is the role of counting in the development of (didactical) number sense?

ACKNOWLEDGEMENT

We thank Véronique Battie (France) for all her work in the preparation of this TWG before the conference. She started as an official group leader, but unfortunately was not able to participate at the conference.

TWG02

Research papers

A study on the changes in the use of number sense in secondary students

Rut Almeida and Alicia Bruno

Universidad de La Laguna, San Cristóbal de La Laguna. Spain, rutalca@gmail.com

Number sense involves the understanding and the ability to use numbers and operations in a reasonable and flexible way. This paper refers to part of a qualitative study that is being conducted to analyse the development of number sense through an intervention designed for this purpose. Our work aims to analyse the strategies used by 8th grade students when solving numerical tasks before and after an intervention. An initial and a final interview were conducted on 11 students to analyse the effect of the intervention on their tendency to use different types of strategies. The results show improvements in the understanding of fractions and on the use of number sense, but also underscore the difficulties still encountered by some students.

Keywords: Number sense, rational numbers, secondary education, strategies.

RATIONALE AND PURPOSE

In recent decades mathematics education has focused on the development of skills that make students competent to use this knowledge in a flexible and justified way. These kinds of mathematical skills include an understanding of numbers and operations and the ability to use them flexibly, exhibiting different strategies for handling numbers and operations, and the ability to evaluate the reasonableness of results, which is commonly called *number sense* (McIntosh, Reys, & Reys, 1992). This term appears in the curricula of several countries and is an important topic to be studied. Research intended to assess number sense in students and teachers in primary and secondary education showed a lack of these abilities (Reys & Yang, 1998; Veloo, 2010; Yang, Reys, & Reys, 2009). Although research indicates this is a problem for many students, there is a minority who made use of number sense. At this point some questions arise: Which of these strategies do they know? Can students learn number sense strategies through a suitable intervention? What changes occur after a classroom intervention regarding the use of number sense strategies?

BACKGROUND

The term number sense refers to a broad set of skills and knowledges, and as such it does not have a closed definition. However, some researchers agree that number sense is recognised in the action itself and that it includes the knowledge and flexible use of numbers, operations and their properties, the use of different strategies to solve numerical problems and being able to recognise the reasonableness of the problem statement and data, the way it is solved and the result obtained (McIntosh et al., 1992; Sowder, 1992). The term number sense is included in the curriculum of different countries, such as Australia, the United States, Canada and Spain, but it seems that this ability is not being sufficiently developed in every country, despite being featured in the teaching objectives.

In an effort to devise a more operational term, there have been attempts to describe it by components (McIntos et al., 1992; NCTM, 1989; Reys & Yang, 1998; Yang, 2003). They all agree on the aspects involved in number sense, though some are more detailed. For this study the framework considered to characterise number sense is composed by the following components: (1) understand the meaning of numbers; (2) recognise the relative and absolute size of numbers and magnitudes using estimates or numerical properties to make comparisons; (3) use benchmarks to estimate a number or magnitude when comparing or doing calculations; (4) use graphical, manipulative or pictorial representations of numbers and operations; (5) understand operations and their properties; (6) understand the relationship between the problem's context and the operation required; (7) realise that there are multiple strategies; (8) recognise the reasonableness of the problem (data, strategies and results).

Research on number sense has focused on evaluating primary education students and teachers (Veloo, 2010; Yang, 2003; Yang et al., 2009), with less research being conducted on secondary education (Reys & Yang, 1998; Veloo, 2010). All of these studies have found that there is a lack of number sense in these groups when solving numerical tasks. A tendency to use algorithms and written computation, and a lack of relationship between good written computations and good number sense have been shown in several studies on high grades of primary education and lower secondary education (Reys & Yang, 1998; Veloo, 2010). In contrast, it was revealed that students with higher academic marks in mathematics performed better in number sense tests (Veloo, 2010) as did those with good mental computation and estimation skills (Sowder, 1992). In an effort to address this situation, interventions to develop number sense have been designed. Markovits and Sowder (1994) established that number sense can be developed, but over a long period of time, and that students, in addition to gaining new knowledge, reorganised prior knowledge. Those studies that included an intervention to develop number sense agree on the idea that activities must contain a process of numerical exploration, the search of number and operation properties and a methodology based on the discussion (Veloo, 2010; Yang, 2003). All of them have shown that this type of learning is more significant than traditional learning and that it is possible to develop number sense and the activities they used for it. These studies only show pre-test and post-test results that enable us to see that the activities worked, but qualitative data concerning the changes in their use of strategies is still needed.

OBJECTIVES AND METHODOLOGY

This work is part of a broader study whose objective is to identify the strategies used by students before and after an intervention to analyse the possible changes in their use of number sense. Since this term encompasses multiple concepts that are developed over the course of mandatory schooling, in this case we have opted to focus our study on three of the lesser studied components in research into this topic involving secondary students. The intervention focused on the development of three components from the framework involving whole, decimal and rational numbers: (3) use of benchmarks; (4) use of graphical representations of numbers and operations; (8) recognise when the result is reasonable. The design was intended to foster these three components, although the use of other components was expected since they are not independent.

The sample consisted of two groups (25 and 22) of 8th grade students (12–13 years old) from a public secondary school in Spain. These students were involved in an intervention designed to develop and encourage the use of number sense. The students' existing knowledge of number sense was in keeping with Spain's curriculum in traditional numerical learning, which at this level involves consolidating students' knowledge of whole, decimal and rational numbers.

Initial test

The students were given an initial written test that included 12 items designed to evaluate the strategies used when facing numerical tasks focused on the use of the three components mentioned above. This initial test revealed the students' shortcomings in the use of benchmarks and in making graphs to aid in estimating numbers and in operations, their preferences for using rules or algorithms, and conceptual errors, especially with fractions (arranging them considering differences between the numerator and denominator, making incorrect graphical representations of fractions and operations) (Almeida & Bruno, 2014). The test yielded background information that was used to design the classroom intervention tasks.

Classroom intervention

The classroom intervention took place over the course of eleven 50-minute sessions and was based on a collaborative environment and on discussions between students of each task. They solved tasks working individually, in pairs, in small groups or as a whole, though always showing the strategies they used so as to discuss them with the rest of their classmates in a final discussion. Since, generally, students tended to use memorized rules, at the end of each task during discussion they were asked to find different strategies in order to explore numbers and find number sense strategies. This methodology allows students to share their knowledge and to discover number sense strategies without the intervention of the teacher/researcher. The students were given written tasks designed by the researchers that were intended to show that an exact answer or calculation is not always necessary to resolve certain questions, to highlight the importance of questioning one's results by evaluating if an answer is reasonable or not, and to develop strategies that involve the use or graphical representations and show the usefulness of taking benchmarks. The tasks themselves involved estimating quantities, sorting numbers and doing operations with whole numbers, decimals and fractions while encouraging debates among the students to find the most suitable strategy.

Interviews before and after the classroom intervention (case studies)

The initial test was also used to select 11 students who were interviewed before and after the classroom intervention with the aim of making a case study of the possible improvement. Both interviews, while designed by the researchers, also relied on previous research (Yang & Huang, 2004; Reys & Barger, 1991). Their aim was to assess the use of the three components being studied. The interviews consisted of two phases. In the first one the students solved all of the tasks without the researcher's intervention. Once they had finished, they were asked to explain each answer by trying to find new strategies without using a written computation method. If they had not used a graphical representation, they were encouraged to find a way to use one. The initial interview had six items and the final one had five. Regarding the analysis of the data from interview, the answers of the eleven students were analysed to identify the correctness (1 for correct answers and 0 otherwise) and the type of strategy used. A category system adapted from Yang and colleagues (2009) was used to classify their reasoning: number sense based (NS), when they used exclusively one or several components of the number sense framework; partially number sense based (PNS), if they combined the use of number sense components by using memorised rules and/or algorithms; not number sense (NNS), when they only made use of algorithms or memorised rules; other (Oth), when students do not provide sufficient grounds to identify the reasoning that led them to the final answer(s); blank (B), when the question is unanswered. The NS and PNS categories also considered the type of component used.

Due to space limitations, in this paper we present the results of one item that was similar in the initial test and in both interviews. This allows us to compare the answers of the eleven students before and after the intervention. Focusing on just one item, we wish to exemplify the type of analysis that we are undertaking. These items were the following: *Initial interview*, "Sort from smallest to largest the following numbers: 2/5, 7/8 and 4/3"; *Final interview*, "Sort from smallest to largest the following numbers: 7/8, 0.3, 4/3, 0.55 and 2/9". We opted for this problem type involving sorting fractions because of the poor results obtained on the initial test, along with the variety of answers given based on rules. It was also presented in the initial and final interviews, and despite having a standard problem statement, it can be solved using the components of number sense that are being studied, which allows us to observe how the students put them into practice. Specifically, the objective of these items concerning the number sense was to encourage students to use benchmarks (component 3) and/or graphical representations (component 4) to compare fractions without the need to use written computation. All of the tasks in the initial and final interviews were designed such that they could be solved using the components in this study. The initial and final interviews were separated by a period of three months. Over this time the students were involved in a classroom intervention. Of the eleven sessions, two were devoted to working on tasks related to the items analysed, i.e. sorting rational numbers. An example of one intervention task is shown below.

The students were given a problem to solve individually for later discussion with the whole group. The statement was: "Sort from smallest to largest the following numbers: 9/20, 8/5 and 3/10". After solving the problem individually, they were asked to present their strategies on the blackboard. In this case the instructor's intervention was not needed and the students found all of the strategies expected: (1) compute the least common multiple to apply an algorithm and express all the fractions with a common denominator; (2) apply the division algorithm to express fractions as decimal numbers; (3) graphically represent the fractions; (4) use the benchmarks ½ and 1 to compare the fractions. The idea was to show every possible way they knew to solve the problem so that the students could see the different possible strategies and be able to choose the one they preferred. In those cases with insufficient variety, they were encouraged to explore numbers in different ways such as understanding the meaning of numbers, the magnitude, use of benchmarks, graphical represention, etc.

RESULTS AND DISCUSSION

The eleven students interviewed answered the two items mentioned above, using different methods when asked to do so. Table 1 shows a summary of the results by the category of the strategy the students used for each task. The number in parentheses shows the component from the number sense framework that they primarily used. The first problem (1st) was the one the students did on their own without the interviewer's intervention, and the rest resulted from asking them to use new strategies to solve the task.

In the answers we find four out of five different categories: *NS*, *NNS*, *Oth* and *B*. A description of the strategies included in each category is presented below. The PSN category did not appear in this item, as the students made exclusive use of number sense components or rules independently, though there were strategies that combined the use of both in other items in the interviews.

Number sense (NS)

Component 1: Using the properties of numbers to express fractions as equivalent fractions or decimals as fractions indicates an understanding of the meaning of numbers. An example of this is provided by student S4, who states for the task in the final interview "(...) we can express decimals as fractions to compare them, for example, 0.3 is equal 3/10 and 0.55 is around ½ (...)".

Component 3: Using benchmarks to facilitate comparisons. The students used different benchmarks, some using more than others to compare against. One example of the use of benchmarks is provided by student S1 who, after the intervention, used four different benchmarks (1, ½, 1/3 and ¼): "7/8 is almost 1, 0.3 is a third, 4/3 is greater than 1, 0.55 is a half and 2/9 is close to ¼".

Component 4: Using graphical representations to ascertain a number's magnitude for comparison purposes, especially for fractions. Figure 1 shows an example from the final interview.

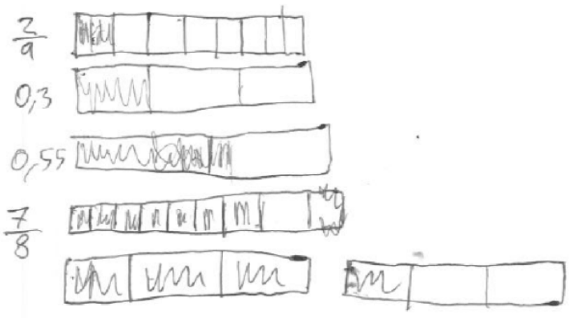

Figure 1: Answer from S2 in the final interview

Not number sense (NNS)

We found two kinds of strategies that made use of rules and/or algorithms. The most common in the initial interview was to compute the least common multiple to apply an algorithm and express the fractions with a common denominator. The other strategy

Student	Initial interview's strategies			Final interview's strategies			
	1st	2nd	3th	1st	2nd	3th	4th
S1	0NS(1)	1NS(3)	0NS(4)	1NS(3)			
S2	1NS(3)	1NS(4)		1NS(3)	1NS(4)		
S3	1NNS	1NS(3)	1NS(4)	1NS(3)	1NS(4)		
S4	1NNS	1NS(3)	1NS(4)	1NNS	1NS(3)	1NS(1)	1NS(4)
S5	0NNS	1NS (3)	0NS(4)	0NS(3)	0NS (4)		
S6	0B	1NS(3)	1NS(4)	1NS(3)	0NS(4)		
S7	1NNS	1NS(3)	0NS(4)	1NNS	1NS(3)	0NS(4)	
S8	0NNS	0NS(3)	1NS(4)	1NNS	1NS(4)		
S9	0NNS	0NS (4)		0NS(3)	0NS(4)		
S10	0Oth	0NS (4)		0NS (4)			
S11	0B	1NS(3)	0NS(4)	1NS(3)	1NS(4)		
0: Correct final answer; 1: Incorrect final answer. NS: Number sense; NNS: Not number sense; Oth: Other; B: Blank. (1) Understand the meaning of numbers; (3) Use of benchmarks; (4) Use of graphical representations;							

Table 1: Strategies classification for the item selected in both interview by student

found in this category was a memorised rule in which they established that a fraction was greater than other if the difference between the numerator and the denominator was smaller, without making sense of the fraction concept and the incorrectness of the rule for cases with different denominators. In the final interview, the most common strategy was to apply the division algorithm to express fractions as decimals.

Other and blank (Oth and B)
Common to the answers in these two categories is the fact that they did not have a justification for the reasoning or, in the case of "Blank", even an answer.

Analysis of the answers
An individual analysis of the students' answers reveals the improvements and/or differences in the use of strategies (Table 1) when solving this item.

NS answers before and after the intervention
Students S1, S2 and S6 used number sense strategies as their initial answers in both interviews, though we observed more confidence in the use of number sense strategies after the intervention, since in the initial interview students argued that they were used to use exact written computation so they were not allowed to use what they named as "logical reasoning" referring to estimates or the use of benchmarks, but in the final interview they made use of number sense strategies without this statement, a hint of changes in the didactic contract during the intervention. S1 used benchmarks and graphical representations correctly in both interviews, whereas students S1 and S6 had problems with the graphical representations of fractions and decimals before and after the instruction. We regard Student 1 as being representative of this group.

In the initial interview, *Student 1* used three different strategies to answer the task, but only one of them was completely correct. In his first answer his reasoning was correct, making use of the fraction's properties to find equivalent fractions, but he made a mistake when estimating the magnitude of 2/5. The student was unable to graphically represent the fractions although he was able to correctly compare them with 1 and ½. After the intervention, the student decided to use this last strategy but in this case using more benchmarks (1, 1/2, 1/3 and 1/4) before stating that he did not know how to represent fractions. This student, although he knew some number sense strategies, did not show any apparent improvement involving the use of graphical representation. He demonstrated a mastery of the use of appropriate benchmarks, even more so after the intervention.

NNS answers before and after the intervention
Students S4, S7 and S8 were characterised by their preference to use rules for the first answer despite knowing other procedures involving either graphical representation or benchmarks. We regard Student 7 as being representative of this group.

Student 7 had similar results in both interviews; in his first answers he gave rule-based reasoning, although in the initial interview this involved computing the least common multiple and in the final one it was related to the division algorithm. For the other strategies used, he followed the same reasoning in each interview, including the use of benchmarks and graphical representations, but although it was correct, he was unable to interpret it. Therefore, the student made no progress in this task after the intervention.

Improvement in NS after the intervention
Students S3, S5 and S11 were characterised by exhibiting a change in strategy between the two interviews toward an improved use of number sense. The case of student 11 is described in greater detail below.

Student 11 used the same strategies in both interviews but with a clear improvement in the second case. Both times she used benchmarks and graphical representations; regarding benchmarks, she exhibited a richer justification in the final interview, choosing two benchmarks (1 and ½), while in the initial interview she said she was not able to do so, and giving more accurate explanations of their comparison; as concerns graphical representations, she demonstrated an improvement in this aspect as well, being able to represent all the numbers. This last improvement is evident since in the initial interview she was not able to represent fractions correctly, dividing the units into unequal portions.

No improvement in NS after the intervention
Students S9 and S10 used incorrect strategies when they attempted to employ improperly memorised rules before the instruction. However, they exhibited a change in intention after the final interview by trying to make sense of fractions and their magnitude instead of using memorized and non-argued

rules. They applied number sense strategies, although conceptual errors related to fractions that remained after the intervention impeded them from obtaining the correct answer. As an example of this group, let us consider the answers given by student 9.

In the initial interview, *Student 9*'s answers demonstrated a lack of understanding of fractions; she applied a memorised rule in which she decided the magnitude of the fractions based on the difference between the numerator and denominator, which led her to an incorrect answer. She also tried to use a graphical representation in which she divided the units without realising that the pieces had to be equal for each fraction. After the intervention, she demonstrated an improvement by attempting to make sense of the strategy used and not applying a memorised rule. She tried to apply the use of benchmarks and graphical representations but the improvement was insufficient, given her misconception of the meanings of the numerator and the denominator: namely, she reversed their meanings (Figure 2).

tions of decimal numbers kept them from obtaining the correct answers (S3, S5 and S11).

As other interventions that aim to encourage the use of number sense have shown, developing these strategies is a long-term process (Markovits & Sowder, 1992). Evidence of this statement is the insufficient improvement of S9 and S10 related with their mathematical misconceptions concerning rational numbers. The use of number sense requires the use of conceptual ideas that, in this case, involve rational numbers, their meaning and properties. Therefore, in cases where misconceptions arise, more time might be needed to develop number sense strategies. These mistakes are particularly evident as they relate to the concept of fraction and to the graphical representations of fractions as a means for obtaining an answer to a problem. Even though not every student showed optimal improvement, some changes were noted as a consequence of the intervention. The results of the interviews led us to delve into the different options students used to obtain an answer: in some cases students used a rule-based strategy, but they were able to use number sense strategies as a second or third option. This flexibility in the use of strategies is one limitation of a written test, since students only show one strategy that conceals the number sense they may possess, perhaps because they think that is what teacher expected or because they feel more confident using written computations.

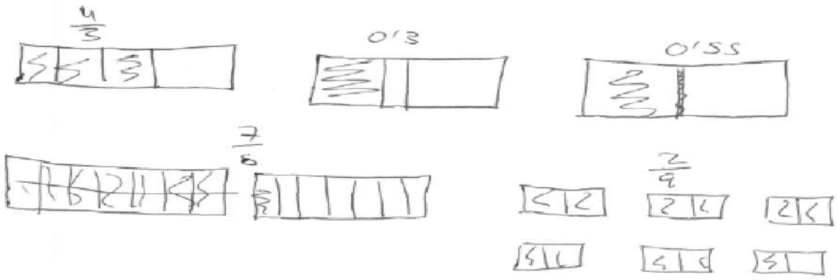

Figure 2: Answer from S9 in the final interview

CONCLUSION

Students who used number sense strategies in the initial interview as their first answer continued to use these strategies, but were more confident using them, knowing that they were allowed to use any strategy they knew (S1, S2 and S6). In contrast, after the intervention some students preferred to use strategies classified as *not number sense* as their first option (S4, S7 and S8). These students expressed a knowledge of other number sense strategies and yet opted to continue with rule-based methods, as they were more at ease with them and because they felt their teachers expected them to use these procedures. There were also students who changed their strategies towards the use of number sense, although in some cases their misconceptions concerning graphical representa-

Student strategies and errors in mental computation with rational numbers in open number sentences

Renata Carvalho and João Pedro da Ponte

Universidade de Lisboa, Instituto de Educação, Lisboa, Portugal, renatacarvalho@campus.ul.pt; jpponte@ie.ulisboa.pt

Mental computation is an important skill for mathematics learning. This paper analyzes mental computation strategies and errors in grade 6 students with positive rational numbers in a teaching experiment based on tasks. The tasks involve the four basic operations and are done in conjunction with a discussion of strategies with the entire class. We focussed on student relational thinking and our findings suggest that open number sentences highlight the meaning of the equal sign and the importance of using properties of operations in mental computation. This is reflected in student's strategies when they use numerical relationships to compute mentally. Mental representations such as propositional representations are strongly linked to strategies based on numerical relationships.

Keywords: Mental computation, rational numbers, student errors, student strategies, relational thinking.

INTRODUCTION

Carrying out mental computation tasks in the classroom helps in the development of important mathematics skills. As Taton (1969) indicates, mental computation develops notions of order, logic, reflection, concentration and memory. It also prepares students for daily life, providing them with tools to perform simple computations without the help of external resources. Former studies (e.g., Caney & Watson, 2003; McIntosh, 2006) highlight the importance of understanding student strategies in mental computation, particularly the numerical relationships they use in solving problems involving rational numbers. This understanding may support teacher planning and teaching activity. This paper is drawn from a teaching experiment based on mental computation tasks involving open number sentences with four operations and the discussion of strategies analyzing mental computation strategies and errors in grade 6 student, focusing on how they use relational thinking.

MENTAL COMPUTATION WITH RATIONAL NUMBERS

Reys, Reys, Nohda and Emori (1995) refer to mental computation as the process of computing exact arithmetic results without external support. In line with this perspective this paper takes mental computation to be the process of computing arithmetic results in a quick and efficient way using number facts (e.g., multiplication tables), memorized rules (e.g., how to multiply by powers of ten) and numerical relationships (e.g., converting between different representations) supported by mental representations (e.g., mental images of fractions or relational thinking based on propositional representations).

The main elements of our framework are the use of (i) number facts; (ii) memorized rules, (iii) numerical relationships and (iv) mental representations (Figure 1).

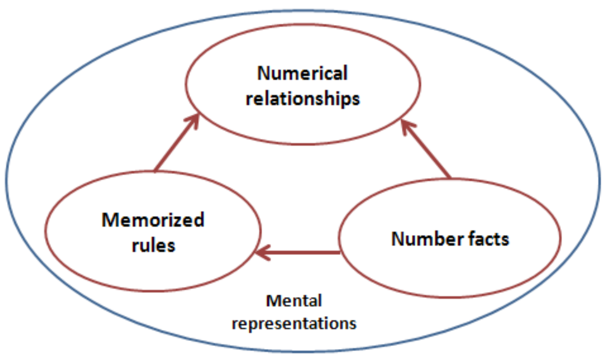

Figure 1: Conceptual framework

To develop mental computation, Heirdsfield (2011) indicates that students need to know number facts but also to understand the size and the value of numbers, the effect of an operation on a number, and to be able to make estimates to check if the solution is reasonable. As computing mentally with rational numbers involves more complex reasoning than computing with whole numbers (Barnett-Clarke, Fisher, Marks, & Ross, 2010), we assume that the use of memorized rules may also support student computation and relational thinking (Empson, Levi, & Carpenter, 2010).

The use of mathematical relationships is evidence of relational thinking. This is related to the capacity to use fundamental properties of operations and the notion of equality to analyse and solve problems. As Carpenter, Franke and Levi (2003) highlight, "many fundamental mathematical ideas involve relations between different representations of numbers and operations on them" (p. 38). From their perspective, the use of open number sentences (e.g., 1/2 − _ = 1/4) may be a viable way to draw a student's attention to relations between numbers and operations and, if students are experienced in looking at these kind of relations, they will be able to use them to compute quickly. For example, if students understand that 3/4 may be split into 3 × 1/4 they quickly compute 3/4 ÷ _ = 1/4. Also, if they understand 10% as a benchmark and know how to multiply/divide by powers of ten, they easily compute 5% by halving or 20% by doubling.

Another important idea to consider in mental computation is the fact that we construct mental representations from the world that surrounds us, which we use in sense making and making inferences. Understanding student mental representations may help us to understand their relational thinking because they use mental representations to relate numbers and operations to their real world knowledge, including knowledge about mathematics. In the theory of mental models (Johnson-Laird, 1990), these mental representations may be mental models, mental images or propositional representations: (i) mental models are generalized perceptions of the world (e.g., using a generalized context of sales to compute 20% of 25); (ii) images involve a more specific perception of a real world where some characteristics are considered (e.g., relating the symbolic representations 1/2 to one part of a pizza divided in two parts); (iii) propositional representations represent true/false propositions that play an important role in the inference process (e.g., to compute 40% of ? = 48, using a sequence of propositions leading to the solution: 'if 48 are 40%, 48 ÷ 4 are 10% which is 12. So, 10% × 10 is 100% and 12 × 10 is 120 which is the missing value').

When students compute mentally, they often make errors that arise from a lack of understanding of rational numbers. This is incorrect usage of the elements presented in Figure 1. Carpenter and colleagues (2003) suggest that such errors may be based on generalizing properties in other situations. For example, knowing that multiplication and addition are commutative may lead students to apply this knowledge to subtraction and division. In adding fractions students often regard them not as a single number but as two separate numbers (Lamon, 2006), thus adding numerators and denominators. As McIntosh (2006) indicates students make conceptual and procedural errors in mental computation. A conceptual error arises when the student fails to understand the nature of the numbers or of the operation involved and a procedural error takes place when the student knows what strategy to use but makes a computation error when putting it into practice.

RESEARCH METHODOLOGY

The study is qualitative and interpretative with a design research approach (Cobb, Confrey, diSessa, Lehere, & Schauble, 2003). This is a developmental study that aims to solve problems identified from practice—the difficulties in learning rational numbers and near absence of mental computation with this number set. It is based on a teaching experiment with mental computation tasks that provide opportunities for discussing student strategies and errors. It was carried out in three phases: preparation; experimentation and analysis. In the preparation phase (2010) a preliminary study in grade 5 was undertaken (conducted by the first author in their classes) in order to collect information on strategies that students use and errors that they make when computing mentally with rational numbers. This showed that practical aspects of students' mental computation practice were potentially important for planning the teaching experiment. Such planning also took into account research on rational numbers and mental computation with rational numbers. In the second phase (2012–13), two experimental cycles were implemented involving two teachers and two grade 6 classes (39 students) from two different schools with the first author as a participant observer. During this phase some refinements were made in the teaching experiment (e.g., changing the sequence of tasks). Data was collected through video and audio recordings of classwork with mental computation and researcher notes. Finally, in the analysis phase, audio and video records of student strategies and errors were transcribed. In this paper we focus on the collective discussions in order to understand student strategies and errors, particularly student relational thinking in questions involving open number sentences. The analysis of student mental computation strategies is carried out using categories taken from previous studies (e.g., Caney & Watson, 2003) and from the concept of mental representations (mental models, images and propositional representations), number facts, memorized rules, and numerical relationships. From these concepts and taking into account the data, three main categories of strategies were defined (numerical relationships, number facts and memorized rules) and in each of these, several subcategories (Table 1). The categorization was made according to the strongest concept involved in student strategy. For example, if there is strong usage of numerical relationships, for example, the part-whole relationship a strategy from the category "numerical relationships" and subcategory "comparison part-whole" was named Mental representations were not considered as a fourth category since they are common to all categories. Thus mental representations were analyzed as a support to student strategies. To analyze student errors McIntosh's (2006) notion of conceptual and procedural error was used. In each of these categories some subcategories are identified as shown in Table 2.

THE TEACHING EXPERIMENT

The teaching experiment relies on the conjecture that a systematic work with mental computation tasks with rational numbers represented as fractions, decimals and percentages, and whole class discussions may contribute to the development of students' mental computation strategies and understanding of their errors. Before the teaching experiment the students had already worked with rational numbers in different representations and operations, with an emphasis on algorithms. The teaching experiment involves ten mental computation tasks (with several number sentences or word problems each) with rational numbers to carry out weekly, all prepared by the first author and discussed in detail with the participating teachers. These tasks (Table 3) were presented at the beginning of a mathematics class, using a timed PowerPoint. The students had 15 seconds to solve each number sentence and 20 seconds to solve each word problem individually, in both cases recording the results on paper.

	Categories		
	Numerical relationships	Number facts	Memorized rules
Subcategories	Equivalence Part-part comparison Part-whole comparison Inverse operation	Two halves make a unit A half of a half is a quarter Two quarters is a half 10% of...	Rule to multiply/divide by powers of ten Rule to add/subtract fractions with different denominators

Table 1: Categories of strategies in mental computation with rational numbers

	Categories	
	Conceptual error	Procedural error
Subcategories	Strong use of additive reasoning in multiplicative problems Ignore the place value in decimal representation Add/subtract numerators/denominator when operating with fractions	Calculation error Solve a part of an expression when a valid strategy is possible to identify

Table 2: Categories of errors in mental computation with rational numbers

Each task has two parts, with 5 numbers sentences or 4 word problems in each part. On finishing each part, there was a collective discussion of student strategies and errors. These mental computation lessons lasted between 30 and 90 minutes. Some examples of the content of the tasks used in the teaching experiment are presented in Table 3. The timed tasks were seen as a way to challenge students to compute mentally. The discussion moments were regarded as the most important part of the lesson, and allowed students to show how they think, the strategies that they use, and the errors that they make. They were important for students to think, reflect, analyze, make connections, share, and extend mental computation strategies, as well as to identify skills that they could develop in numbers and operations.

In the teaching experiment the students began to compute mentally with rational numbers represented as fractions (addition/subtraction in task 1 and multiplication/ division in task 2), then with decimal and fraction representations with the four basic operations (task 3), and then solely with decimal representation (addition/ subtraction in task 4 and multiplication/ division in task 5). Then they solved word problems in measurement and comparison contexts involving fractions and decimals (task 6). The percent representation was used in task 7, as the teacher began working with statistics. Then, students used the three representations (decimal, fractions and percent) in tasks 8, 9 and 10. In task 10, they solved word problems.

The design of tasks is based on three principles, taking into account previous research on mental computation and rational numbers.

Principle 1. Use contexts to help students to give meaning to numbers. Structured knowledge is associated with the context in which it was learned and most of the time it is difficult for a student to bridge this knowledge to new situations. Therefore, number sentences and word problems were used to provide students with a variety of contexts and help them to establish connections between them.

Principle 2. Use multiple representations of rational numbers. Fractions, decimals, and percent representations were used in the same task and in several tasks across the teaching experiment (e.g., , question from task 3). We used even numbers and multiples of 5 and 10, benchmarks such as 25% or 1/2 to facilitate equivalence between decimals, fractions and percent, and to stress numerical relationships (e.g., multiplying by 1/5 is the same as dividing by 5) and part-whole relationships (e.g., if 10% corresponds to 5, then 100% is 10 times bigger). The rational number representation used was related to the topics that students were working on in class with their teacher because the tasks had been integrated into the teachers overall planning. This option provided students with a further opportunity to learn rational numbers on different mathematical topics throughout the mathematics curriculum.

Principle 3. Use tasks with different cognitive demands. For example, taking into account mental computation levels (Callingham & Watson, 2004) tasks in which the students have to use the concept of half to compute (e.g. 50% of 20 or 1/2 + 1/2=_) or need to use more complex numerical relationships (e.g., 20% of _ = 8) to do the computation were designed.

In planning the lessons, we tried to anticipate possible student strategies and errors, to prepare better collective discussions. All classroom activities were led by the teachers with the first author making occasional interventions to clarify aspects related to student strategy presentation.

STUDENT MENTAL COMPUTATION STRATEGIES AND ERRORS

Student relational thinking through their strategies and errors, supported by mental representations in

Think fast! What is the exact value?	
Task 1 :	3/4 - 1/2 = _; 1/2 - _ = 1/4
Task 6:	The area of the base of a cylinder is 4.2 m^2 and the volume 12.6 m^3 Calculate the height of the cylinder.
Task 7	90% of 30 = _
Task 8:	_% of 20 = 18

Table 3: Examples of tasks

open number sentences was analysed. Examples of related questions were chosen (regarding numbers or the numerical relations between them).

In task 1, students were challenged to mentally compute "3/4 – 1/2 = _" and "1/2 – _ = 1/4". These sentences involve two possibilities to reach 1/4. To solve "3/4 – 1/2 = _" Ivo explained: "I made the rule. 2 multiply by 2 gives 4 and then following this I multiplied by 2 also. Then 3 minus 2 is 1. 1/4." Ivo used a strategy based on memorized rules where he applied the procedure to subtract two fractions with different denominators, which may have been supported by a mental image of a written algorithm. Concerning "1/2 – _ = 1/4", we present a dialogue where it is possible to understand Marta's and Rogério's relational thinking and Eva's error:

Eva: I put two quarters.
Teacher: First, Eva will explain to us why she put two quarters.
Eva: Because if we multiply by 2 ... We need to have the same denominator and if we multiply the 2 by 2 it gives us 4. It gives us 4 and then 2 multiplied by 1 gives 2. One quarter ... gives two quarters.
Teacher: Now, you are going to listen to your colleagues and then I will talk to you.
Ivo: Eh, I had a quarter and I crossed it out!
Teacher: Do you think that a quarter is correct Ivo?
Ivo: Yes.
Teacher: Why?
Ivo: Because 2 minus 2 is not one . . . Because following this in the numerator, 2 minus 2 is not 1. If you use two quarters you have to multiply the numerator by 2 and the denominator also, and it is not 2 minus 2.
Teacher: Marta.
Marta: It gives a quarter. I saw that 1/4 + 1/4 is 1/2 then, if we take a quarter from a half, it gives us a quarter.
Teacher: Rogério, did you hear Marta?
Rogério: I put a quarter.
Teacher: Explain your reasoning. Let's see if it's the same as Marta or not.
Rogério: We have a cake. A half of a cake. We ate a half [from this cake] and left only a quarter. So, it is half less a quarter.

Marta and Rogério presented a number fact strategy, but supported by different mental representations. Marta used the number fact "1/4 + 1/4 = 1/2" and the propositional representation: (if 1/4 + 1/4 is 1/2 then, 1/2 – 1/4 is 1/4) to relate this knowledge with the open number sentences that she needed to solve. She applies a property of subtraction (to get the subtractive, we take the difference from the additive). Rogério also used a number fact (a half of a half is a quarter) but he used a mental image ("A half of a cake"; "We ate a half"; "and left only a quarter"). Eva had a strategy to solve the question but she only focused on the fraction equivalent to 1/2 and did not make the subtraction between 2/4 and 1/4 so she made a procedural error. It seems that she was trying to apply the same rule that Ivo used above and a similar mental representation (mental image of a written algorithm). The explanations of Marta and Rogério show that a strategy based on number facts may be supported by different mental representations, probably according to the student's strongest experience. Marta used mathematical knowledge in her propositional representation and Rogério used a real world experience in his mental image, which shows their relational thinking. A student's experience is crucial in defining the mental image that supports their strategies. Rogério used a different mental image from those used by Ivo and Eva. A strong mental image of a written algorithm (like Ivo and Eva used) does not emphasize student relational thinking and may lead them to make some errors (like Eva did) because they are focused on the procedure and not on the relationships between numbers and operations.

In the second part of task 6 students were challenged to compute word problems mentally. To solve the problem shown in Table 3 involving the concept of volume the students could use open number sentences like "12.6 = 4.2 _". To solve the problem Pedro, Maria and Acácio used different strategies supported by propositional representations. They explained: "It gives 3. I divided 12.6 by 4.2" (Pedro), "I didn't divide. I multiplied. I tried to find a number. 4.2 times a number to get 12.6 and I found 3" (Maria) and "It gives 3.3. I divide 12.6 by 4.2. 4 plus 4 is 8, plus 4 is 12. 2 plus 2 is 4, plus 2 is 6" (Acácio). They probably had in mind the open number sentence that we had indicated. Pedro and Maria used relational thinking, taking advantage of the properties of operations (Pedro) and relations between the numbers on each side of the equal sign (Maria). Pedro used the inverse operation strategy and a propositional representation based on the proposition "if 4.2, then ," showing knowledge about the relation between multiplication and division. Maria used an equivalence strategy supported by a propositional representation based on a sequences of true/false propositions where she "tried to find a number" that could make the equivalence true (4.21 = 12.6 (false); 4.22 = 12.6 (false) and 4.23 = 12.6 (true)). Acácio made a conceptual error because he was not able to understand how to give meaning to his result. He identified the correct operation (12.6 4.2 like Pedro did) and used a splitting strategy (separating the integer and the decimal points of the number in order to operate/compare them) but was not able to understand that the relation concerning the whole number must be seen and not each part separately. His strategy may be supported by a propositional representation based on a false proposition: 12 is and 6 is. If 12.6 is "a twelve plus a six" and 4.2 is "a four plus a two" then the result is 3.3, "a three plus a three"). The origin of this error could lie in the additive reasoning used by Acácio. The three students used different strategies but the same type of mental representation in their relational thinking. This suggests that propositional representations play an important role in this process, where different mathematical knowledge must be analyzed and related. Acácio could have achieved success in his relational thinking if his reasoning were more multiplicative and not as strongly additive.

In task 7, students had to compute "90% of 30 = _", which is related to the open number sentence "_% of 20 = 18" from task 8. To solve these sentences, Dina and João used different strategies based on propositional representations. Dina explained: "100% of 30 is 30. 10% of 30 is 3. Then, from 100% to 10% this gives 27". She used a part-whole comparison strategy supported by a propositional representation: (if 100% is 30 and 10% is 3, then 100% - 10% is 90% and 30 - 3 is 27). She used 10% as a benchmark, compared 90% with the whole and removed 10% from 100%. To solve "__% of 20 = 18", João used a part-part comparison strategy and explained: "I saw that 10% was 2. So I divided 18 by 2 which is the same as dividing the total [result 18] by 10% which gives me 9. Then I multiplied 9 by 10 to get 90." He used 10% as a benchmark (like Dina did) and probably, 10% of 20 as a number fact (he did not explain how he computed 10% of 20) to relate part to part based on a propositional representation: (If 10% of 20 is 2 and % of 20 is 18, then ?% / 10% = 18/ 2), He divided 18 by 2 not to "divide the total by 10%" but to relate part to part. He gets 9 and multiplies it by 10 to get 90 because the whole is 10 times bigger than 10%. Dina's and João's strategies show that they understood that the equal sign expresses a relation, an important aspect in relational thinking. Once more, propositional representations seem to play an important role in student relational thinking. The part-whole (Dina) or the part-part strategy (João) used by students requires a systematic analysis of the relation between the whole and its parts which is supported by true propositions. These propositions help students to make inferences about the relationships between numbers and operations on each side of the equal sign.

CONCLUSION

Students' mental computation strategies are mostly based on using equivalence, number facts, operation properties, and part-part or part-whole comparison, supported by mental representations. Their relational thinking is more evident when they use strategies based on numerical relationships. We also identified conceptual and procedural errors (McIntosh, 2006). The source of some of these errors may be a lack of some mental representations as well as a lack of understanding of multiplicative structures, especially in operating with rational numbers. The theory of mental models (Johnson-Laird, 1990) helps us to understand and interpret the mental representations used by students as a support of their mental computation strategies. For example, a strong use by students of mental images of written algorithms suggests a lack of knowledge of relationships between numbers and operations and a poor repertoire of mental representations, obstacles to relational thinking and conceptual understanding. In contrast, as has been shown, the use of propositional representations based on true propositions is evidence of student relational thinking. It highlights student understanding of properties of operations and how they use them to establish numerical relationships and use the equal sign to express relationships between numbers and operations. This was more explicit in sentences like "_% of 20 = 18". Such open number sentences lead students to analyze numbers and operations in a systematic way on both sides of the equal sign as they did in the part-part comparison strategy.

We understand that in analyzing procedural errors students have a viable strategy to compute mentally but a computation error has led them to an incorrect solution. An emphasis on applying memorized rules and procedures based on mental images of written algorithms may also contribute to such an error. Students that make strong use of additive reasoning (as Acácio) make conceptual errors easily as they fail to understand the multiplicative relation that exists in the rational numbers set.

This study provides suggestions for the teachers practice in the classroom in developing student mental computation and relational thinking. It provides information to teachers about the kinds of knowledge that students need and use to compute mentally such as number facts, memorized rules, numerical relationships, and mental representations. It also shows the kind of errors that need to be clarified and discussed in the classroom to improve student mathematics learning.

Spatial structuring, enumeration and errors of S.E.N. students working with 3D arrays

Carla Finesilver

King's College London, London, UK, carla.finesilver@kcl.ac.uk

The move from understanding and working with arithmetical structures in one dimension (i.e. additive) to two or more dimensions (i.e. multiplicative) requires a significant change in children's thinking. This paper investigates the varied and developing strategies and understandings of young people struggling with that change, through a series of 3D array enumeration tasks. Participants relied heavily on counting-based strategies, and a new analytical framework is proposed with which to diagnose initial (mis-)conceptions and observe microprogressions on the path towards multiplicative understanding.

Keywords: Numeracy, counting, arithmetical strategies, multiplicative thinking, low attainment.

THEORETICAL BACKGROUND

2D and 3D arrays

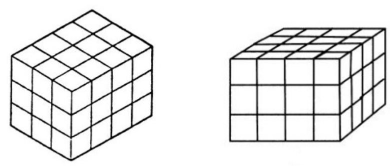
The 2D rectangular array is a standard visuospatial representation for working with multiplicative structures, such as solving simple multiplication and division problems, or connecting replicating spatial patterns with repeated addition and multiplication. By age 11, all students in UK mainstream education will have encountered rectangular arrays (both dots and grids), and these representations linked to multiplication. The 2D array is thought to have particularly good potential for supporting reasoning in multiplication, and is one of the best for demonstrating the commutative and distributive laws (Harries & Barmby, 2007).

While clearly a powerful tool, the 2D array is limited in terms of enumeration. With a 3D array, the options are more complex: when all dimensions are >2 units, simply counting the visible cubes will not work, as there are non-visible interior cubes; successful enumeration must rely on conceptualising the organisational structure of the array as a space-filling object.

While the expected final, formal strategy for students would be a three-dimensional multiplicative formula, on the way to this stage, there are various potential concrete, visuospatial strategies in which the cuboid structure is deconstructed into manageable parts, such as a stack of 2D layers.

An influential series of writings on 3D array tasks (Battista & Clements, 1996, 1998; Battista, 1999) introduced the concept of *spatial structuring,* which I adopt.

> We define spatial structuring as the mental act of constructing an organization or form for an object or set of objects. The process . . . includes establishing units, establishing relationships between units . . . and recognizing that a subset of the objects, if repeated properly, can generate the whole set (the repeating subset forming a composite unit). (Battista & Clements, 1996, 282)



Figures 1a-b: Isometric and perspective cuboid images

Ben-Haim's work during the 1980s on 3D arrays involved students interpreting isometric drawings of cuboids (e.g. Figure 1a), so requiring participants to interpret a pattern of identical rhombuses as a solid object. Thus, his set of proposed error types reflects students' tendency to interact with the presented image as a flat object ("1. counting the actual number of faces showing" (Ben-Haim, Lappan, & Houang, 1985), or to have difficulty picturing the cubes not shown. During the 1990s Battista's research on 3D arrays used line drawings with perspective projection (e.g. Figure 1b). His expansion of the set of error categories

(Battista & Clements, 1996) reflects similar difficulties. Thus, there is impetus to observe the strategies and errors when participants are, instead, simply presented with the solid shape itself.

Counting in multiplicative tasks

The use of counting 'in ones' as a major strategy in additive and multiplicative situations is generally associated with younger children, but persists through adolescence and indeed, adulthood as a supplementary or back-up strategy. However, there is a distinction to be made between retaining counting as a backup, and relying on it as a primary enumeration strategy. Studies (e.g., Siegler, 1988; Geary, Bow-Thomas, & Yao, 1992; Gray & Tall, 1994) indicate that children with arithmetical difficulties are more likely than their typically-attaining peers to rely on counting-based strategies (compared with, e.g. retrieval or derived fact strategies).

Anghileri (1995, 1997) describes a progression in children's counting in multiplicative scenarios, beginning with 'unitary counting', through 'rhythmic counting', to 'skip counting' (or 'step counting'). I propose a refinement: that 'rhythmic counting' is actually made up of two sub-stages, (a) grouping of the numbers and (b) regular rhythmic emphasis of vocalisation or gesture. I use 'grouped counting' for the former, reserving 'rhythmic counting' to describe the specific phenomenon of the musical 'drive' that results from temporally equally-spaced sounds/movements and emphases.

METHOD

The data derive from tasks set during a series of individual or paired problem-solving interviews (with the author), which took place as part of a larger project using microgenetic methods to study emerging and developing multiplicative structure in low-attaining students' use of visuospatial representations. The thirteen participants were aged 11–15, attending mainstream schools in inner London, and identified by their mathematics teachers as numerically weak (compared with peers). All names have been changed.

In each interview, students were presented with a cuboid block formed of multilink cubes, and informed that the blocks were solid, not hollow. The blocks were:

(1) One 3×4×5 cuboid (colours mixed randomly);

(2) One 3×3×5 cuboid (as above);

(3) Two 2×3×6 cuboids, one constructed in three differently-coloured 2×6 layers, the other in six differently-coloured 2×3 layers; students were given the choice which of the two to enumerate;

(4) Two identical 2×2×3 cuboids, both coloured in 2×3 layers; students were asked for the total number of cubes.

The intention was that through these tasks students should come to perceive and use the multiplicative structures inherent in the objects, and their initial and changing conceptualisations could be diagnosed. Specifics of each block were based on the previous observed performances. No time constraint was imposed (actual time varied from 1–15 minutes). If necessary, I provided a series of minimal prompts (described below). Students were allowed to handle the blocks but not pull them apart.

Documentation was via audio recording, photographs, scans of students' papers and observation notes made during and immediately following each interview.

FINDINGS

Task 1: Initial responses

When presented with the first block, all students used counting-based strategies, and all 13 gave incorrect answers. Battista and Clements's analytical categories, while intended for drawn array images, include descriptors also applicable to solids (e.g. "counts outside cubes on all six faces" (1996, 263). However, my students not only made errors in which cubes to count, but in the counting process. Thus one must distinguish an erroneous strategy from errors made in carrying out a correct strategy.

Two students independently made perceptive, effective use of one deconstruction of the array structure, and would have been successful had they not made minor counting errors delivering answers of 59 and 61 rather than 60. With the block on the table, they placed a finger on one of the cubes in the top (4×5) layer and said "1, 2, 3", referring to the touched cube and the two vertically beneath it, then moved the finger along, continuing to group-count threes for every cube in the top layer of 20. It is notable that neither appeared to recognise the set of multiples of three.

Ten of the remaining students began by counting the top layer, then moved onto the other faces of the block, turning it around and attempting to count all the external cubes. Although some students asked for confirmation that the shape was solid as opposed to hollow, their face-based counting strategies nevertheless ignored non-visible interior cubes. Meanwhile, the lack of clear points at which to start and stop counting, and of an obvious 'route' around the six faces, also led to some cubes and/or whole faces being counted more than once, while others were missed. Close observation of gestures and comments indicated that four of the students were attempting to avoid double- or triple-counting cubes, but the other six gave no sign of noticing. The last student unsuccessfully tried to count cubes one colour at a time.

Prompts

If a student was consistently trying to enumerate the squares making up the surface area rather than the cubes making up the volume, I used two prompts: (a) picking up a single loose cube, reminding that these were the items to count; and (b) pointing to a vertex cube, demonstrating how it might be double- or triple-counted. After one or both of these, all students were observed attempting not to over-count edge and vertex cubes. Further prompts drew attention to the layered structure, i.e. the vertical replication aspect of the cuboid shape. The 'layers' prompts were:

> Enquiring how many cubes made up the top layer;
>
> Enquiring how many were in the layer underneath (and, if necessary, the next layer);
>
> Commenting explicitly that all layers contained the same numbers of cubes;
>
> Stating the numbers in each layer in the form of an addition (and, if necessary, supporting or performing that calculation).

Six students responded to one of the first three prompts by stating the number of cubes in each layer and calculating a total of 60, while others heard a full demonstration and gave verbal indications that they understood. One (Paula) gave no such indication that she understood either the addition procedure or its relevance.

One student's response indicates the potential effectiveness of a single prompt.

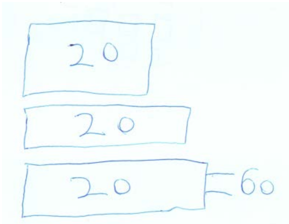


Figure 2: 'Drawers'

CF: How many are in just the top layer?
Leo: *[Step-counts 5, 10, 15, 20]* Ah!
CF: Does that help at all with getting the total number?
Leo: Well now I think I have a solution to this! If you were able to split this, if you chop the layers off, it'll be 20 there – underneath that is another 20, and underneath that is <u>another</u> 20! *[draws Figure 2]* That's 20 there and 20 there. You could just pull it out like a drawer, then pull that out like a drawer. It would be 20, 20, 20.

Task 2

The second interview, I presented a slightly smaller/easier 3×3×5 cuboid. Two students used a full layers strategy correctly, and three others (including Leo) began by stating the number in the top layer, but then needed one or more prompts. Of the two who had used the columns strategy the first time, one reused it, while the other tried horizontal rows instead. Four students reverted to counting around the faces, but switched to layers when prompted. Paula again gave no sign of understanding.

Task 3

So far only four students could carry out effective strategies without prompts; one appeared not to follow even complete demonstrations, and all others were at a stage of partial understanding and operationalisation. Hence, in the third interview I highlighted the physical structure by constructing blocks with each layer a different colour. Rather than force students into a single colour structure (and thus numerical structure), I gave them the choice of two equal-sized blocks: a 3-colour block in horizontal 2×6 layers or a 6-colour block in vertical 2×3 layers. This time 11 students used the layers structure; of these, nine were independently successful, while two required prompts. Only two students' initial response was still face-based, and Paula was for the first time able to comprehend and work through the task (with support). The coloured layers were also indicated to be helpful by student comments, such as "[if there are] 6 cubes there [i.e. in one layer] then you know there's six in the rest".

Task 4

The final interview introduced an additional structural aspect: I presented students with two identical colour-layered blocks, and asked for the total number. With a numerical structure of 2(2×3×3), this task extension allowed increased calculation possibilities for the more confident students. Ten produced a correct answer without any arithmetical or strategic support, and the other three succeeded with prompts. All made clear use of the cuboid structure – in particular referring to the coloured layers.

Regarding the duplicate blocks, five students used some form of layer-organised counting for the first, then continued the count similarly for the second. Two students pushed the two blocks together to make them a single mass. Five worked out there were 18 cubes in the first block and doubled (or added another 18) for the total; one more thought of doing this, but was unsure the two blocks were really the same, and insisted on counting the second as well.

ANALYSIS

The data are considered under three distinct but connected analytical aspects: *structuring* (i.e. how the physical structure of the blocks is used by students, and the corresponding numerical structures drawn from them); *enumeration* (i.e. how students used the numbers they derived from the physical blocks), and *errors* (what went wrong in their invention, selection and application of enumeration strategies).

Structuring

The classification for spatial structuring is based on that of Battista and Clements (1996), adapting their descriptors to apply to actual physical objects, re-ordering them into a loose hierarchy, and expanding the category structure.

Apart from the two C3-strategy students, initial responses to the task lacked awareness of the array structure. Students interacted with one face at a time,

M	**The student conceptualises the set of cubes as a 3D multiplicative structure**	
		Student finds the length, width and height of the block, and multiplies.
L	**The student conceptualises the set of cubes as a stack of 2D layers**	
	1	*Layer multiplication*: Student computes or counts the number of cubes in one layer, counts the number of layers, and multiplies the two.
	2	*Layer addition*: Student computes or counts the number of cubes in one layer and uses addition or step-counting to get total.
	3	*Counting subunits of layers*: Student's counting of cubes is organised by layers, but the student unit-counts or step-counts by a number smaller than the number of cubes in a layer
C	**The student conceptualises the set of cubes as a 2D array of columns**	
	1	*Column multiplication*: Student counts the number of cubes in one column, counts the number of columns, and multiplies the two.
	2	*Column addition*: Student counts the number of cubes in one column and uses addition or step-counting to get total.
	3	*Counting subunits of columns*: Student's counting of cubes is organized by columns, but the student unit-counts or step-counts by a number smaller than the number of cubes in a column.
F	**The student conceptualises the set of cubes in terms of its faces**	
		Student counts one or more faces of the cuboid. They may be counting cubes (partial volume) or counting squares (surface area).
O	**Other**	Student uses a conceptualisation other than those described above.

Table 1: Spatial structurings of a 3D array

failed to coordinate orthogonal views from different perspectives, and in many cases did not even have a complete faces-based conceptualisation (i.e. surface area). All showed increased awareness of structure following prompts, but the amount of prompting required and strategic change observed varied widely. There was a general move from F towards L strategies, as would be expected. Only Paula and one other attempted an F strategy on all occasions, and both could identify and use layers (with colours and prompts) eventually. However, there was no clear trend within conceptualisation types, i.e. from L3 to L2 to L1 (or equivalent).

On finding a successful strategy, some students repeated it, while others tried alternatives. Battista and Clements consider layers strategies an indication of "see[ing] the array as space-filling" and having "completed a global restructuring of the array" (1998, 234), while "Those in transition, whose restructuring was local rather than global, utilized [column-based] strategies . . . They had not yet formed an integrated conception of the whole array" (ibid). It is unclear why a columns-based spatial structuring should be considered any less sophisticated than a layers-based one. The former deconstructs a 3D array into a 2-dimensional array of 1-dimensional stacks, the latter a 1-dimensional stack of 2-dimensional arrays; both are equally valid (and complementary) space-filling conceptions.

Enumeration

The *enumeration* classification is based on that of Anghileri (1997), and may be used in combination with the spatial structuring categories (producing, e.g., C3R).

All students began with some form of counting-based strategy, and overall these were by far the most popular. Four students clearly used multiplication in Tasks 3–4, and there were other instances where language implied multiplicative thinking. However, between unitary counting and multiplication was observed a spectrum of ad-hoc grouped-, rhythmic-, step-counting, and addition, and mixed methods.

1	**Multiplication**	
		Student calculates a total without any interim step-counting.
2	**Step-counting/Addition**	
		Student counts in steps formed of the cardinal number of each layer or column, without any interim numbers (i.e. using a number pattern).
3	**Counting**	
	S	Step-counting (within a layer or face)
	R	Rhythmic counting: Student counts each cube individually, in rhythmically consistent sequence, with clear emphases on cardinal numbers of subgroups.
	G	Grouped counting: Student counts each cube individually, but with the count sequence organised into subgroups.
	U	Unitary counting: Student counts each cube individually, with no grouping.

Table 2: Enumeration strategies for a 3D array

Spatial structuring (SS) Student uses an incomplete or incorrect conceptualisation of the array structure, e.g. double-counting edge cubes, not accounting for interior cubes.
Numeric calculation or retrieval (NC) Student makes an error in calculating or retrieving a number fact while multiplying, adding or step-counting, e.g. "three twelves... 12, 24, 38".
Verbal count sequence (VC) Student makes an error in their counting, e.g. "26, 27, 29, 30".
Visuospatial/kinaesthetic (VK) Student makes an error relating to the physical aspect of counting, e.g. desynchronisation of verbal count and gesture, repeating a layer/column, etc.

Table 3: Types of error in enumerating 3D arrays

Errors

Under the analytical aspect *error* are proposed the four types below, between which are covered all errors observed in this dataset.

SS: Issues of spatial structuring have already been covered. While most students' initial responses to Task 1 involved mis-structuring, there were only nine subsequent SS errors.

NC: On nine occasions, students mis-recalled addition facts and number patterns, or unsuccessfully attempted formal 'vertical' addition notation for the layers; however, the predominant preference of low-attaining students for counting-based strategies meant that recall of arithmetical facts or procedures was not often required.

VC: Students were all confident in their ability to unit-count individual cubes, yet there were examples of missing and repeating a single number, and missing out a decade.

VK: The most common error type, 22 instances were observed. Some appeared related to fine motor skills, e.g. 'jumping over' a cube. Students also skipped rows, layers and faces, lost track of their start point, etc. Spatial structuring affected this error type: end point and rotation issues happen when working on faces, but with a columns or layers conceptualisation, the block can remain immobile throughout.

Issues of classification

The framework above is useful for identifying individual trajectories and group trends. However, there may be issues in identifying strategies used, e.g. with a student who works silently or with minimal gestures, and does not have the verbal skills to explain coherently how answers were obtained. With students who do verbalise their work, there may be inconsistencies between what they report and what is observed. On several occasions, students used language of multiplication (e.g. "it's three twelves"), but employed a counting strategy; they perceived the multiplicative structure yet were unable to carry out the multiplication operation in any other way.

CONCLUSIONS

Students' understanding of multiplicative structures

Contemplating the visuospatial patterns within physical structures can reasonably be expected to increase awareness of the numeric structures embodied within, at both more advanced stages and the most fundamental stages. E.g. the motion required to move a pointing finger to the next row (etc.) causes a pause in the verbal count, naturally grouping the counting sequence and emphasising the last number spoken. Thus even an incorrect faces-based spatial structuring of a 3D array contains enough structure to serve a useful purpose for the very weakest. While one might assume that students' enumeration of arrays stems directly from their spatial structuring, the relationship is bidirectional; enumeration can also guide structuring. E.g., a student better at step-counting long sequences of small steps than adding a short sequence of larger numbers may (sensibly) opt for a C2 strategy, despite perceiving the layers. Students may seize on familiar number patterns; e.g. noticing there were five units in a row, column or stack could make that the salient grouping of the physical/numeric structure. If struggling students have access to more than one potential structuring, they can choose the one that best suits their capabilities and preferences.

Development of strategies over time and in response to prompts

On finding their initial solutions incorrect, one might expect the kind of cognitive conflict which results in reflection and adaptation; this did not happen. Some students immediately started to re-count in the same way as previously, i.e. they believed in the efficacy of their strategy, but mistrusted their ability to have carried it out properly. Some acquiesced to failure, while others were engaged enough to argue and insist their answer was correct. However, none independently responded by thinking critically about the strategy they had used and improving it or attempting an alternative. Strategic progression in every case required external input. I suggest individuals' willingness (or otherwise) to try alternatives is linked to their relationship with mathematics (or school); on finding a successful strategy, arithmetically insecure students cling to it, while security allows for experimentation.

Further reflections

This simple task proved extremely rich in information about the nature of individuals' current multiplicative thinking, the 'gaps' in their multiplicative understanding, and the variety of enumerative strategies in use. Presented with a task that could be solved by counting, but where that counting was non-trivial and non-routine, adolescents had to reconsider this most basic of numerical skills, and how to apply it. Use of task variants with the same students on four occasions allowed tracking of their progression in terms of spatial structuring, enumeration and error patterns.

Although the layered spatial structure of a cuboid seems obvious to a teacher, and indeed, seemed obvious to some students once given a minimal prompt, others struggled significantly to conceptualise the array as a coordinated, space-filling structure. The use of minimal, sequential prompts, along with the introduction of colour-defined structure, demonstrated the variation in how much input and effort it can take for a student to 'see it'. Furthermore, individual students took their own paths from an essentially 2D, faces-based conceptualisation to a coordinated space-filling structure, with paths through layers, columns, rows, stacks, and combinations of these. While the ability to perceive multiple structurings is unnecessary in the short term (i.e. for solution of this particular task), I assert that in the wider scheme, it is mathematically advantageous and to be encouraged.

Computing by counting in first grade: It ain't necessarily so

Michael Gaidoschik[1,2], Anne Fellmann[1] and Silvia Guggenbichler[2]

1 Alpen-Adria-University Klagenfurt, Institute for Mathematics Education, Austria, michael.gaidoschik@aau.at

2 University College of Teacher Education Carinthia, Klagenfurt am Wörthersee, Austria

Regarding first-grade strategy use, counting-on is widely promoted as an alternative to counting-all. However, there are concepts of initial arithmetic education that aim at developing derivation strategies systematically from the outset, skipping counting-on. This paper refers to an ongoing study that provides some empirical evidence in support of the latter approach. Students of four Austrian classes whose teachers participated in a professional development programme designed to promote derivation strategies were interviewed to ascertain their computation strategies at the end of first grade. We present first results comparing them to those of a previous study that, using the same tasks, examined a random sample of children whose arithmetic education followed a distinctly different pathway.

Key words: Counting-on, derivation strategies, difficulties in learning mathematics, in-service teacher education.

INTRODUCTION

In the German-language literature on mathematics education it is widely held that the use of counting-based strategies constitutes "a *necessary* stage in each child's learning process" that "*none* can skip" (cf. Lorenz, 2003, p. 105; our emphasis). Less frequent, but still to be found, are explicit recommendations such as by Schipper, Wartha, and von Schroeders (2011, p. 14) that children first be encouraged to use counting-on rather than counting-all. In the respective English-language literature – as far as we oversee it [1] – similar recommendations are the rule. According to van de Walle (2004, p. 164), counting-on is "the most widely promoted strategy" in the USA. In the UK, Australia and New Zealand the working out and consolidation of counting-on constitutes a central element of national programmes to promote numeracy (cf. e.g. New Zealand Ministry of Education [NZME], 2010). Nota bene: Counting-on is promoted merely as a *transitional strategy*; also, there is broad international consensus that children should *eventually* overcome the use of whatever kind of counting-based strategy (cf. Schipper et al., 2011; NZME, 2010). Reliance on counting to add or subtract in higher grades is considered to be a main characteristic of so-called mathematics disabilities (cf. Häsel-Weide & Nührenbörger, 2013).

It is mainly in view of mathematics disabilities which prompts us to call for a revision of notions concerning counting-on like the ones cited above – knowing that we are not the first to do so. Referring to the state of research we shall set forth that promoting counting-on is by no means *necessary* nor, as we argue, is it *conducive*. We shall then discuss first interim results of an ongoing study that promises to provide valuable empirical material for the further exploration of potential alternatives.

EMPIRICAL AND THEORETICAL FRAMEWORK

The recommendation that early mathematics education should *first* systematically foster counting-on is, as a rule, embedded in developmental models suggesting that numeracy evolves through stages of counting-all and counting-on to finally arrive at fact retrieval (cf. NZME, 2010). Usually such models draw upon, although not always explicitly, Siegler's (cf. 2001) "Model of Children's Strategic Choices".

As for the notion of a quasi-natural sequence of stages it has already been pointed out that at least the last stage, fact retrieval, is obviously *not* achieved by *all* children. What is empirically validated is the first step: Most children are able to solve one-digit additions and subtractions already at preschool age, mainly by counting-all (cf. Verschaffel, Greer, & De Corte, 2007). However, also at an early stage they use other strategies as well, e.g., counting-on, which they often, and prior to any classroom instruction, discover as a short-cut (cf. Baroody & Tiilikainen, 2003). In parallel, or even earlier, many children come to devise strategies using their fingers. Some of these strategies do *not* include counting (see below). Many children do soon retrieve from memory at least single tasks. Already at preschool age, some draw on tasks committed to memory to derive other tasks (cf. Gaidoschik, 2010, p. 332–340). Thus, not only is the *usual development* too varied to be captured by a stage model. It also differs from child to child and, most important, does not remain unaffected by exterior influences (cf. Verschaffel et al., 2007, p. 565). In this light, there is no reason to claim that each step is *necessary*: With influences changing, a different development is at least conceivable. That the strategies pursued by children *usually* also include counting-on does not provide sufficient justification to direct the influence of classroom-instruction towards the elaboration or consolidation thereof.

For such an approach to be justified, counting-on would have to prove *conducive* to overcoming counting strategies. This is what Siegler's model of strategic development suggests. According to Siegler (2001, pp. 377–383), each time a child provides a correct solution by counting, the "bonds of association" between task and solution in long-term memory will get strengthened. As soon as the "associative strength" between a task and the resulting number exceeds a certain value, the child would abandon counting and retrieve the result from memory instead. Counting-on is considered to be instrumental for this process to succeed in that it increases both the probability and speed with which correct solutions are obtained (cf. Schipper et al., 2011, p. 16).

What speaks against this model are empirical findings like those by Gray (1991). Gray's theory of the "proceptual divide" distinguishes between children who come to abandon counting following their recognition of relationships between numbers and numerical operations, and those for which the use of counting-based strategies is rather an obstacle in developing viable concepts. The "schema-based view" proposed by Baroody and Tiilikainen (2003) argues in a similar way, maintaining that the decisive factor in abandoning counting strategies is conceptual knowledge of numbers and operations, i.e., the ability to recognise relationships as a basis upon which to derive tasks from other tasks. Intercultural studies also add evidence in support of the targeted promotion of derivation rather than of counting-on. Geary, Bow-Thomas, Fan, and Siegler (1996), e.g., comparing children in the US with their Chinese counterparts found that on problems up to 20 the latter had by and large abandoned counting strategies already by the end of first grade, whereas the former still used counting on 40 % of tasks by the end of third grade. Those differences certainly ensue, at least in parts, from different teaching traditions – unlike in the US, in China it is common to promote derivation as an alternative to counting from early on. As intervention studies show the learning of derivation strategies based on insight facilitates the abandonment of counting strategies (cf., e.g., Steinberg, 1985). To the same direction points a recent study by Rechtsteiner-Merz (2013) which evaluated a similar teaching conception.

This is further corroborated by a longitudinal interview-based study conducted by Gaidoschik (2010; 2012) which investigated into the calculation strategies of 139 randomly selected children at the beginning, in the middle, and at the end of first grade. A significantly higher share of children who by the middle of the school year had solved a task by derivation did retrieve the same task from memory by the end of the year compared to those that formerly had relied on counting-on. Teacher interviews indicated that in all of the children's 22 classes arithmetic lessons followed a rather uniform pattern in two central respects: derivation strategies were widely neglected, while counting-based strategies were fostered at least during the first term. Against this backdrop, by the end of the year some 27 % of children would work out solutions to problems up to 10 mainly by counting whereas some 33 % would use non-counting strategies (cf. Table 2). These children, except for two, had repeatedly used derivations also in the course of the interviews. Children who predominantly resorted to counting were not observed making use of derivation strategies (cf. Gaidoschik, 2010, p. 438).

Interim conclusion: Studies conducted to date do not allow inferring a *necessity* to pursue counting-on for a considerable period of time. Nor do findings corroborate the thesis that fostering the consolidation of counting-on is *conducive* to overcoming the use of counting strategies. Studies on the relationships between the development of strategies and conceptual knowledge as well as theories derived thereof, in fact, suggest promoting derivation as an alternative to counting-on early in first grade.

PRESENT STUDY

The recent study on which we elaborate in the following may be characterised as an ad-hoc field study designed to investigate a number of questions arising from the findings by Gaidoschik (2010, p. 519–521) as set out above. "Ad hoc" means that the four classes covered by the study had actually been selected to serve another end, notably the conduct of a design study on second-grade teaching of multiplication. Decisive for the selection of classes was their teachers' participation in a professional development programme which is offered (so far without any participation of the authors of this study) in the Austrian province of Carinthia under the name "EVEU – Ein Veränderter Elementar-Unterricht" [2]. As one of its main elements, EVEU recommends the systematic working out of derivation strategies on additive basic tasks in first, and on multiplications in second grade. With a view to optimise the cooperation with the teachers, visits to the four classes were made already at the end of first grade. These included sitting in individual arithmetic lessons and interviewing teachers about their teaching derivation strategies over the school year. Inquiries were made also into children's ways of working out solutions to addition and subtraction tasks up to 20. Both the lists of tasks and the procedure were the same as those administered in the interviews conducted at the end of first grade in the framework of the previous study (Gaidoschik, 2010, p. 237–245). This allows us to compare strategies as applied by two different groups of children at the end of first grade drawing on identical tasks. On the basis of guideline-based interviews with their teachers tentative conclusions may be drawn concerning these children's arithmetic lessons. The overall analysis will particularly be devoted to answering the following questions:

A) During first grade, did EVEU teachers – unlike the teachers of the 2010 study who had not participated in any specific professional development programme – actually work out and consolidate derivation strategies? If so, how, with what intensity and consistency?

B) By the end of first grade, are there any important differences between EVEU children and the sample surveyed by Gaidoschik (2010) regarding the use of calculation strategies? If so, may these differences (also) be attributed to differing teaching concepts?

Sample and design

The sample surveyed for the present study was comprised of teachers and pupils (six and seven-year-old) of four first-grade classes (A-D) from four public elementary schools in Carinthia. The teachers had completed the first year of the EVEU programme (8 half-days) outlined above. The interviews covered *all* children of each class provided firstly that 2013/2014 was actually their *first* school year and secondly they had a *command of the teaching language* – qualifications that had applied also to the 2010 study. In addition in eight cases parents refused to give their consent. Due to these restrictions, the sample covered 11 children (out of 23) from school A, 16 (out of 20) from school B, 19 (out of 22) from school C, and 25 (out of 25) from school D.

The interviews were conducted by the authors themselves in June 2014, towards the end of the school year, in some extra rooms near the classrooms. The children were presented with 22 tasks up to 10 (like 3+4, 3+7, 4+6 or10-9, 7-4, 10-7), and 14 tasks up to 20 (like 6+6, 5+8 or 12-6, 14-9; for more details cf. Gaidoschik, 2010, p. 239–241). Each task was read aloud by the interviewer, at the same time the child was shown the task written on a DIN A7 card. The children were asked to solve the task mentally in the same way as they would usually do and state the result verbally. Immediately thereafter, in case the solution was not provided spontaneously or by using a strategy that could be perceived by observation without any doubt (see below), the child was asked to explain or show how it had obtained the solution.

The video-based evaluation was carried out analogously to Gaidoschik (2010, p. 243–245), i.e. the children's strategies were coded on the basis of the children's utterances, their gestures and facial expressions, and the time needed to produce a solution, as well. The videotapes, without using transcriptions, were analysed repeatedly by one, respectively (in randomly selected 10 % of cases), two members of the interviewing team; disagreements on single codings were resolved through discussion. The main categories that were applied are as follows: *Fact retrieval*, if a correct solution was produced spontaneously (within two seconds); *erroneous retrieval,* if a spontaneously uttered solution was incorrect; *derivation*, if the solution followed an at least short, recognizable reflection and the child described a fitting derivation strategy as his or her solution path thereafter; *counting*, differentiated into counting-all, counting-on and partial finger counting, if fingers were obviously used as a counting-device, or if there were signs of intrinsic counting (nodding of the head etc.) or attempts at using fingers surreptitiously. In the latter case the children were asked to explicitly demonstrate their problem-solving pathway, what they usually did without any further concealing.

We are aware of the flaws inherent in the chosen method (cf. Verschaffel et al., 2007); however, in the absence of a more valid alternative we did our best to classify the children's strategies as appropriately as possible.

First results with regard to participating teachers (cf. question A)

The four teachers stated unanimously that enabling children to compute without counting had been one of their priorities and that they had strived to work out derivation strategies based upon a solid conception of numbers as composed of other numbers. As the main element of classroom practices they referred to classroom discussions, which set the stage for children to put forward proposals as to the most appropriate solution to a task. The teachers also noted that efforts had ever been directed at enabling possibly all children to use non-counting strategies, whereas counting-strategies were not encouraged at any stage of arithmetic lessons.

A content-analytical evaluation of the semi-structured interviews yielded clear evidence of differing intensities and consistencies of the instruction in mainly two aspects. Firstly, with regard to "helping facts" such as doubles (e.g., 4+4=8), ten facts (e.g., 3+7=10), or partitions by the power of five (e.g., 8=5+3), teachers A, B and C stated that, once elaborated, these facts were continuously exercised as an important derivation basis with a view to automatisation. Teacher D, on the other hand, conceded that she might have failed to make sure that these facts were thoroughly known by all children. Secondly, teachers A, B and C made a point of emphasising how essential it was to push children tenaciously, virtually in every arithmetic unit, to explain their solving strategies and again and again put single derivation strategies centre stage. Teacher D reported self-critically, that the effortlessness with which many children went about derivations during classroom discussions, misled her into believing that other children would solve problems in the same way, i.e., by non-counting strategies. Not least, she confessed, did she often feel overtaxed given the rather large size of her classroom (25 children).

First results with regard to the participating children (cf. question B)

Table 1 shows the frequency at which counting strategies were used on problems by the children of the four EVEU classrooms and those surveyed in 2010. In the

	Number of instances in which tasks were solved by counting out of 14 nontrivial tasks with sums/minuends up to 10				Number of instances in which tasks were solved by counting out of 8 problems with one digit-numbers and totals greater than 10			
	mean/ median	standard deviation	min	max	mean/ median	standard deviation	min	max
2010 overall	5.5 / 5	4.6	0	14	3.7 / 4.0	2.6	0	7
2014 class A	0.1 / 0.0	0.3	0	1	0.0 / 0.0	0.0	0	0
2014 class B	0.0 / 0.0	0.0	0	0	0.0 / 0.0	0.0	0	0
2014 class C	1.0 / 0.5	1.6	0	5	0.9 / 0.5	1.5	0	5
2014 class D	1.9 / 1.0	2.6	0	10	1.7 / 1.0	2.0	0	6

Table 1: Problems solved through counting in different groups of students

framework of the 2010 study, a total of 14 problems up to 10 had proved nontrivial, i.e., were known by rote by less than two thirds of children. Table 1 compares means, medians, standard deviations, as well as the minimums and maximums of solutions to these 14 problems as well as to 8 additions and subtractions with one-digit numbers and totals greater than 10 that were achieved by counting-strategies.

As can be seen from Table 1, in the course of interviews conducted in classrooms A and B there was only one single instance of counting-on. In classrooms C and, more significantly, D, besides the vast majority who mostly or entirely used non-counting strategies, there were single children who were still making relatively abundant use of counting. The Kruskal-Wallis test reveals significant differences ($p < .001$) between medians across the five groups of students with regard to both sorts of tasks. Post-hoc pairwise comparisons based upon the Mann-Whitney U test show that in each of the four EVEU classrooms problems from both sorts of tasks were solved by counting to a significantly less extent ($p < .001$) than in the previous sample. Taking into consideration teachers' statements cited above it appears legitimate to draw a distinction in terms of the quality of mathematics education between classrooms A, B and C as a subgroup on the one hand and classroom D on the other. Differences are significant ($p < .001$) also between these subgroups within EVEU classrooms.

With regard to the children's strategy preferences during their first year of school, within the random sample surveyed by Gaidoschik (2010, p. 425–461) six types of strategy development could be distinguished (empirically grounded construction of types, cf. Kelle & Kluge 1999). Given the fact that EVEU children were interviewed only once, assignment to a certain type must be done with caution. Still, it is instructive. Table 2 shows frequencies only of the two types representing the poles in strategy preference at the end of the school year on problems up to 10.

The type "Counting, no derived facts", while not occurring at all in EVEU classrooms A and B, is rare also in classrooms C and D comprising only 5, and 8 %, respectively. In the previous sample, the percentage of children who could be assigned to this type, with solving more than two thirds of problems up to 10 by counting and not a single one by derivation, was about 27 %. In EVEU classrooms A and B, conversely, *all* children belonged to the type "Retrieval and derived facts", i.e., they displayed a high level of retrieval complemented by a flexible use of several derivation strategies. In the 2010 sample, only one third corresponded to this type. In EVEU classrooms, two subtypes could be distinguished within this type – the first being comprised (mostly) of children with a clear prevalence of direct fact retrieval even on tasks involving going-through-ten. Derivation, therefore, was not needed any more in most cases; if, however, it was done quickly and could be clearly explained. On the other hand, there were a few children who frequently resorted to derivation even on tasks up to 10. For a few, this obviously was an arduous process with single derivations taking 30 seconds and longer. Still they would not regress to a counting strategy. These children too were able to provide plausible explanations of their derivation pathways.

In classrooms C (3 children) and D (4 children) a type could be identified that the random sample surveyed in the previous study did not display so distinctly: children who, although not resorting to counting, used fact retrieval or derivation on less than two thirds of tasks up to 10. On the rest they would use non-counting finger strategies – e.g., to figure out the solution to 9-8 they would, without counting, put up nine fingers *in one move* and subsequently, again in one move and with obvious routine, put down eight fingers (four of each hand) to "read off" the result from their finger pattern.

DISCUSSION AND OUTLOOK

The study provides some further empirical support for van de Walle's (2004, p. 164) dictum according to which counting-on "is not necessary if other strategies are used". The EVEU children, according to teachers' statements, had not been encouraged in the classroom

	2010 overall	2014 class A	2014 class B	2014 class C	2014 class D
Counting, no derived facts	27 %	0 %	0 %	5 %	8 %
Retrieval and derived facts	33 %	100 %	100 %	63 %	44 %

Table 2: Distribution of strategy preferences on tasks up to 10 at the end of first grade

to use counting-on as a strategy at any point of time. Rather, and deliberately, computation was addressed only after it had been attempted to consolidate children's conceiving of numbers as being composed of other numbers. From the very beginning, tasks were dealt with in relation to other tasks; relationships were used to derive other tasks. In two out of four classrooms students had almost entirely abandoned counting even on problems with totals greater than 10; in the other two classrooms only one and two children, respectively, relied predominantly on counting strategies. Such level of achievement by the end of first grade is not at all a matter of course – it is at least *this* which can be derived from the comparison with the random sample surveyed by Gaidoschik (2010).

Given the ad-hoc character of the present study, conclusions on the EVEU children's levels of achievement at the *beginning* of first grade must be drawn mainly based on teachers' statements. Teacher A noted that her students were "high performers" in comparison to previous classrooms. Teachers B, C and D described their classes as "average". All the four schools are characterised by a mixed catchment area; socioeconomic backgrounds, however, could not be established for all children. Actually many spheres of influence on children's learning remain largely obscure. While we are far from attributing the children's differing uses of counting/non-counting strategies *exclusively* to the respective classroom practices (which were, moreover, established with limited methods), still we find it plausible that these may *also* have been important.

Evidence of didactically important differences regarding classroom concepts can be found also between the four EVEU classes. Thus, in classroom D both the preparation and reinforcement of derivation was obviously done less consistently than in the other classrooms. This may at least partially account for the significantly higher share of counting strategies use in classroom D. The frequent occurrence of non-counting finger strategies in classrooms C and D, on the other hand, corresponds with teachers' C and D statements that this kind of strategy was explicitly encouraged any time children were observed using their fingers for counting. Whether children who, by the end of first grade, still rely heavily on non-counting finger strategies will in second grade move on to fact retrieval and derived facts strategies; whether this requires targeted support, and what kind of support, are just a few of the many questions we intend to address in a follow-up study.

Implementing the classroom concept set out above was perceived as a great challenge by each of the four teachers surveyed. It is indeed plausible that the larger the classroom and the greater its heterogeneity, the more demanding the teacher's role (cf. teacher D quoted above). This is why we consider it all the more important that teachers in implementing innovative concepts regarding *central* contents of elementary school mathematics be given *long-term* support within the framework of design studies. Professional development programmes, while providing didactic stimuli, cannot, as a matter of principle, translate into a technology. An analysis of teacher interviews against the backdrop of the theory of recontextualisation (cf. Fend, 2006) reveals a mismatch, particularly in case of teacher D, between the knowledge explicated in the EVEU programme and the teacher's implicit knowledge [3]. Such kind of difficulties should not come as a surprise, so this is why expert teachers' visits on a weekly basis form an integral part of the EVEU approach. As to our discipline of mathematics education, we would essentially have to provide scientific expertise to such kinds of measures seeking to work out, together with teachers, solutions to concrete questions arising in the classroom day-by-day and to evaluate the impact of relevant decisions in order to create the basis for the design to be developed further.

Particular attention should be paid to children with learning difficulties. In our study, there were three students in classroom C, and five in classroom D, who had considerable difficulties especially with sums greater than 10. Unable to apply any of the non-counting strategies taught in the classroom, they – as some explicitly admitted – regarded counting strategies as something they were not supposed to use. As a result, they seemingly did not know what to do at all. All teachers convincingly stated that solving tasks by counting had not been *forbidden* at any point of time. Yet, with classroom practices persistently pursuing alternatives to counting, it may be difficult for some children not to think of counting as something they are simply not allowed to do. This might be disregarded if at the same time non-counting strategies were available for all students, which in classrooms C and D was not the case. That for these students counting is a necessity which must not be withheld from them is a conclusion we think is premature – especially in view of the encouraging findings of this study. We do see, however, the need for further development of designs that promote alternatives to counting as a computation strategy from the very beginning.

What is a better buy? Rationale and empirical analysis of unequal ratios tasks in commercial offers contexts

Bernardo Gómez and Amparo García

University of Valencia, Department of didactics of mathematics, València, Spain,
bernardo.gomez@uv.es, garcianadal.amparo@gmail.com

In this work, the comparison of unequal ratios tasks in commercial offers contexts is studied. A rational and empirical analysis of tasks helps to identify the critical components and students responses to each task. The results confirm the deficits in the relative thought of pre-service teachers, and also that their difficulties are not in the algorithmic aspects and "norming" techniques, but in conceptual aspects and ratio referents.

Keywords: Ratio and proportion, relatively, norming, didactic phenomenology.

INTRODUCTION AND RESEARCH OBJECTIVES

"The box of Bites (net weight 16 oz.) costs \$3.36 and the box of Bits (net weight 12 oz.) costs \$2.64. Which cereal is the better buy?". This example is used by Lamon (2012, p. 106) to encourage thinking flexibly in unitizing. Examples of this type involve the comparison of relative quantities, which are ratios, though the explicit formulation of the problem needs a relational term, the word "relatively", to specify the price comparison must be in relation to the weight of the product. The ability to compare the large amounts in this way widens the range of applicability of certain words, such as the word "more" which has two meanings, one absolute or additive and one relative or multiplicative, both of them are correct.

As Streefland (1985, p. 75) says: "In mathematics programs for elementary instruction as far as ratio is concerned, one is often struck by the poverty and brevity of the approach chosen by their authors". The poverty of this approach to ratio can be more generally characterized as follows: the concept building is exercised with mathematical objects unrelated to reality; the lack of real applications, and isolation of the subject "ratio", which is not connected with any other subject.

In this way, Freudenthal (1983) in his didactic phenomenology, highlights the importance of considering ratios in situations in which the idea of "relatively" (or comparatively) and the complex of techniques designated by *norming* are required.

Understanding "relatively" in the sense of "in relation to..." involves the use of the term ratio as Smith (2002, p.14) proposes: "I will use the term ratio to describe a relational number that has two properties: (1) it relates two quantities in one situation, and (2) it projects that relationship onto a second situation in which the relative amounts of the two quantities remain the same". This use of ratio is in accordance with the very meaning of ratio: "to speak about equality (and inequality) of ratios, without knowing how large the ratio is" (Freudenthal, 1983, p. 180).

All of this situates our interest in problems of quantitative comparison of ratios. In particular, in commercial offers comparison, which offer discounts that are given as relative amounts. As a standard norming percentages are usually used to express discounts.

In order to provide relevant tasks for a didactic phenomenology of ratio involving these ideas, a test has been designed. The tasks, which are typical of commercial offers, have been analyzed in a rational and empirical way. This allowed for a better understanding of critical components and their relationship with the response patterns of students.

According to Cramer, Post & Currier (1993, p. 2), "the critical component of proportional situations is the multiplicative relationship that exists among quantities that represent the situation". In the quantitative comparison of ratios problems, the multiplicative relationship that exists between the quantities represented in the situation can be equal or unequal. These multiplicative relationships express relative quantities, that is, quantities put in multiplicative relationship with other quantity of reference. This is usually called "the referent". So, we consider that the critical components (c.c.) in these situations are: not only the multiplicative relationships, but their equality or inequality and their referents.

Note that tasks that have been experimented can be used not only with the intention of assessing knowledge, but also in teaching situations and for teacher training. It allows them to promote the metacognitive reflection about their own cognitive processes and the didactic task complexity and the mathematical contents involved. So, the research questions are: which are the critical components of tasks?, what strategies do the students use?, and what difficulties do the students show?

CONCEPTUAL FRAMEWORK

As we have just said before, comparing relatively is to put something in relation to, and norming is a process of reconceptualization of a system in relation to some fixed unit or standard (Lamon, 1994, p.94). One of the common forms of norming is the unification of the antecedent (numerator) or consequent (denominator) of the ratios to favor the comparison. This can be done by an algorithmic process that links them to the unit (e.g. the unit rate obtained by quotient), the decimal numbering system (percentage or decimal) or equivalent fractions. These techniques connect the various forms of ratio: fraction, decimal, percentage or quotient, and are linked to the flexibility of thinking in order to choose convenience.

The norming techniques are used with the intention to make more visible the comparison of pairs of phenomena that Freudenthal (1983) calls "expositions" or "compositions". When two distinct defined expositions are compared on the same set, e.g., Ω is a set of countries, each with its assigned inhabitants and its area by the ω_1 and ω_2 functions. Then ratio ω_1/ω_2 expresses the population density. Comparison of density couples allows to state whether a country has in proportion to its area the same number of inhabitants or a higher or lower number than another country. In the comparison of two compositions on the same set, e.g., Ω is an alloy composed by copper and zinc to form bronze and each component is assigned a different mass in each alloy by the ω_1 and ω_2 functions. Comparison of the pairs of internal ratios, copper mass/zinc mass, allows one to know which alloy has relatively more, less or the same amount of copper to zinc (Freudenthal, 1983, p. 186).

The "best buy problems" can be interpreted as a pair of expositions or compositions. Under this interpretation, we define the objectives of this study. The first one is to determine, through the rational analysis, the critical components of the tasks such as: the multiplicative relationships, the equality or inequality of ratios and their referents. The second one is to determine, through the empirical analysis, the relationship between these components and students' performance.

METHODOLOGY

The work is based on the methodology of the empirical and rational analysis of tasks. According to Lamon (2007, p. 641), the distinction between empirical and rational analysis is adopted to distinguish between children's mathematics (children's actual performance on tasks); and the exam of content from a mature mathematical perspective, making assumptions about the ways of thinking that are necessary to solve problems. The rational analysis begins at the theoretical level, in order to identify the critical components of tasks and their procedural cognitive and conceptual objectives, to support theoretical inferences from the data obtained in the empirical analysis. The empirical analysis begins with the implementation of tasks given to students in order to interpret their responses. This is taken as criteria for analyzing the critical components identified in the rational analysis.

We choose 4 tasks for a pencil and paper test. They are called Pizza, Beer, Softener and Mosquito repellent. They are realistic tasks taken from offers in current commercial brochures. Due to their typology they are characterized as quantitative comparison of ratios tasks, where one has to judge which of two ratios is higher, lower, or perhaps the same, so you can do it roughly or precisely. Moreover, they may be characterized by their phenomenology as pairs of expositions or compositions involving comparing relatively and applying norming techniques, as Freudenthal says. So, we choose these tasks because they are real applications of ratio and one has to judge equality or inequality of ratios, as Streefland and Freudenthal require. The test was implemented using individual worksheets given to 9 groups of students working in a normal mathematics class time in their second year of the teaching degree, at the beginning of the course (341 students). The study was conducted during 2013–2014 at the University of Valencia.

We select these participants because, according to Ben-Chaim, Ilany & Keret (2002), we think that the pre-service teachers need to improve their knowledge and their attitudes toward mathematics, in general, and all of the components and aspects of ratio and proportion, in particular. And we think that realistic tasks, such as the commercial offers, are suitable for teaching the topic of ratio and proportion in pre-service elementary teacher education.

TASKS

In Pizza, one asks: What is better, two regular pizzas 30cm in diameter for 14.95€ each or a large pizza 50cm diameter for 27.95€? Justify your answer. In Softener, the question is: Which of the two options is more expensive, the concentrate on the left or the non concentrate on the right? Justify your answer.

In Beer, the text says: Usually beer cans are 1/3 liter or what is the same, 33'3cc. One option offers a 15% discount on the price and the other option has 14% more beer. What is more expensive? And, in Mosquito repellent: Fogo and Bloom sell for the same price and have the same volume without any promotion. What discount is better? Explain your answer. Softener and Mosquito are easier than the other two because the text provides all the data needed for doing a correct comparison.

Rational analysis and critical components of tasks

In Pizza and Softener the critical component is the equality or inequality relationship of the two relative quantities. These quantities are given by composed ratios formed by the pair (€, washes) or (€, cm^2). It is required to apply norming by quotient for making the comparison visible. In Pizza, the solution process requires finding the areas and the cost of the pizzas, and comparing prices with areas or vice versa. Alternatively, one can compare areas, prices, and then

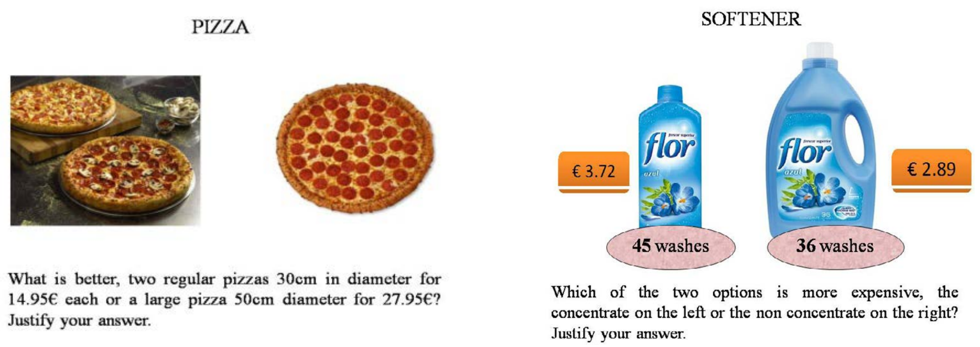

Figure 1: Pizza and Softener

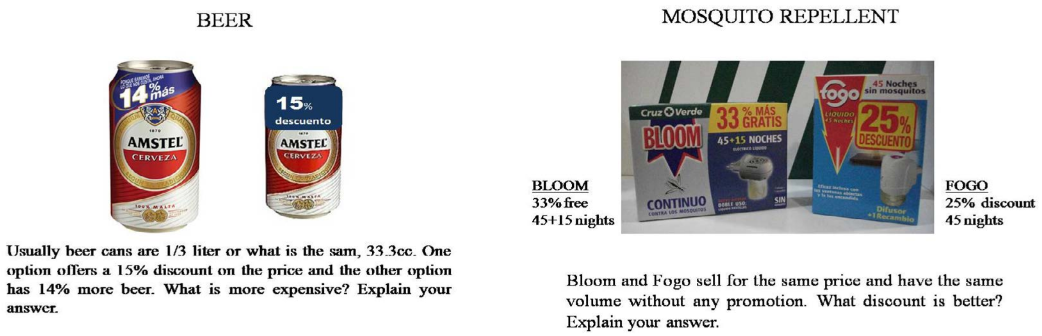

Figure 2: Beer and Mosquito repellent

compare both comparisons. In Softener, the process is reduced to compare the relative quantities €/washes. In Beer and Mosquito, it is needed to convert the gift in a discount or vice versa, i.e., to change one of the two referents. Beer task requires finding the volume of the larger can and calculating what percentage discount is equivalent to the extra volume. Once found, we can compare two discounts. Likewise, the mosquito repellent task requires finding what discount percentage is equivalent to the 33% extra free nights. Once found, you can compare the discount percentage in Bloom with the 25% discounts in Fogo. In both tasks, the reciprocal process (to transform a discount percentage into a gift percentage) is similar.

The processes that account for these transformations, calculations and norming techniques, are displayed in tables from 1 to 6, as pairs of expositions or compositions. In the case of pair of expositions, Ω is formed by the set of offers; and, in the case of pair of compositions, Ω is composed by the parts that form each offer.

As we can see in tables 1 and 2, in comparing norming ratios by quotient, $\omega_1(\Omega)/\omega_2(\Omega)$=cost/cm² or cost/washes, the unit rate (u.r.) or its reciprocal (r.u.r.) are obtained. These comparisons are the main c.c., because they show which offer pays more, less or the same compared to what is acquired (comparing how many € per cm² or per wash). Alternatively, in Pizza, while comparing the internal norming ratios, $\omega_i(\Omega)/\omega_i(\Omega)$=cost

PIZZA \ Ω	Large Pizza	Regular pizzas	Internal comp. →
ω_1: Ω → Cost	$C_L = 27.95€$	$C_R = 2·14,95 = 29.90€$	$\frac{C_L}{C_R} = \frac{27.95}{2 \cdot 14.95} = 0.94$
ω_2: Ω → Area	$A_L = \pi·25^2 cm^2$	$A_R = 2·\pi·15^2 cm^2$	$\frac{A_L}{A_R} = \frac{\pi \cdot (50/2)^2}{2 \cdot \pi \cdot (30/2)^2} = 1.39$
External comp. ↓	$\frac{C_L}{A_L} = \frac{27,95}{\pi \cdot 25^2} = 0,014 \frac{€}{cm^2}$	$\frac{C_R}{A_R} = \frac{2 \cdot 14,95}{2 \cdot \pi \cdot 15^2} = 0,021 \frac{€}{cm^2}$	

Table 1: Couple of expositions. Pizza task

SOFTENER \ Ω	Concentrate softener	Non concentrate softener
ω_1: Ω → Cost	$C_C = 3.72$ €	$C_{NC} = 2.89$ €
ω_2: Ω → Washes	$W_C = 45$	$W_{NC} = 36$
External comp. ↓	$\frac{C_C}{W_C} = \frac{3.72}{45} = 0.082 \frac{€}{wash}$	$\frac{C_{NC}}{W_{NC}} = \frac{2.89}{36} = 0,080 \frac{€}{wash}$

Table 2: Couple of expositions. Softener task

BEER \ Ω	Part free	Part paid	Internal comp. → (increase percentage)
ω_1: Ω → C_L (large can)	$F_L = 14$	$P_L = 100$	$\frac{F_L}{P_L} = \frac{14}{100} = 14\%$
ω_2: Ω → C_S (small can)	$F_S = 15$	$P_S = 85$	$\frac{F_S}{P_S} = \frac{15}{85} = 0,176 = 17\%$

Table 3: Couple of compositions. Beer task

MOSQUITO \ Ω	Part free	Part paid	Internal comp. → (increase percentage)
ω_1: Ω → Bloom	$F_{Bloom} \cong 15$	$P_{Bloom} = 45$	$\frac{F_{Bloom}}{P_{Bloom}} = \frac{15}{45} = 33\%$
ω_2: Ω → Fogo	$F_{Fogo} \cong 11$ (45-25% · 45)	$P_{Fogo} = 34$ (45-11)	$\frac{F_{Fogo}}{P_{Fogo}} = \frac{11}{34} = 33\%$

Table 4: Couple of compositions. Mosquito repellent task

BEER \ Ω	Large can	Small can
ω_1: $\Omega \to$ free part	$F_L = 14$	$F_S = 15$
ω_2: $\Omega \to$ total product	$T_L = 114$cc.	$T_S = 100$cc.
External comp. ↓ (discounts)	$\frac{F_L}{T_L} = \frac{14}{114} = 12\%$	$\frac{F_S}{T_S} = \frac{15}{100} = 15\%$

Table 5: Couple of expositions. Beer task

MOSQUITO \ Ω	Bloom	Fogo
ω_1: $\Omega \to$ free part	$F_{Bloom} = 15$	$F_{Fogo} = 11$
ω_2: $\Omega \to$ total product	$T_{Bloom} = 60$	$T_{Fogo} = 45$
External comp. ↓ (discounts)	$\frac{R_{Bloom}}{A_{Bloom}} = \frac{15}{60} = 25\%$	$\frac{R_{Fogo}}{A_{Fogo}} = \frac{11}{45} = 25\%$

Table 6: Couple of expositions. Mosquito repellent task

regular pizza/cost large pizza, or regular pizzas area/large pizza area, we see that for almost the same price, the large pizza has got more area.

When comparing the norming ratios by quotient, $\omega_1(\Omega)/\omega_2(\Omega)$=free part/total product or $\omega_i(\Omega)/\omega_i(\Omega)$=free part/part paid, after homogenizing the referent with respect to the part paid (h.p., tables 3 and 4) or with respect to the product acquired (h.a., tables 5 and 6) decimals or percentages are obtained. All of these processes are the c.c., because they show which discount or increase percentage are higher, lower or the same.

EMPIRICAL ANALYSIS OF TASKS

The empirical analysis takes into account the response patterns of students in relation to their strategies and their difficulties. Apart from the difficulties related to the c.c. other conceptual difficulties have been observed such as: the linearity (specific of Pizza) and the misinterpretation of the r.u.r. We highlight also two strategies that have appeared in the tasks and they are different from the strategies pointed in tables from 1 to 6.

Most significant alternative strategies and difficulties: Examples

Difficulty in linearity of the unit rate in Pizza task. Students adopt a relative approach, comparing external ratios and applying norming by quotient to obtain a u.r. Rather than comparing prices with pizza areas, they compare prices with pizza diameters (example 1). In this case, the difficulty is in the referent of the relative quantities that they have to compare.

> (14.95/30)·2 = 0.996; 27.95/50 = 0.559. A cm of the large pizza is cheaper. That is, the large pizza is more economical.

Example 1: Student's response to Pizza task

The student compares the relative amounts given by the ratios between the diameters and the prices, i.e. the u.r. of each offer. This strategy could be valid if there was only one item in each offer because more diameter implies more area. Note that the student multiplies the u.r. of a regular pizza by 2 [Regular: (14.95/30)·2=0.996]. This calculation suggests us that he is not aware of the invariance of the ratio.

Difficulty in interpreting the reciprocal of the unit rate. Students adopt a relative approach, comparing external ratios and applying norming to obtain a unit rate, but they interpret the unit rate in the reverse way that corresponds to the stated ratio. In this answer, the difficulty is the loss of meaning of the referent when they apply norming techniques.

> b) 100% - 15% = 85% price → 33cl; a) 14% of 33.3 = 4.662 cl more. 33.3 + 4.662 = 37.962 cl in can A; 33/85 = 0.388; 37.962/100 = 0.3796. In offer B you pay 0.388€ per cl, while in offer A you pay 0.3796€ per cl so that, offer A is cheaper.

Example 2: Student's response to Beer task

The student compares the ratios cc-acquired/percentage-paid and applies norming by quotient: 33/85=0.388 and 37.96/100=0.3796, but interprets these unit rates as what is paid per cc, which is the reciprocal of the ratio: cc acquired per unit paid. This leads to giving the opposite answer expected.

Comparison of quantities of the same nature. This strategy consists of comparing the areas, the volumes, the number of washes, the costs and the percentages among them, and if it is necessary compare the results of these comparisons. They can adopt an absolute approach (not using ratios) or a relative approach (see Table 1, internal comparison). In the first one, the comparison is rough and uses the reasoning: there is more, less or equal in one than in the other. It includes also the usual additive calculations (no example included). The answer may be insufficient (examples 3 and 4), or not (example 5). The second one has been explained above in Pizza.

This student assigns the arbitrary price of 1€ to a 33cc can. Then, the student calculates the larger can volume, 37.96cc, which will cost 1€, and calculates the cost of the smaller can after the discount, 0.85€. Finally, the costs are compared. This data is insufficient to determine which one is the most expensive can.

The student sets an arbitrary price, 10€, then, calculates 33% of 10 and adds it to the price, 13.30€. The student calculates 25% of 10 and deducts it from the price, 7.50€, and compares it with the discount given.

> A large pizza is better because the sum of the area of two regular pizzas is lower and, moreover, is more expensive: $2 \times 30 = 706.5 \times 2 = 1413$ cm^2; $\pi \cdot r^2 = \pi \cdot 15^2 = 706.5$ cm^2; $\pi \cdot r^2 = \pi \cdot 25^2 = 1962.5$ cm^2

Example 5: Student's response to Pizza task. Adequate

The student compares the difference between the areas with the difference between the prices. It is sufficient only in this case because the data favor it.

Cost comparison increasing or decreasing the matching amounts. Students establish the total cost or the cost of a unit of a product. After that, they determine if by increasing or decreasing the amount of the product to match the other you get the same total price. While in the intermediate process students can use relative quantities (example 7), they finally compare absolute amounts. It seems to be that this strategy has not been identified in the previous research.

This student fixes an arbitrary price of 40€ to the non promotional products. He finds the cost of Fogo, 30€ after the discount. Then, he calculates what the Bloom reducing to 45 nights would cost and if it keeps proportionate to their offer price. It is concluded "it is the same because in both of them, 45 nights cost 30€".

A) is more expensive because although there is 14% extra beer, in the other one costs less although there is less beer.

A) 100%→33.3; 14% → x; x=4.662cc 33.3cc + 4.662cc = 37.96cc; 1€→37.96cc

B) 100% →1; 15% → x; x=0.15€ 1 - 0.15 = 0.85€

A) 37.96cc→1€; B) 33.33cc→0.85€

Example 3: Student's response to Beer task. Inadequate

Bloom would have the best discount because the free added percentage implies paying 33% more in the total cost.

(1)10 → 100; x → 33; x = 33·/100 = 333/100 = $\underbrace{\underline{3.30}}_{\text{€ discounted}}$+10 = $\frac{13.30€}{10}$

(2)10 → 10; x → 25; x = 250/100 = $\underbrace{\underline{2.5}}_{\text{€ discounted}}$ 10-2.5 = $\frac{7.50€}{10}$

Example 4: Student's response to Mosquito repellent task. Inadequate

BLOOM	← 40€ →	FOGO	
60 nights		45 nights	40 → 60 → 40·45 = 1800:60 = 30€ x →45
		25% of 40 = 10 40-10 = 30€	Is the same because 45 nights cost 30€ in both of them.
Price 40€		Price 30€	

Example 6: Student's response to Mosquito repellent task

At first glance, it is obvious that the concentrate is more expensive, as it costs 3.72€, which is 0.082cents per cup. On the other hand, the 36 wash product has an added cost of 0.080 for each of the 9 cup difference and results in a price of 3.61€, making it cheaper than the concentrate and therefore, less expensive than the one on the right.2.89/36 = 0.080 2.89 + 0.72 = 3.61; 0.080·9 = 0.72→cup difference from the concentrate.

Left: 45 cups = 3.72. Right: 45 cups = 3.61.

Example 7: Student's response to Softener task

This student finds the difference between the 2 softeners: 9=45-36; calculating both unit rates: 3.72/45=0.082€/wash the concentrate softener, and 2.89/36=0.080€/wash the non concentrate softener, and uses one of them to calculate the total cost that the non concentrate softener would have if there were a 9 wash increase. If he had 36+9 washes, it would cost 2.89+9·0.080=3.60€, which is cheaper than the 3.72€ concentrate.

RESULTS

The absolute frequencies are displayed in Table 7. The columns (from left to right) show: the number of students that use the strategy of u.r., those who have difficulties in this strategy, students who homogenized the referent, the participants who compare the quantities of the same nature, those who use the strategy of cost comparison after matching amounts, and the group of qualitative answers, random, blank, etc (others).

Regarding the critical components of the tasks, we observed that in Beer and Mosquito there are more students who compare absolute quantities instead of relative quantities. Nevertheless, in Pizza and Softener tasks the contrary occurs. Moreover, there are very few students who homogenize the referents (4 in Beer, 2 in Mosquito). They may not interpret the gift like a discount or vice versa. It highlights how students are inclined to calculate the u.r. although it is not needed in this case. If we focus on the strategies and difficulties identified, in Pizza there are few students who calculate the u.r. or its reciprocal without difficulties because of the linearity. In fact, 175 students calculate the u.r. with the diameter instead of the area. In contrast, in Softener the u.r. strategy dominates as we expected. Only 23 students show difficulties calculating the r.u.r. Finally, there are students who give blank, random, qualitative or incomplete responses, especially in Beer (82 students) and Mosquito (44 students).

CONCLUSIONS

Predominance of the unit rate strategy in Beer and Mosquito tasks can be due to the lack of flexibility and the application of a mechanical rule learnt at school. The use of this strategy implies to assign an arbitrary price although it is not needed. It does not imply that their responses are wrong, but it is an indicative of a price-dependence attitude. Note that, there are other more efficient strategies. In addition, resistance is also observed in accepting that an increase percentage can be interpreted as a discount and vice versa. Moreover, there are students who misunderstand the r.u.r., suggesting a mechanical knowledge of the rule. Finally, the use of linearity is widespread in Pizza, and very few students perceive the invariance of the ratio calculating the u.r. of two regular pizzas instead of the u.r. of one regular pizza. They do not realize that both of them are equivalent.

These results confirm the deficits in the relative thought of pre-service teachers, and that, according to Ben-Chaim, Ilany & Keret (2002, p. 81), their knowledge is frequently technical, unrelated and incoherent. Moreover, the difficulties shown by the

Strat. / Task	Unit rate		Difficulties with u.r.		h.p. o h.a.	Same nature		Matching amounts	Others
	u.r.	r.u.r.	Recip.	Linearity		Absolute	Relative		
Pizza	13	1	2	175	-	87	1(lin.)	42	20
Softener	215	5	23	-	-	41	1	33	23
Beer	103	3	16	-	4	113	-	20	82
Mosquito	107	2	11	-	2	168	-	7	44

Table 7: Tasks' results

students are not the algorithmic aspects and norming techniques, but in conceptual aspects, ratio referents and the "price-dependence" when they are comparing discounts in commercial offers. The next step is to design a teaching sequence that helps the students to widen their knowledge of ratio and, according to Lamon (2012, p. 107), to help them to develop flexibility in situations like the best buy problems, to encourage multiple correct strategies and to discuss which strategies are easier, faster or more reasonable.

Replacing persistent counting strategies with cooperative learning

Uta Häsel-Weide

University of Siegen, Siegen, Germany, haeselweide@mathematik.uni-siegen.de

Persistent counting strategies often come along with a weakness in arithmetic. Due to this, the central objective is to replace counting strategies by teaching how to realize, recognize and use structures. Within the context of the project ZebrA1 (Zusammenhänge erkennen und besprechen – Rechnen ohne Abzählen) cooperative learning settings were developed to encourage children to use different interpretations of patterns and structures instead of counting. Results show that working in pairs of children with heterogeneous competences is productive for both partners. Especially activities like "comparing" and "sorting" are suitable to make children interact about mathematics and help them become aware of mathematical structures.

Keywords: Counting, cooperative learning, difficulties in learning mathematic, design research.

INTRODUCTION

Meta-analysis verified that forms of cooperative and peer-assisted learning at elementary schools go hand in hand with stronger effects in content knowledge than in traditional forms of teaching (Rohrbeck, Ginsburg-Block, Fantuzzo, & Miller, 2003). The learning performance of children with learning difficulties improves especially in well-structured, heterogenous and tutorial learning environments (Gillies & Ashman, 2000). Research also seems to show that children with difficulties in learning mathematics can profit from cooperative learning. For that reason cooperative learning is chosen for an intervention intended for children who use counting strategies as a persistent strategy. It is well known that persistent counting is one of the central symptoms of weakness in arithmetic. It is thus necessary for further success in mathematics that children replace counting strategies with mental computation and the use of adaptive strategies.

This paper intends to show how learning environments could be of such design that all children profit from cooperative situations. On the one hand children with a weakness in arithmetic get a first understanding of mathematical structures and relations which are important to replace counting strategies (Häsel-Weide & Nührenbörger, 2013). On the other hand children who already use mental computation and adaptive strategies can deepen their knowledge and improve their competences in verbalising and reasoning. Working together in pairs of children with heterogeneous competences may be a chance for both of them.

THEORETICAL UND EMPIRICAL STARTING POINTS

Replacing persistent counting strategies

The central symptom for a weakness in arithmetic is the persistent use of counting while problem-solving. Children who use counting as a main strategy in grade 2 and beyond often develop wide problems in mathematics since counting is not a calculation strategy that can be built up to work in higher number spaces. Besides, persistent counting often comes along with a mechanical, non-reflected procedure as well as isolated problem solving. There is a risk that the missing insights evolve to comprehension problems in mathematics education.

To replace persistent counting strategies children have to develop alternative strategies like mental computation or the use of derived-fact strategies. Most importantly an understanding of numbers and operations has to be built up which than can be followed by exercises to memorize the central problems. Fostering

1 Recognizing and speaking about connections – calculating without counting on

children in replacing persistent counting strategies should enable them to represent numbers and operations and imagine them as well as to recognize and use the relationship between numbers and problems. The central objective is also a comprehensive structural view on numbers and operations. This means in effect that those children who have problems in recognizing structures need to be enabled to see them. In practice children with persistent counting strategies should be enabled to realize, decompose, represent and describe numbers as structured quantities. The following four aspects characterise the comprehensive objective: (1) The ordinal conception of numbers – which often comes along with counting procedures – needs to be complemented by a conception of quantities; especially the part-whole-concept needs to be understood. (2) Counting in ones needs to be extended with counting in steps and furthermore be used to identify quantities. (3) Children need to figure out that addition and subtraction come along with changes of quantities. In a fourth step based on this, (4) basic problems can be memorized and first relations could be used in calculation (Häsel-Weide, Nührenbörger, Moser Opitz, & Wittich, 2014). All mentioned aspects are not "extraordinary" ones as they contain competences that are essential for all pupils to be achieved during the first years in elementary school. The competences are so fundamental that they are taught not only in grade 1 but are continuously taught and extended on in the next grades of primary school. The respective lessons are suitable for cooperative learning because children with heterogeneous competences can work on the same contents but on different levels of understanding. In this setting, children with persistent counting strategies can profit from the work of their partner that might probably be different, more elaborated and structure-focused.

Therefore the learning environments need to be designed in a way which allows working at various levels. In addition the children should be motivated to recognize and talk about the mathematical structures.

Cooperation and interaction in mathematics education

As mentioned above, cooperative learning seems to be a successful teaching method. This is true especially for forms of cooperative learning which are strongly structured and use clear and common methods (Tarim & Akdenzi, 2008). Nonetheless the way children interact in cooperative situations is vitally important. The success of cooperative learning seems to depend on interaction activities like verbalising, defending, asking and arguing (Pijls, Dekker, & van Hout-Wolters, 2007). Learning opportunities occur for children if they interpret actions and comments of others.

Children need to learn to communicate about mathematics, to describe their solution process, to defend their ideas or to question the idea of another child. In classroom interaction as well as in cooperative learning (young) pupils may need the moderation of the teacher. Teachers are invited to ask open questions and give children the opportunity to show their insights and perceptions. The best way to support the cooperation process of students is to give them help in structuring the cooperative process instead of supporting the finding of the (right) solution (Dekker & Elshout-Mohr, 2004). Teacher activities should lead children to stay and participate in discussions and support them to disagree with each other (Wood, 1999).

All in all for the designing of cooperative learning environments it is also important that the tasks and the methodical setting initiate different perceptions which will be communicated between the children. The methodical setting of cooperative learning needs to be complemented by a content structure in the tasks encouraging different views. In order to replace counting strategies and focus on relations between numbers and operations cooperative learning environments need to initiate different perspectives of numbers, number representations and operations.

DESIGN OF THE STUDY

The present study is a part of the project ZebrA (Zusammenhänge erkennen und besprechen – Rechnen ohne Abzählen). It combines the design of learning arrangements and the empirical research of the interaction and learning processes that can be reconstructed when children work in their environments. In that way the design of the study follows the idea of mathematics research as design science (Wittmann, 1995) and comes along with many elements of design research (Gravemeijer & Cobb, 2006).

According to the idea of design science 20 lessons – cooperative learning environments – have been constructed to foster children in replacing persistent counting strategies (Häsel-Weide et al., 2014). The learning environments focus on an understanding, demonstration and imagination of numbers and operations as well as on realizing the relations between them. The children learn the cooperative methods by working in the learning environments.

The environments are used at the beginning of grade 2 in primary school (ages 7 and 8) or grade 4 in special education schools. This period seems to be a proper time for two reasons: (1) In Germany the children in grade 1 work with numbers up to 20, figure out relations between those numbers and add and subtract with numbers up to 20. Obviously, children are allowed and encouraged to make experience with higher numbers, but according to the German curriculum the number space is opening up to one hundred at the beginning of grade 2. Here children orientate themselves in the new number space, they work with representations of numbers and focus on the relations between them. These contents run in parallel to a deeper understanding of numbers and operations in the lower number space. (2) The limits of counting strategies become very obvious when children operate with numbers up to one hundred. If the familiar counting strategies become exhausting, children can easily be encouraged to try an alternative strategy (Gaidoschik, 2012).

The study was realised from September to December 2010. All children of the class are taking part in the lessons. Each child who uses counting as its main computational strategy works with a partner who uses different strategies. The pairs are put together by the teachers considering their own estimation of children`s competences and strategy utilization, as well as the results from a test that was developed, realized and analysed in the scope of further researches of the project ZebrA.

The project is accompanied by two empirical studies which allow focusing the replacement of persistent counting strategies from different empirical points of view. Whereas the quantitative study researches the effects of cooperative fostering the study presented in this paper focused on the interpretations of children dealing with the problems and discussing with the partner. We are interested to explore if and how children using counting strategies can be encouraged to consider and use mathematical structures. Therefore the work of five children using counting strategies as persistent computation (three boys and two girls) and their partners – belonging to four different classes and three schools – was video-graphed in ten lessons of the ZebrA-project. Corresponding transcripts have been made and interpreted by a group of researchers. The analyses has been compared in an interactive way with empirical findings of other studies and theoretical approaches (Häsel-Weide & Nührenbörger, 2013). Only the results are presented in this paper.

SELECTED RESULTS

Learning environments

In the tradition of mathematics education as design science the designed arrangements are central part of research output (Wittmann, 1995). So the design principles are pointed out below and it is shown exemplarily in which way they become apparent in the learning environments.

Structure-focused view on numbers and operations

To replace counting strategies children need – among other things – to figure out that operations change quantities. Subtraction needs to be understood as taking away or determining the difference. To help children build up this idea a transparency is used (Figure 1). The transparency allows covering an amount of dots at one go. So subtraction in the model of taking away is linked with the action of "covering" and not by "counting" (back).

The transparency can be used to cover concrete dots or dotfields which allows finding the difference by a quasi-simultaneous determination of the uncov-

Figure 1a & b: Representation of 15-5=10 and 35-5=30 ered dots. The children are taught in two learning environments to handle the transparency. First, in a dotfield only the ones are covered, so that problems, e. g. 25 – 5 = 10, are represented and solved. In this environment called "subtraction to tens" we focus on the decimal structure of the number systems. The children may realize that these types of problems are easy to solve and that they can manage them without counting – even in higher number spaces. In a second learning environment other "easy" subtraction problems, e.g. "minus 1", "minus 10", "minus tens" and "minus ones" are focused on.

Sophisticated tasks

The contents of the developed learning environments for replacing counting strategies are designed for all children of a class. Children with persistent counting strategies have the possibility to work on a central understanding while other children deepen their competences. But therefore the given task has to be so complex that different levels of understanding and working are possible. Learning environments according to this so-called "natural differentiation" (Krauthausen & Scherer, 2013) are characterised by tasks that are (partly) open and/or include descriptions, explanations and arguments. Open problems allow the children to pick up on their own mathematical ideas, to deepen their understanding of contents or problems and sometimes to extend their own limits.

In the learning environment "subtraction to tens" each pair of children gets a couple of cards. There are some cards with quantities until 20 and some with quantities up to hundred (Fig 2). The children are free to choose which cards and how many. They are asked to cover the ones and note the corresponding subtraction problem. If children manage already without the transparency, they are free to do so.

Cooperative settings and discursive tasks

According to the research result that successful cooperation is based on structured settings, two cooperative are developed. The cooperative setting "path fork"[2] starts with a period of individual work which is followed by a period of working together on a further task. This task is build upon the individual work and focused on interaction about the insights and strategies. In the second cooperative method "seesaw"[3] the children work together on a problem from the beginning. They undertake different activities which are referred to each other. In the consequence they pick up the interpretation of their partner and carry on. The tasks for the cooperative method need to allow different interpretations so that a discussion can follow.

The learning environment "subtraction to tens" follows the cooperative setting "path fork". First, the children work with the cards on their own as described above. Then they collect their problems with the difference 10 on a worksheet (Figure 3). In the cards not all numbers from 10 until 19 are represented as

2 Weggabelung

3 Wippe

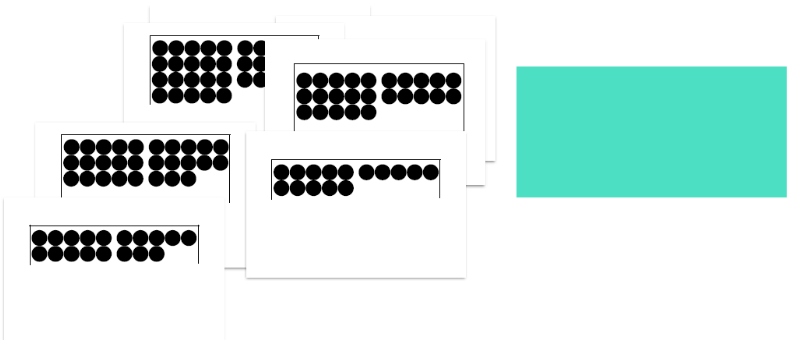

Figure 2: Material for sophisticated learning

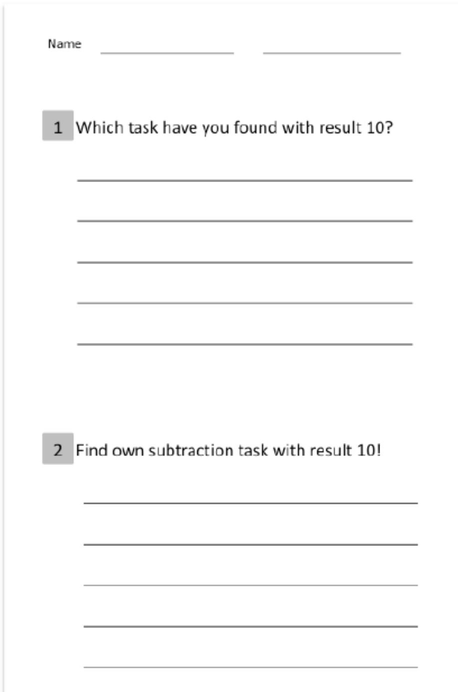

Name

1 Which task have you found with result 10?

2 Find own subtraction task with result 10!

Figure 3: Cooperative worksheet

quantities, so the children are challenged to find the missing ones. They could use the discovered structure or find other problems such as 30 − 20 = 10 or 45 − 35 = 10. The freedom in the interpretation of the formulation on the worksheet allows and probably stimulates interaction.

In some environments "discursive tasks" are used to strengthen the difference and the discussion. Children of a pair are not given the same tasks but tasks which refer to each other (Figure 5). After each of them has solved their card they should compare and describe common and different features. Moreover "sorting" is used as an alternative method to induce different interpretations and an interaction about them (Häsel-Weide & Nührenbörger, 2013).

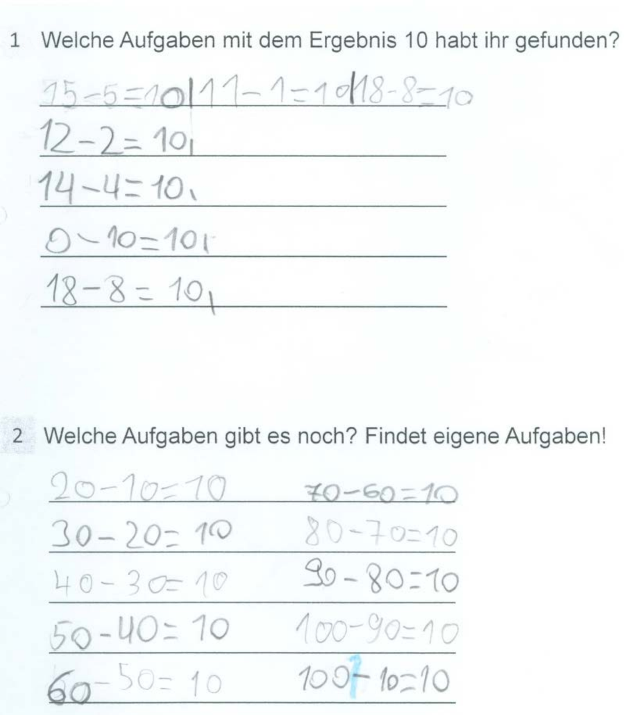

Figure 4: Document of Kolja and Medima

Results of the analyses of cooperative situations

The interaction of the children is analyzed to figure out in which way the interpretations of the children are affected by the cooperative interaction with their partners. Especially the interpretation of relations between numbers and problems in the interaction are analyzed. As pointed out above, it was of interest if and how the interpretations of the children with counting strategies differ from the interpretation of their partner and if these children modify the interpretations in the course of interaction. In this paper selected *results* of the analyses are presented and *illustrated with examples*. For a deeper insight into the interpretation process see Häsel-Weide and Nührenbörger (2013).

All children of the study were able to work and to cooperate in the learning environments. *Children with persistent counting strategies bring in own ideas and act as real partners.*

Example 1: After Kolja and Medima have noticed the problems according to the cards in the learning environment "subtraction to ten" they are now asked to find new problems. Kolja, a child with persistent counting strategies, suggest the problems 20 − 10 = 10 and 30 − 20 = 10. It is not clear if he wants to create a new, different pattern of problems or if he expresses common problems with the result ten. In the interaction his partner Medima notes the problems without questioning and the children find a structured column of problems in turns (Figure 4). On the basis of Kolja's idea they find a structured sequence of problems. Even if Kolja was not aware of the new structure he suggested, he could pick it up and find the next problem. Since Medima seems to realize the structure immediately nobody feels a need to para-

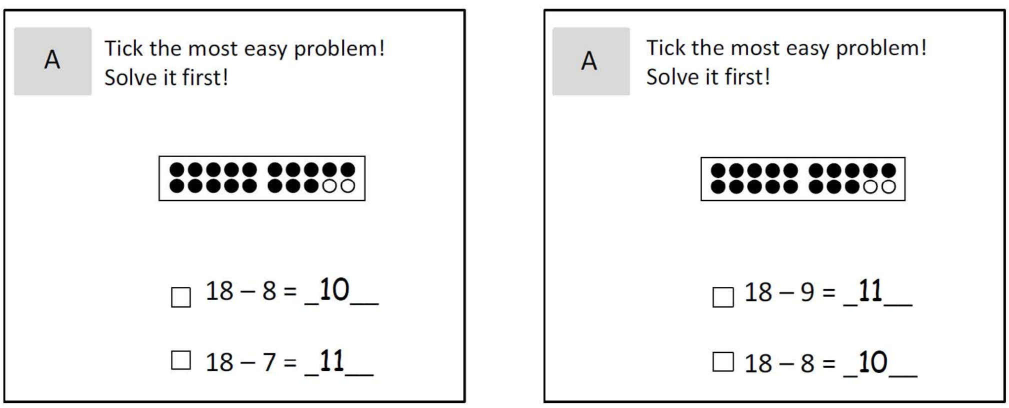

Figure 5: Discursive tasks with reconstructed results of Thomas and Max

phrase the action. Both children are pleased to note the problems and also do not notice the mistake.

The example as well as the results of the analyses made clear that children need reasons to negotiate different interpretations (Nührenbörger & Steinbring, 2009). *First of all comparing and sorting as formal cooperative settings function as reason to interact.* In informal situations some interactions come up by mistakes.

Example 2: Asked to compare the cards (Figure 5) in the second period of the cooperative setting "path fork", Thomas said:

Thomas: Hey Max, Max, I have noticed something. Here I have ten above [*points at the 10 on the left card*] and you have ten here below [*points at the 10 on the right card*].
Max: Oh. I have notice something, too. I have something different, too. There must be nine [*rubs out the result 11 and notes 9*]. Nine. Look, because nine plus nine equals eighteen.

Thomas notices that the difference ten can be found on both cards on different positions. He focuses on a concrete mathematical sign and describes its physical position. But it seems as if his interpretation causes a process in Max's thinking. Perhaps Max realizes that there are two other equal results, but not two other equal problems. His statement is not clear at that point. However, it seems to be a consequence of Thomas's comment that Max now realizes that he has made a mistake. He corrects it and explains to his partner why the new result should be correct now. Here Max uses the inverse relation between the addition problem 9 + 9 = 18 and the given problem 18 − 9 = 9.

In this episode, relations between problems are realized and described in the cooperative setting, probably initiated through the discursive tasks. It is open how far Thomas, the child with persistent counting strategies, understands Max's argumentation and realizes the relations and differences for himself, because the interaction ends at this point. But there is a chance that he picks up this argumentation later on.

Thomas's interpretation which focuses on corresponding signs was one of the typical interpretations of children using persistent counting strategies. According to results from Gray, Pitta and Tall (1999) the analysis show, that *children with persistent counting strategies focus often on similar signs*. Furthermore the *children focus on relations between numbers instead of relations between problems* as Thomas did in comparing the cards as well.

Thomas: Hey, here is nine [*points on the "9" in the problem 18 − 9 = on the right card*] and there it is eight [*point on the "8" in the problem 18 − 8 =*]. It is one more and there [*point on the problem 18 − 7 =*] it is one less.

Here, Thomas describes the relations between the subtrahends. He seems to formulate their relation based on a cardinal concept of numbers.

It becomes clear that the children see correct aspects, however they do not seem to realize the relations between problems as whole. As a consequence it is difficult for them to use the relations for deriving. Realizing corresponding signs and first relations between numbers is essential but not sufficient for developing derived fact strategies. It needs to be pointed out that children who already solve problems *without* counting, formulate relations between problems only in few episodes. Mostly they also focus on concrete objects and relations between numbers (Häsel-Weide, 2013). Analyses shows that even teachers are pleased if children do so and do not ask them to figure out the consequence of the relation between numbers for the relations between problems. Probably children with counting strategies benefit less than possible from the cooperation because the interpretation of their partner did not differ essentially from their own.

CONCLUSION AND OUTLOOK

The presented study aims at developing and researching cooperative learning environments which enables a structure-focused view on relation between numbers and problems for all children in grade 2. The design results and the results of qualitative research show that it is possible and productive for children with heterogeneous competences to work together. Children with counting as persistent strategy act as real partners in the cooperation and bring in own interpretations and solutions. Although informal cooperation processes are observed the formal cooperative settings, especially the activities "comparing" and "sorting", are suitable to make children interact about mathematics.

The children's interpretations show that the children focus on relations between numbers. In the next step children need to focus on relations between problems. This could only be observed in very few episodes of the study. Since even children without problems in mathematics focus mainly on the relation between numbers, further research has to show if another combination of pairs (perhaps with partners of higher age) or a more direct moderation by the teacher make all children recognize and describe structures between problems. Besides, it has to be figured out how far an explicit focus on relations between problems goes along with non-counting procedures (Gaidoschik, 2012).

Students’ argumentation schemes in terms of solving tasks with negative numbers

Mathias Hattermann and Rudolf vom Hofe

Bielefeld University, Faculty of Mathematics, Bielefeld, Germany, mathias.hattermann@uni-bielefeld.de

In the context of an experimental project targeted at improving the teaching and learning of negative numbers, we explored the argumentation schemes of students in terms of solving respective tasks. The test items used to record the learning progress of the students were taken from the large-scale PALMA-study. While learning gains were above average, the argumentation schemes of our experimental students show both, expected and unexpected patterns. Interestingly, we find well performing students with a preference for metaphorical reasoning instead of a mixed argumentation including formal reasoning.

Keywords: Negative numbers, lesson studies, metaphorical reasoning.

THEORETICAL FRAMEWORK

The Theory of Grundvorstellungen (GVs)

The theory of Grundvorstellungen (GVs) has a long tradition in Germany (e.g., vom Hofe, 1995). It reflects on the fact that the intuitive level of thinking is often responsible for the understanding and building up of mathematical knowledge as well as for problems in mathematical thinking in the sense of Fishbein:

> It is very well known that concepts and formal statements are very often associated, in a person’s mind, with some particular instances. What is usually neglected is the fact that such particular instances may become, for that person, universal representatives of the respective concepts and statements and then acquire the heuristic attributes of models. (Fishbein, 1987, p. 149f.)

In contrast to the opinion that mathematics is pure logic, GVs take social aspects into account as well as the environment in which mathematical concepts are built up. The theory of GVs has its anglo-american correlate in the term concept image which forms a fundamental part of Tall and Vinner’s theory of mental models:

> We shall use the term concept image to describe the total cognitive structure that is associated with the concept, which includes all the mental pictures and associated properties and processes. It is built up over the years through experiences of all kinds, changing as the individual meets new stimuli and matures. (Tall & Vinner, 1981, p. 2)

The concept image must be differentiated from the concept definition that consists of formal definitions dealing with mathematics. The theory of GVs (e.g., Kleine, Jordan, & Harvey, 2005) exemplifies the given idea of concept image in more detail and widens the perspective to descriptive and prescriptive utilization.

> GVs as a prescriptive notion describe adequate interpretations of the core of the respective mathematical contents which are intended by the teacher in order to combine the level of formal calculating with corresponding real life situations. In contrast, the term GV in descriptive empirical studies is used also as a descriptive notion to describe ideas and images which students actually have and which usually more or less differ from the GVs intended by mathematical instruction. (vom Hofe et al., 2008, p. 49)

GVs can be formulated in different contexts, such as fractions (part of a whole, operator, ratio), subtraction (taking away, supplementing, comparing) or functions. On the one hand the descriptive and prescriptive characters of GVs allow on the one hand the formulation of desirable GVs in different contexts and on the other hand the testing of individuals’ GVs .

GRUNDVORSTELLUNGEN AND METAPHORICAL REASONING

Metaphorical reasoning is fundamental to human thinking and can lead to the construction of mental models (English, 1997). According to Lakoff and Nunez (1997) metaphors can serve as a tool to understand difficult and new concepts in mathematics. They see mathematics on the one hand as a product of human imagination and on the other hand as a product of the embodied mind. Sfard (1994) emphasizes that metaphors allow the translation of bodily experiences into abstract mathematical ideas. This means that a metaphor maps from a source domain (experiences) to a target domain (mathematics) and theses experiences help to understand the abstract ideas in mathematics. Lakoff and Nunez (1997) propose four grounding metaphors to understand basic arithmetic. These four grounding metaphors (*Motion along a Path* (numbers as point locations or movements), *Object Collection* (bringing together, taking away), *Object Construction* (combining, decomposing), *Measuring stick* (comparing) link structures from every-day life to mathematics. But these grounding metaphors are insufficient to handle operations with negative numbers, so Lakoff and Nunez (1997) propose to stretch these metaphors to be useful for the explanation of the enlarged number domain including zero and negative numbers, aware of the fact they get more contrived the more they are stretched. In this respect metaphors can be used to build up GVs for different contexts in mathematics. However, it is well known that the use of metaphorical reasoning also has disadvantages since it is less efficient compared to facts or algorithms. Thus, it is important to investigate the relation between prescriptive GVs of an individual that is based on metaphorical reasoning (in our case a card game called Plus-Minus-Game) and the competence of the individual to solve computational tasks.

THE PALMA-PROJECT

The Project for the Analysis of Learning and Achievement in Mathematics (PALMA) focused on students' development in mathematics throughout grades five to ten in Bavaria, Germany (vom Hofe et al., 2008), with probands of eleven to sixteen years of age. The theoretical framework stressed the differences between the performance of algorithmic operations and the activation of basic concept images/GVs. Because of its longitudinal design, the PALMA study allowed new insights into the achievement development of students as well as into the impact of modelling competences that require the utilization of basic concept images/GVs. PALMA included annual assessments between 2002 and 2007. About 2000 students from 83 classes and 42 schools participated in the study so that the development of achievement was observed over a period of 6 years (vom Hofe et al., 2008).

CURRENT RESEARCH ON NEGATIVE NUMBERS

The genesis of negative numbers in mathematical history is of historical-cultural significance (Schubring, 1986). Since decades negative numbers have been part of the curriculum in many countries and for Germany it was Freudenthal who pointed out that dealing with them must be studied in detail (Freudenthal, 1973). He talks about didactic models of negative numbers, a problem that is still relevant today. Nearly all existing models dealing with everyday life and negative numbers contain specific insufficiencies, so that an ideal model for their teaching and instruction does not exist. Fishbein takes reference to the fundamental article by Glaeser (1981) and refers to this issue as follows:

> The difficulty of accepting the negative numbers as meaningful mathematical entities derives from the difficulty of identifying a good intuitive, familiar model which would consistently satisfy all the algebraic properties of these numbers, says Glaeser. As a matter of fact, such a model does not exist. One may create some models, but only by using a system of artificial conventions. (Fishbein, 1987, p. 100)

Current research in Germany concerning negative numbers is insufficient. Nevertheless, schoolbooks around the world (with only a few exceptions) promote the utilization of didactic models such as temperatures, balance-debt-models or elevator-models. With regard to our focus of interest, two publications are of peculiar interest. Chiu (2001) analyzes the utilization of metaphors (in the sense of Lakoff and Nunez 1997 standing in line with the discussed theories of GVs and concept images) for the explanation of computations with negative numbers in a quantitative study and with the help of additional clinical interviews. He concludes

> ...that both novices and experts have the same arithmetic metaphors but use them differently. [...]. Experts used metaphors less often in favor of more efficient methods. Both used metaphors when they faced difficulties. However, novices had more difficulties and used metaphors more often. (Chiu, 2001, p. 113)

In her work with 99 students Kilhamn (2008) also examines forms of metaphorical reasoning. 23 probands justified their answers to the task "-3 – (-8) = " by metaphorical reasoning using the thermometer, money debts or movements along a number line in their explanations. The result of the study is surprising because all students who solely referred to metaphorical reasoning failed (n = 14), whereas every student who used both metaphorical reasoning and arithmetic rules succeeded (n = 9) in solving the task -3 – (-8) = (Kilhamn, 2008, p. 6). In spite of the small amount of probands, it seems as if both, metaphorical reasoning and formal computations are substantial elements when dealing with tasks related to negative numbers.

RESEARCH PROJECT: DESIGN, QUESTIONS AND METHODOLOGY

Design

Our current project focuses on the generation of specific GVs and argumentation schemes based partly on metaphorical reasoning with regard to negative numbers in a long term-study. As the cited studies show, GVs as well as metaphorical reasoning are very relevant for the effective learning of negative numbers, even though a formalized understanding must complete the GVs. It is known that the stretching of the grounding metaphors (see the theoretical part) to handle negative numbers is problematic and yields not always to the desired results, so we will use a card game to build up GVs and to research students' argumentation schemes for the addition/subtraction of integers. Our project, lasting from 2012 to 2015, is based on a collaboration between Bielefeld University and the Laboratory School Bielefeld. The latter is innovative with respect to both, its educational profile as well as its Teacher-as-Researcher Model (Hollenbach & Tillmann, 2009). This model allows teachers to easily perform educational or subject-related research that compensates for parts of their teaching obligations. Three teachers and three researchers have collaborated to plan a 12-weeks-unit of instruction for negative numbers in grade 7 (n = 21 students), in which GVs play a fundamental role. The unit is divided into three parts: 1. introduction, 2. addition/subtraction, 3. multiplication/division of negative numbers. In the second part we introduced the Plus-Minus-Game which is explained in the next paragraph. It is designed to build up GVs and to foster metaphorical reasoning for the addition and subtraction of negative numbers. Teachers and researchers worked together on the methodological basis of Lesson Studies (e.g., Hart, Alston, & Murata, 2011). This collaborative method has proven to be effective with regard to teachers' professional development.

The Plus-Minus-Game

The game consists of a dice with a green, a blue, a red, a yellow, a black and a white face, 11 green and 11 red cards. The 11 green cards are labelled with the numbers from 0 to 10. The 11 red cards are labelled with the numbers from -10 to 0. The game is played by three to four players. After having shuffled the cards, you put a deck of green cards and a deck of red cards on the table. Every player draws a card and puts it on the table without covering it. The youngest player begins to throw the die. For each colour the die shows, there are specific instructions what to do. Green: Take a green card from the deck. Blue: Give any green card to your left neighbor. Red: Take a red card from the deck. Yellow: Give any red card to your left neighbor. Black: Give the red card with the highest absolute value to your left neighbor. White: Give the red card with the lowest absolute value to your left neighbor. The aim of the game is to get the highest score in total. The game is over when all cards are collected. After playing the game, we introduced the notation presented in Figure 1 to motivate the utilization of brackets as claimed by Malle (2007). We used brackets to differentiate between a card value and a score. In an equation, we interpret the first summand as a score (without brackets), the second summand as a card value (with brackets) and the result as a score (without brackets). Figure 1 focuses on the notation in addition and subtraction tasks. The interpretation of the minuend as a score in a subtraction task is crucial. Example: 3 – (-6) = 9 Interpretation: The player has several cards (e.g. (5), (-6) and (4) which are added up to 3). He has to give away the card (-6), so the player's new score is 9. If someone interprets the minuend as a card value instead of a score, the interpretation will fail because it is not possible to give away the card (-6) while holding only the card with value (3). Problems resulting from such misinterpretations are analyzed in detail in Hattermann (2013). For more information concerning teaching experiences see Hattermann, vom Hofe and Viehmeister (2014).

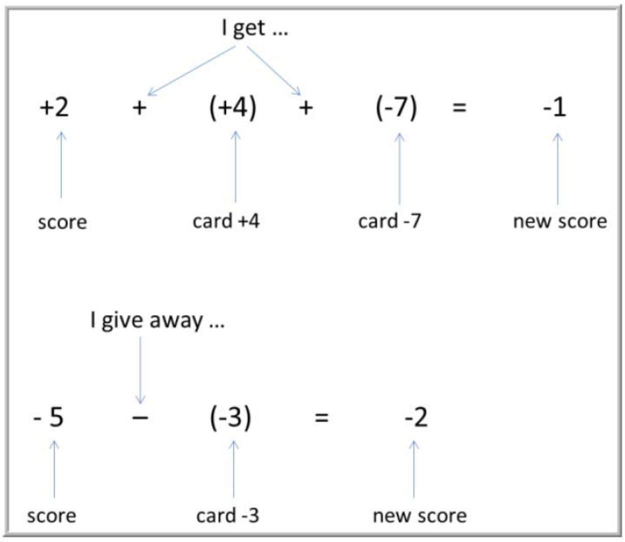

Figure 1: Notation and interpretation for addition and subtraction tasks with integers

Research questions

In this paper we focus on three selected research questions of the project. Since the students who took part in the PALMA study did not participate in lessons focusing on the development of GVs, as it was the case with our experimental group, we formulate the first question: 1. How does the experimental class from the Laboratory School perform in answering the PALMA-items on negative numbers in comparison to the PALMA-students after the instruction unit on negative numbers? 2. What argumentation schemes (GVs) can be identified in the students' explanations for the tasks "(-5) + (-7) =" and "(-9) − (-4) =" after having finished the course of addition/subtraction of negative numbers? 3. Are there any particular interrelations between both, the argumentation schemes identified and the students' success by solving computational tasks?

Methodology

After the second and the third part of the course the students took part in an evaluation in which they computed different tasks and answered questions that sought to identify underlying conceptions and GVs. In the first evaluation students had to answer the following question:

> Imagine your classmate Jacob was ill last week and he was not able to attend class. Write a short letter in which you explain to him what has to be done in the following tasks and explain why: a) (-5) + (-7) = and b) (-9) − (-4) =. You may use all devices for an explanation that we used in class.

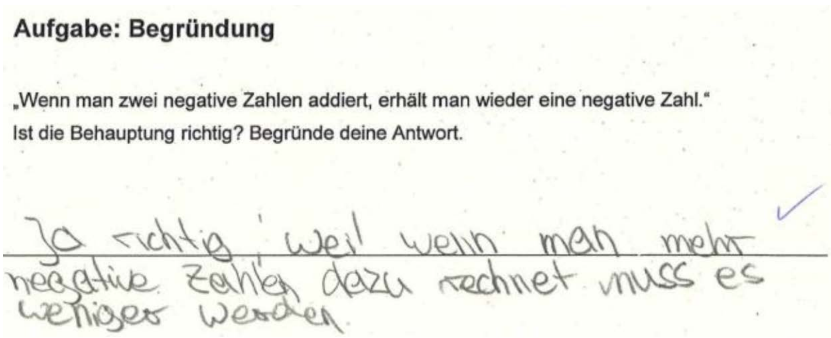
The written letters were analyzed with regard to the argumentation schemes used by the students by means of a qualitative text analysis. In a first analysis the research group analyzed together five letters to create categories of argumentation schemes. In the following two researchers analyzed independently students' letters to Jacob and decided for one of these categories. In a last step inconsistent classifications were discussed and the categories were revised. In a second step the identified individual argumentation schemes were confirmed with semi-standardized interviews. In these interviews tasks as "(-3) + (-7) =" occurred (as in the letter to Jacob) and students' were motivated to solve these tasks and to explain their argumentation explicitly. They could use a number line, the plus-minus-game or other explanations. The video analysis was carried out by two researchers. They assigned independently argumentation schemes to students' statements in the interview. Finally, the argumentation patterns of the students were compared to their performance in solving 14 computational tasks e.g. "(-12) + (-7) =". Our students worked on the PALMA items on negative numbers at the end of the school year (like the students in PALMA).

RESULTS

Exemplary results from the experimental class in comparison to PALMA

To answer our first research question, we compared the solution rates with regard to PALMA-items (grade 7) on negative numbers of the representative PALMA-sample and with our experimental group at the Laboratory School Bielefeld. For example, the task termed *Justifying* from PALMA had a solution frequency of only 19%, the lowest solution rate of all items on negative numbers in the PALMA-sample. It read: "If you add two negative numbers, you get a negative number again. Is this statement correct? Justify your answer." (Figure 2)

Figure 2 displays the task in German together with the solution of Leo (pseudonym) from our experimental group. Leo writes: "Yes, it is right, because if you add more negative numbers it becomes less." The overall solution rate of 43% of our experimental group for



Aufgabe: Begründung

„Wenn man zwei negative Zahlen addiert, erhält man wieder eine negative Zahl.“
Ist die Behauptung richtig? Begründe deine Antwort.

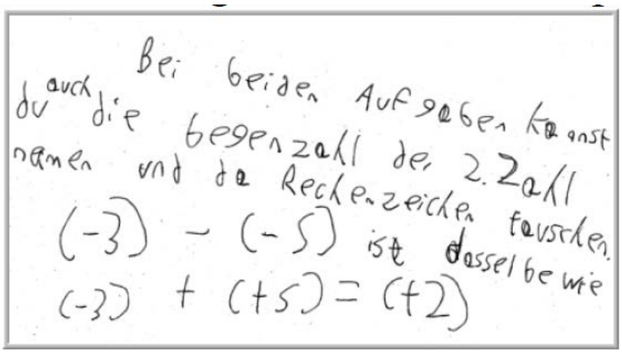
Ja richtig, weil wenn man mehr negative Zahlen dazu rechnet muss es weniger werden

Figure 2: Task for justification from Leo from the experimental class

this exemplary task provides evidence for our success in building up GVs for mathematical concepts. Altogether, the students worked on 20 PALMA-items dealing with negative numbers. The solution rates of the experimental class were at least 10% higher compared to the PALMA-rates for six tasks. One example of these tasks is the following: "The water level of a water reservoir declines to 8cm. On the next day the water level rises about 3cm. How does the water level change in these two days." In contrast to that, the experimental group solution rate was at least 12% lower than for the PALMA-group for four items. These are the following items: (+9) · (-8) = ; (-27) + (+3) = ; (-6) · (-8) = In the fourth task the probands had to determine a temperature on a thermometer and the solution rates were 71% (experimental group) respectively 86% (PALMA). We explain these results by the fact that the plus-minus-game was not used to explain the multiplication of integers. Furthermore the solution rates of the thermometer task are high in comparison to the other solution rates. This gives evidence that this task is one of the easiest tasks and mistakes occur by carelessness. For the ten tasks remaining, the difference of solution rates did not exceed 9%. One example of these tasks is the following: "Mr. Knodel has 450€ on his bank account. He transfers an invoice amount. The actual balance is -300€. What amount did he transfer?" Despite of the small amount of probands in our experimental class, the results show that the average achievement of our experimental group is comparable to the achievement of the PALMA-probands, who came from Bavaria being one of the high-performance regions in Germany.

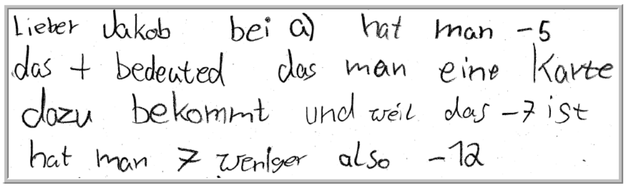
Exemplary results from the evaluation and the interview-study

In the letters that were written to Jacob during the first evaluation, we identified four consistent argumentation schemes that were verified in the following interviews. The first one is called *formal reasoning*: e.g.



Bei beiden Aufgaben kannst du auch die Gegenzahl de 2. Zahl nemen und da Rechezeichen tauschen (-3) − (-5) ist dasselbe wie (-3) + (+5) = (+2)

Figure 3: Example for formal reasoning



Lieber Jakob bei a) hat man -5 das + bedeuted das man eine Karte dazu bekommt und weil das -7 ist hat man 7 weniger also -12

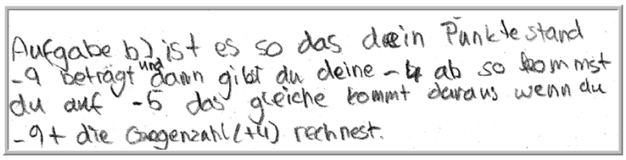
Figure 4: Example for metaphorical reasoning

"In both tasks you can use the additive inverse of the second number and change the arithmetic operator (-3) − (-5) is the same as (-3) + (+5) = (+2)."

The second scheme is called *metaphorical reasoning*. In our case, the students' respective justifications were based on the number line or the Plus-Minus-Game: e.g. "Dear Jacob, in a) you have -5, the + means that you get a card and because this card is -7 you have 7 less so -12. "

The third scheme is called *mixed argumentation.* It contains parts of both *formal* and *metaphorical reasoning*: e.g. "In task b) your score is -9 and then you give your [card] -4 so you get -5 you get the same by calculating -9 + additive inverse (+4)." This example shows both metaphorical reasoning and formal reasoning. Whereas the explanation with the card game is identified as a kind of metaphorical reasoning, the identification of +4 as the additive inverse of -4 hints to a formal understanding.

In the fourth category *no justification* can be identified, e.g.: "Because I learned it this way." In a last step we compared the students' argumentation scheme(s) with their results on 14 computational tasks on negative numbers as for example "(-12) + (-7) =" (Figure 6). We show only the results of these 17 out of 21 students who wrote a letter to Jacob and took part in the evaluation.



Aufgabe b) ist es so das dein Punktestand -9 beträgt und dann gibt du deine -4 ab so kommst du auf -5 das gleiche kommt daraus wenn du -9 + die Gegenzahl (+4) rechnest.

Figure 5: Example for mixed argumentation

As Figure 6 displays, 13 out of 17 students score at least 11 out of 14 points. Four students score less than 11 points whereas three of these students are not able to justify or explain their strategies in the letter to Jacob or to the interviewer. We find very good results (13 or 14 points) of students who used *mixed argumentation*, *formal reasoning* or *metaphorical reasoning*, whereas the *mixed argumentation* seems to be dominant with high achievers. This result is in line with those of Kilhamn (2008). In contrast to her study, however, we find students with results of 11 and 13 points in spite of their preference for only *metaphorical reasoning*. An explanation for this result is the structure of the Plus-Minus card game, which undoubtedly represents a form of *metaphorical reasoning*, while it also represents the mathematical structure very clearly and omits other contexts, such as those of everyday life. In addition, however, we find three students who used *metaphorical reasoning* only and scored only 9 and 11 points of 14. One reason for this might be the fact that the Plus-Minus-Game represents addition and subtraction tasks within a maximal number range from -55 to +55, whereas the students had to solve tasks such as -530 + (-210) in the computation part as well.

PERSPECTIVES

In the near future, we will revise the unit on negative numbers and teach it again in more classes. We will use several models, such as the balance-debt-model, the Plus-Minus-Game and a model dealing with the number line to identify more argumentation schemes that are specific for these models. Our aim is to gain more insight into individual problems, when dealing with specific models. Furthermore we will work on an effective combination of models and underlying argumentation schemes for addition/subtraction and multiplication of negative numbers.

Student number	Argumentation scheme in the letter and the interview	Result in computational tasks (in points, max. 14)
1	mixed argumentation	14
2	formal reasoning	14
3	mixed argumentation	14
4	mixed argumentation	14
5	mixed argumentation	13
6	formal reasoning	13
7	metaphorical reasoning	13
8	mixed argumentation	13
9	formal reasoning	12
10	formal reasoning	12
11	mixed argumentation	12
12	metaphorical reasoning	11
13	metaphorical reasoning	11
14	metaphorical reasoning	9
15	no justification	7
16	no justification	7
17	no justification	5

Reversible and irreversible desemantization

Milan Hejný, Darina Jirotková and Jana Slezáková

Charles University in Prague, Faculty of Education, Prague, Czech Republic,
milan.hejny@pedf.cuni.cz, darina.jirotkova@pedf.cuni.cz, jana.slezakova@pedf.cuni.cz

A child's first experience with mathematics comes from their everyday life. The child does not know what three is but knows what three fingers, apples or candies are. Later, in consequence to abstraction, this semantic anchoring of mathematical ideas is expanded by ideas and concepts that are not directly dependent on semantics. We call this process "desemantization". If the process of desemantization ousts semantic links from a pupil's mind as a result of too fast a drill of additive and later multiplicative structures, we speak of irreversible desemantization whose consequence is mechanical knowledge of a child. The paper develops this concept.

Keywords: Desemantization, cognitive process, mental schema, generic model.

INTRODUCTION

Czech pupils' and students' negative attitudes to mathematics which can be observed e.g. in international surveys TIMSS and PISA and their low level of understanding of mathematics are a prevailing problem of school mathematics in the Czech Republic and a challenge for mathematics educators. Our experience and research imply that responsible for inauspicious situation is not the content of mathematics but the way it is taught at school. We are convinced that in most cases the teacher presents and explains new subject matter and their pupils only imitate the teacher, they reproduce what has been said and by repetition try to store it in their memory. A pupil is not expected to use their natural will to discover, he/she is reduced to the role of a consumer of knowledge transmitted by the teacher. Knowledge of mathematics enters a pupil's mind from the outside and makes a mosaic of more or less isolated items of knowledge. The chance that this knowledge will not be forgotten and that it will be linked to other knowledge is very low. It has been known for many years that if transmissive model of teaching is replaced by constructivist approach, where new knowledge is born in a pupil's mind as a result of the pupil's intellectual activity, the situation changes (Noddings, 1990; Pehkonen, 1997; Gruszczyk-Kolczyńska, 2012). The here presented study casts the light on the possible causes of why key knowledge of arithmetic is often stored as mechanical knowledge in a pupil's mind and thus becomes unusable in the future when the pupil meets new topics and solves new problems. It also looks for a solution of the first three main questions formulated for TWG02 both on CERME 8 and CERME 9.

The stories used in the paper as illustration of our points come from several different research projects from different periods of time.

THEORETICAL BACKGROUND

We understand the cognitive process in mathematics as a pentad of stages in the sense of the Theory of Generic Models (for details see Hejný, 2012):

1. motivation, it guides the cognitive process and provides energy;
2. creation of items of initially disconnected experience – isolated models;
3. discovery of generalized knowledge – generic model;
4. discovery of abstract knowledge;[1]
5. crystallization when the new item of knowledge becomes organic part of mathematical knowledge of the individual. This stage in fact underlies all the first four stages.

1 The difference between generalized and abstract knowledge is illustrated in Story 4.

This learning process was introduced to CERME audience in (Hejný & Kratochvílová, 2005). Hejný (2012) states that unlike a number of other theoretical studies describing the cognitive process, the Theory of Generic Models (TGM) is well comprehensible both to researchers and teachers. The division of the cognitive process into stages allows a comprehensible application of the theory both into primary and lower secondary education. TGM explains what the sources of development pupils' mechanical knowledge are and how this can be prevented and reeducated. A complete set of textbooks covering all areas of primary mathematics were developed based on this theory. Over the past 8 years the set of textbooks has spread into 20% of all elementary schools in Czech Republic and currently it is being piloted at several schools in Poland and Slovakia.

The Theory of Generic Models has been also used as a tool for analysis of experiments related to cognitive processes as well as when conceiving textbooks for pre-service teacher education.

Sets of generic models in a pupil's mind create mathematical mental *schemas* that are the bearers of an individual's mathematical knowledge (Hejný, 2012).

Attention should be paid to two abstraction transfers:

isolated models
→ generic models
→ abstract knowledge,(*)

in which a pupil's semantic experience changes into abstract cognition.

Let us remark that the process (*) as a tool for discovery of mathematics happens not only in ontogeny, but also in phylogeny. Ernst Haeckel's biogenetic law, which states that ontogeny recapitulates phylogeny, is inspiring also for didactics of mathematics. P. M. Erdnijev (1978, p. 197) formulated the idea as follows: "The growth of the tree of mathematics knowledge in an individual's mind will be successful only if we recapitulate to a certain degree the history of development of mathematics." We also work with this idea. When exploring the issue of desemantization we build on our former studies as well as works (Krpec & Zemanová, 2011) and (Zemanová, 2014).

THE CONCEPT OF DESEMANTIZATION

The term *desemantization* refers to the process (*). It emphasizes the fact that once abstract knowledge is formed, it is no longer dependent on the initial semantic ideas and exists independently.

Story 1

I ask a five-year-old Adam how much two plus three is. The boy looks at apples on the table and asks: "Two apples and three apples?" and when I agree he first takes two apples, then three apples, puts them together, counts them and says: "five apples". Then I point at a bowl with candies and ask: "How much is two candies and three candies?" The boy proceeds analogically and says: "five candies". He does not realize that in both cases it is the same calculation. This is surprising for Adam's father who was observing us. The father was convinced I should have told the boy that he could use the first calculation in the second case. The father was disappointed that his son failed to see the analogy.

Half a year later, when asked how much two and three is, the boy used his fingers to find out the result is "five". Another year later the boy answers "five" was without counting. When he later mastered numbers in the language of higher abstraction, he was able to record this knowledge in the abstract form: $2 + 3 = 5$.

What has taken place in the boy's mind is *desemantization.* If the symbol 2^* describes a semantically anchored number 2 and similarly symbols 3^* and 5^* semantically anchored numbers 3 and 5, then the described desemantization can be described as the transfer $(2^* + 3^* = 5^*) \rightarrow (2 + 3 = 5)$. When practicing addition and subtraction at school, the link gets automated. However, when his younger sister asks him how much two plus three is, his advice is to count it on fingers. This implies that the abstract knowledge $2 + 3 = 5$ is still connected to semantics in Adam's mind. The boy is able to make the abstract item of knowledge $2 + 3 = 5$ comprehensible to his sister using the relation $2^* + 3^* = 5^*$. The desemantization that Adam went through has not broken the individual stages of the process (*). The boy naturally goes back to the stage of isolated models. That is why we speak in this case of *reversible desemantization.*

Story 2

Adam is in the second grade and is one of the fastest arithmeticians in his class. He can add, subtract, multiply and partially also divide very quickly and reliably. He is not so good at word problems. The class is solving the following problem:

Problem 1. Mum paid 163 CZK for her shopping. She has 509 CZK after this purchase. How many crowns did mum have before she went shopping?

Adam sees the signal word "spent" but is not sure whether to subtract, as he finds the text a bit strange. He prefers to ask his teacher: "Miss, is it plus or minus?" The teacher answers plus. Adam then quickly answers six hundred and seventy two. And the teacher commends him for his answer.

The teacher overvalues calculation skills and fails to realize that Adam fails to understand mathematics. She does not realize that calculation in word problems is only secondary, what is of primary importance is understanding the assignment, the pupil's ability to grasp in their mind what the problem asks and requires. When the teacher commends the boy, she deforms his metacognitive belief that mathematics is about being fast in calculations rather than about thinking. The boy's mathematical cognition is no longer supported in his semantic ideas. If we ask him to pose a problem with addition 163 + 509, he will use the standard addition of two sets of data. If we ask him to use the word "spent" in the assignment, he will not manage to do so. Desemantization in the boy's mind is in this case *irreversible.*

Story 3

Adam is in the seventh grade. He can now add fractions. This knowledge entered his mind not by the process (*) but through structural deduction. First the pupils were introduced to reduction and raising of fractions and based on this knowledge the teacher deduced the relation: $a/b + c/d = ad/bd + bc/bd = (ad + bc)/bd$. Adam does not understand the presented deduction and thus has no idea of what is actually happening as there are very few real-life problems based on this concept of fractions. Adam has only learnt a rule and knows that when adding fractions he must follow this specific rule.

When his younger sister asks him how to add one half and one third, he shows her the rule. When she asks him for an explanation of this rule, he says it cannot be explained, it must be learnt.

In this case Adam's knowledge of addition of fractions is not supported by semantic ideas as it entered the boy's mind from the outside with very little semantic support which is, moreover, not further developed in the subsequent lessons. On the contrary, the little semantic support that existed was forced out through the subsequent drill. Desemantization is very weak in this case and the support in semantic ideas ceases to exist. In this case we also speak of *irreversible* desemantization. More precisely we speak of mechanical knowledge that does not enter pupils' minds by (*) but by direct transmission.

ISOLATED MODELS

Adam's story shows how a pupil with clear ideas about mathematics turns into a pupil without any ideas. The story also illustrates the important stages of isolated models. Once we master abstract thinking and cognition, we often believe it is a waste of time to be learning isolated models. That is the case of Adam's father from Story 1 and the teacher who was teaching Adam to add fractions. This common mistake can be avoided if the teacher carefully monitors how their pupils understand mathematics and if they look for ideas in history of mathematics. Let us present here one historical illustration which is underlain by phylogenetic parallel to Adam's ontogenetic activity in Story 1.

Phylogenetic parallel

We can find evidence of the fact that addition can be dependent on the objects we calculate with also in phylogeny. For example the Japanese numeral "two" is "ni" and is recorded by the character (二). However, this concept is not on the level of abstract cognition as in the semantic context the Japanese supplement this numeral by a particle called numerative. This means that in our transcription they do not work with number 2 but with anchored number 2*. Thus two people are futari (二人), two small animals are nihiki (二匹), two large animals are nitó (二頭), two elongated cylindrical objects are nihon (本), two glasses are nihai (二杯) etc.

The number of Japanese numeratives shows that creation of a generic model may require a considerable number of isolated models. It is almost impossible to find out how many different calculations $2^* + 3^* = 5^*$ had been carried out by Adam in Story 1 before he grasped the relation $2 + 3 = 5$.

Both isolated models of the relation 2* + 3* = 5* presented in Story 1 were of the same type:

A) number + number = number.

But the relation 2 + 3 = 5 has more semantic contexts. For example two more types:

B) address + operator of comparison = address (I live on the 2nd floor, Michal lives 3 floors higher. Which floor does Michal live on?)

C) operator of change + operator of change = operator of change (I make 2 steps, then 3 steps. How many steps have I made?)

The spectrum of different contexts of isolated models is crucially important for the quality of future desemantization. First of all it brings a variety of ideas into the nascent schema of "addition and subtraction" and enriches semantic background of arithmetic. Moreover it prepares the grounds for new concepts and relations and also type

A) prepares the grounds for the concept of fraction as we can add 1/2 of an apple + 1/3 of an apple;

B) prepares for grasping the concept of a number line on which there will be all numbers;

C) prepares for work with vanishing models of numbers (e.g. three steps, three winks, they vanish once they have been carried out) and negative numbers.

The presented stories, their analysis and further considerations show that a well-built rich system of isolated models is prerequisite to good and successful desemantization. Although we discuss here only introduction to arithmetic, the conclusion is universally valid. It applies also to fractions, decimal numbers, equations, perimeters and areas of plane figures, combinatorics. Combinatorics will be the setting of the story in the following chapter.

FIRST ABSTRACTION TRANSFER

Based on the analysis of several dozens of video recordings of the cognitive processes, the stage of isolated models was divided into four sub-stages:

1) First experience enters our mind – the seed of future knowledge.

2) Gradual entry of more isolated models that are not interlinked yet. It may happen that we accept quasi-models and refuse surprising models.

3) Some of the models start pointing at each other, we group them together and separate them from other models. We get the feeling that these models are somehow alike.

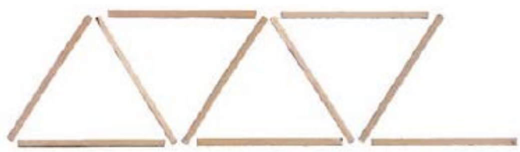
4) Discovery of this alikeness results in creation of a community of at least a subset of all isolated models.

As soon as the pupil has reached stage four, he/she chooses one of the isolated models and says "and this is how it always works". This isolated model becomes a generic model, which shows how to solve problems of this type. In Adam's case from Story 1 this generic model was the addition 2 fingers + 3 fingers = 5 fingers.

Story 4

In the second grade pupils were solving problems with sticks. The following is one of the problems.

Problem 2. Continue making other triangular windows and write down into the table how many sticks you need.



cells	1	2	3	4	5	6	7
sticks							
cells	8	9	10	11	12	13	14
sticks							

Figure 1: How many sticks?

The problem was solved about 10 days ago and the pupils had found out that for creation of 3 (4, 5) windows they needed 7 (9, 11) sticks. None of the pupils had noticed the number of sticks was increasing by two. It means that the pupils reached the 1st and 2nd sub-stage of isolated models.

Later, Ben was solving the problem at home on his own. When he put numbers 3, 5, 7 and 9 in the table, he saw the numbers were increasing by two. (Ben reached the 3rd sub-stage.) Therefore he added number 11 beneath number 5 and checked the result. He was happy to see that his conjecture worked. (Ben reached the 4th sub-stage.) He filled in the whole table and ran to his father to show. The father commended his son and asked how many sticks would be needed for 50 windows. The boy realizes that this will require a lot of writing and calculations. He takes his things and goes to work in his room. He makes Table 1.

While filling in the table he notices that beneath numbers 19 and 29 there are numbers 39 and 59. Then he realizes that beneath numbers 20 and 30 there are numbers 41 and 61. He is convinced that beneath numbers 40 and 50 there will be numbers 81 and 101. He runs to his father to show him this discovery. He commends his son and asks him what number there will be beneath number 57. Ben creates table for numbers 50, 51 to 57 and beneath numbers 101, 103 and 115. The father asks what number there will be beneath number 100. Ben writes 100 and beneath immediately 201. The father asks what there will be beneath number 113. Ben writes 110, 111, 112 and 113. Beneath 221, 223 and 225. The father applauds.

The father resisted the temptation to disclose to his son that the rule works for all numbers, not just tens. Ben discovered this rule later together with his other two classmates and recorded it in a very simple way: $sticks = 2 \cdot windows + 1$. Later when Ben was explaining it to his friend, he wrote briefly $s = 2 \cdot w + 1$.

Ben's solving procedure contains all 4 sub-stages of isolated models. The first two took place in the classroom when pupils were solving the problem for 3, 4 and 5 windows. The third sub-stage was supported by the use of the table thanks to which the first discovery was made: the numbers increase by two. Ben discovered the instruction on how the process continues. This was the 4th sub-stage that immediately transcended into a generic model. Generic models of this type are therefore called *processual*.

The father, by asking about number 50, guided the boy to search for the rule how the number of sticks can be derived from the number of windows immediately, without having to make a long table. The boy first discovered the answer for numbers 10, 20, 30, ... This is a discovery of the model that we will call *partially conceptual*. Finally the third discovery made with classmates is a fully *conceptual model*.

The story shows a complex, several day long process of discovery of a generic model. Each of the three AHA-effects accompanying the process was a very exhilarating experience. And this experience guarantees that the knowledge about the relation of windows and sticks given by the abstract formula $s = 2 \cdot w + 1$ is the consequence of reversible desemantization. Ben is able to recapitulate the whole process even a year later.

ISOMORPHISM OF GENERIC MODELS

In the paragraph on Isolated models we presented several different semantic types of anchoring of the knowledge $2 + 3 = 5$. The rich spectrum of sematic anchoring of most knowledge in mathematics helps reversibility of desemantization. Let us illustrate this on an example of knowledge of combinatorics: () = 10.

Problem 3. Alice has birthday. She invited her friends Betty, Cecil, Dee and Elis to her party. Each who came kissed each other girl who had already come to the party. How many kisses were there?

Problem 4. Find out how many matches will take place in a football tournament if there are 5 teams, each of them playing each other once.

Both problems serve as a semantic illustration of combinatorial number ().

Problem 3 is of processual, problem 4 of conceptual nature.

Story 5

Problem 3 was assigned to 5th graders. Jana was solving it by a simulated dramatization and then she drew 5 points *A*, *B*, *C*, *D* and *E* on a sheet of paper. She joined

15	16	17	18	19	20	21	22	23	24	25	26	27	28	29	30	31	32	33	34	35	36
31	33	35	37	39	41	43	45	47	49	51	53	55	57	59	61						

Table 1: How many cells and sticks?

A to points *B*, *C*, *D* and *E* and wrote 4. Then she joined *B* with *C*, *D* and *E* and wrote + 3 next to 4. Thus she continued with *C* and *D* and finally gained the result 4 + 3 + 2 + 1 = 10. Jana finished very fast so the teacher asked her to try to solve the problem for 6 and even 10 girls. Jana started to work. She got engulfed and was working only on this problem until the end of the lesson. Ivan found the problem difficult but together with his friend managed to get the result.

A month later the same class was working on problem 4. Hynek wrote down the names of 5 teams: Sparta, Ostrava, Brno, Hradec, Jihlava. Then he wrote down all the matches: Sparta – Ostrava, Sparta – Brno, ... In the end he stated that there were 11 matches because he had calculated Brno – Hradec and Hradec – Brno.

Jana gave up looking for the solution. She said she did not understand football. The teacher knew Jana liked playing chess and so she advised the girl to solve the same problem for a chess tournament. Jana then started to solve the problem and later, when the problem was discussed by the whole class, she contributed with a very powerful idea.

The first to speak was Hynek (deliberately, because his solution 11 was wrong). When he wrote Sparta – Ostrava, Mirek suggested he should write only S – O to speed up the process. So Hynek changed it and discovered on his own that if there is B – H, he cannot add H – B. There were more pupils who had

	A	**B**	**C**	**D**	**E**
A		X	X	X	X
B			X	X	X
C				X	X
D					X
E					

Table 2: How many tournament matches?

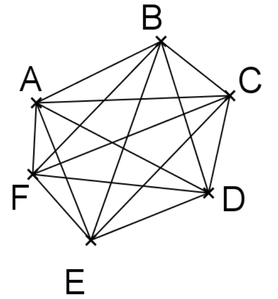


Figure 2: Jana's drawing

been solving the problem analogically to Hynek. Each such solution is an isolated model of the result of problem 4. The most popular solution (especially with boys) was Ivan's solution. He created a table of the tournament and showed there would be 10 matches. This table (Table 2) is closer to a generic model than to an isolated model.

Lada was waving her hand to get the attention of the class to explain that this was the same as kisses on Alice's party. Some pupils agreed but most did not understand. Then Jana suggested it was pretty clear: before each match the captains shake hands, which is the same as when the girls kiss. She ran to the board, drew 5 points and joint each point with all the other points (Figure 2). She said this was how it could be drawn – both Alice and the matches. Everybody could understand this explanation. Jana's drawing became a generic model and Hynek's and Ivan's solution were in this perspective merely isolated models.

When they reached 7th grade, these pupils learnt that the combinatorial number () is

the number of all 2-element subsets of an n-element set. The first to understand this difficult definition was Jana. She pointed out that for $n = 5$ it is the same as with Alice or with the matches. Understanding of the abstract concept () is now for some pupils based on the generic model "Alice's party for n girls", for other pupils on the generic model "tournament for n teams" but for more pupils on isomorphism of both these models represented by an n-gon, its all sides and diagonals. Obviously the understanding of the last group of pupils is the deepest.

CONCLUSION

The above presented stories were used to cast light on the process of desemantization and to point out the phenomenon of reversibility and irreversibility of this process, which is of paramount importance with respect to understanding arithmetical phenomena. We showed that desemantization is impossible where the abstract idea enters a pupil's mind from the outside, without previous semantic preparation. Story 5 illustrated the case where semantic preparation took place three years before the abstract concept was introduced from the outside.

The scope of this paper does not allow us to discuss the issue of desemantization in detail. Some of the phenomena had to be omitted. For example the importance of *counting backwards* for reversible desemantization, *amalgamation process-concept* (Gray & Tall, 1994), or *grasping, coding and transformative power of language* for second abstraction transfer (Kvasz, 2010).

Let us conclude this study by a summary of the main findings of our research:

— Desemantization is a long-term mental process whose mechanism can be described by two abstraction transfers (*).

— Desemantization is reversible if the pupil even after having achieved the abstract level is able to project abstract ideas into generic models.

— Reversibility of desemantization has positive influence on the richness of generic models and links between them.

— Knowledge that enters a pupil's mind from the outside in its final form (i.e. mechanical knowledge) has no semantic anchoring. In this case we cannot speak of desemantization. However, semantic anchoring can be developed later.

ACKNOWLEDGEMENT

The research was supported by the research project No. 15 (PRVOUK) School and the teaching profession in the context of increasing demands on education.

Sixth grade students' explanations and justifications of distributivity

Kerstin Larsson

Stockholm University, Stockholm, Sweden, kerstin.larsson@mnd.su.se

Equal groups and rectangular arrays are examples of multiplicative situations that have different qualities related to students' understanding of the distributive and the commutative properties. These properties are, inter alia, important for flexible mental calculations. In order to design effective instruction we need to investigate how students construct understanding of these properties. In this study sixth grade students were invited to reason with a peer about calculation strategies for multiplication with the goal of explaining and justifying distributivity. Their discussions demonstrate that the representation of multiplication as equal groups helps them to explain and justify distributivity. At the same time this representation hinders their efficient use of commutativity.

Keywords: Multiplicative reasoning, distributivity, commutativity, equal groups.

INTRODUCTION

Three fundamental properties of arithmetic, the distributive, the commutative and the associative property all apply to multiplication. These properties underpin flexible mental calculations and later algebraic understanding (Carpenter, Levi, Franke, & Koehler, 2005; Ding & Li, 2010; Lampert, 1986; Young-Loveridge, 2005). Although the significance of these properties is well known, researchers have only recently "begun to discuss ways to teach these ideas in the elementary grades" (Ding & Li, 2010, p. 147). To design effective teaching of the arithmetical properties more knowledge about students' understanding of the properties is needed. This study's aim is to investigate how students make sense of the arithmetical properties in multiplicative calculations. The distributive property (DP) is the main focus, but the commutative property (CP) for multiplication is also investigated since students need to manage the CP when they undertake calculations involving the DP. The associative property is not discussed here, which is not a reflection on its importance but this paper's focus. In the next section some general concepts central to this study are presented followed by a review of findings concerning students' understanding of the DP and the CP before, finally, the aims for this study are clarified.

BACKGROUND

The DP, which states that $a\cdot(b+c)=(a\cdot b)+(a\cdot c)$, underpins mental multiplication by splitting one factor to make two multiplications which are then summed. For example one might solve $7\cdot14$ as $7\cdot(10+4) = (7\cdot10)+(7\cdot4) = 70+28$. Students can develop this mental strategy when they view multiplication as repeated addition and focus on the invariance of the total (Schifter, Monk, Russel, & Bastable, 2008). When this implicit use of the DP is transferred to problems where both factors are multi-digit numbers, a common error is to solve multiplications such as $26\cdot19$ by only multiplying the first terms and the second terms with each other; $(20+6)\cdot(10+9) = 20\cdot10 + 6\cdot9$ (Lo, Grant, & Flowers, 2008). Ding and Li (2014) suggest that the difficulties students have learning arithmetical properties, leading to calls for more concretisation, stem from their abstractness and "lack [of] close relevance to learners' lives" (p. 103). Concretisation by contextual and visual representations, in order to build a mental image of the operation and its properties, is argued to help students to structure and "organize their thinking and reasoning" (Yackel, 2001, p. 27). Both contextual and visual representations can reflect different multiplicative situations such as equal groups and rectangular arrays. A simple equal group situation is 4 bags of 8 apples in each bag, while a simple rectangular array can be a chocolate bar with 4 rows of 8 squares. In asymmetrical situations, such as equal groups, one factor is the multiplier (number of bags) and the other the multiplicand (number of apples). In symmetrical situations, such as rectangular arrays, the two factors have the same role.

A contextual representation suitable for illustrating the DP is the total cost for 4 cups of coffee and 4 cakes, where the answer would be the same whether you first multiply the cost for one coffee by 4, then the cost for one cake by 4and then add the products or if you first add the cost for one coffee and one cake and then multiply that sum by 4. A visual representation for equal groups can be used for discussing the ways the total number of objects could be calculated, by means of the DP (Lampert, 1986). A rectangular array of dots or squares can also illustrate how 7 rows, each with 14 objects, can be partitioned flexibly by use of the DP into for example $2 \cdot 14 + 5 \cdot 14$ rectangles (Young-Loveridge, 2005).

The CP, $a \cdot b = b \cdot a$, allows numbers to change places in multiplication and addition. Young students seem to discover and understand the CP for addition without instruction but not for multiplication (Squire, Davies, & Bryant, 2004). The rectangular array model is well suited to concretise the CP, as its rotational quality makes it perceptually self-explanatory, for example a box of 18 eggs in 3 rows of 6, which, when rotated 90° is simply perceived as 6 rows of 3 eggs. With an equal groups situation, it is not perceptually transparent that 7 bags of 14 coins is equivalent to 14 bags of 7 (Lo et al., 2008). Carpenter and colleagues (2003), however, found young students justifying an equal groups approach to the CP by rearranging the objects in the group, as exemplified by a students who said: "I would always get new groups that are the same size as the number of groups I started with and the number of new groups I would get would be the same as the number I had in each of the old groups" (p. 95). Some researchers argue that rectangular arrays should be introduced to enrich students' images for multiplication and to illustrate the DP (Carpenter et al., 2003; Young-Loveridge, 2005). Indeed, the illustration of integer multiplication as a rectangular array can explain standard algorithms and illustrate the extension of multiplication to rational numbers.

Squire and colleagues (2004) investigated 9–10 year old students' ability to use the DP and the CP in varied contextual situations. They gave a multiple-choice test whereby a multiplicative situation was given as a cue, and the problem was to solve a word problem of the same situation by means of either the DP or the CP. The DP problems presented the total number of objects in a groups of b objects (an equal groups problem) and asked for the total number of objects in a+1 groups of b objects. For example the students were given a multiplicative word problem incorporating the assertion $26 \cdot 21 = 546$ and invited to solve a similar problem involving $27 \cdot 21$. The CP problems were constructed analogously; if the cue stated the total number of objects in a groups of b objects the task objective was to find total amount of objects in b groups of a objects. They concluded that 9–10 years old English students could manage the CP in all situations but not the DP. DP problem reflecting equal groups were more often solved correctly than any other situations, leading Squire and colleagues to suggest that the representation of equal groups might be a natural way for young students to imagine what happens when the multiplier is changed by one. They conclude that equal groups should be employed when introducing students to the DP. This is in line with Lampert's (1986) findings that fourth grade students (about 10 years old) made sense of the DP by means of stories in combination with drawings illustrating equal groups. She argues that equal groups is more intuitive for young students than array models as that is how they model multiplication. This is also confirmed by literature in the field of early algebra (Schifter et al., 2008).

In short, we know that younger students (9–10 years old) do not invoke the DP as easily as the CP; that equal groups are more intuitive for the understanding of the DP than rectangular arrays, even though rectangular array is proposed to enrich students' understanding of the DP. But for middle grade students (12–13 years old) there is a lack of research of how they understand the DP and what representations they employ when reasoning about multiplication. Given the importance of arithmetical properties for the understanding of algebra as well as flexibility in calculation, it is appropriate to pose the question: how do sixth grade students understand distributivity?

METHOD

Students from two sixth grade classes already enrolled in a research project were invited to take part in this study. The 19 students who agreed to participate do not form a random or representative sample but a typical mix of Swedish students; some have diagnoses concerning concentration or dyslexia, some struggle with mathematics while others excel. In order to en-

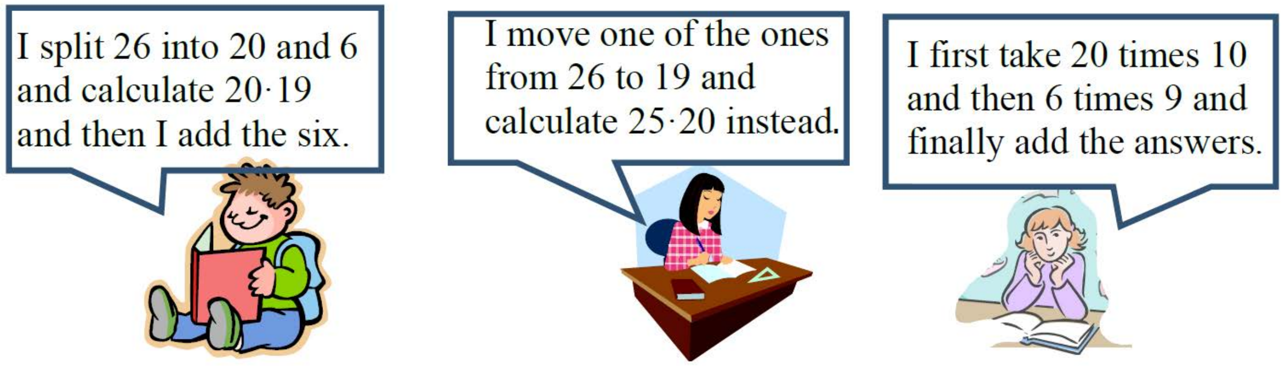

Figure 1: Problem 1 (P1), Problem 2 (P2) and Problem 3 (P3)

hance the possibility of a rich discussion, students were placed in homogeneous pairs (one worked alone) based on the evidence of earlier tests and interviews concerning the forms of multiplicative reasoning they had previously shown. They were presented with three problems written on separate cards, see Figure 1, each comprising a strategy from a fictitious student for the calculation of 26·19. The students' tasks were to discuss each problem with their peer and a) evaluate the validity of the suggested strategy and b) reason why the suggested strategy was valid or not. They were not informed that the suggested strategies were incorrect. A separate card with the multiplication problem (26·19) was visible throughout the discussions.

Problem1, (P1), reflects an incomplete use of the DP, where one factor is partitioned and multiplied by the other factor but the last part of the partitioned factor is added to the product without any multiplication.

Problem 2, (P2), is analogous to a common method for addition, where a suitable part is moved from one term to the other, in order to make an easier calculation.

Problem 3, (P3), reflects a well known error (Lo et al., 2008). However, all three strategies derived from (incorrect) strategies exploited by this group of students the previous year when they were tested on multiplication of two-digit numbers.

Each of the three problems is an example of how students have partitioned the numbers in order to simplify calculation. When using the DP correctly partitioning is the starting point, but to demonstrate understanding of the DP involves explaining what to do with the parts as well as why. By inviting students to evaluate and explain an incorrect use of the DP it was possible to draw conclusions from their reasoning about how they understand the DP.

The students' discussions, which took place in a room adjacent to their normal classroom, were video and audio recorded and all written material collected. The tasks were explained to the students, who were explicitly told that they did not need to do any calculations themselves. Each card was read aloud and left on the table. The discussions for all three problems lasted between 10 and 25 minutes including the oral information about the tasks. The transcribed student discussions were repeatedly read and their answers categorised according to the arguments they employed to explain their decisions about the validity of the strategy. Some students used multiple arguments for each problem and some arguments were used in all problems while other arguments were used for one or two of the problems.

RESULTS

In this section the categories of arguments that emerged from the data are presented and exemplified by excerpts from the students' discussions. These are followed by a discussion about the different types of reasoning in respect to the DP.

General justification reflects the arguments of four students who not only solved P2 by justifying why the suggested strategy was invalid but also investigated the strategy further in order to find out under what conditions it would work and when the answer would be bigger or smaller. Their arguments clearly reflect a discussion *about* multiplication and its properties.

Emil	If you increase the smaller number and decrease the larger number, then it always gets bigger.

Marcus: It might not work with zero point, but with ordinary numbers, whole numbers, then it always...

Here, Emil concluded that the product gets bigger if you move one from the larger factor to the other, and Marcus' statement reflected a discussion-derived argument concerning which numbers Emil's claim is valid for. In this case, "zero point" refers to decimal numbers.

Equal groups is a category where students made contextual references and represented 26·19 as 26 sets of 19 objects or 19 sets of 26. This argument was used in all three problems and reflected an awareness of why the DP is valid in multiplication.

Lucas If you take away one pile, then you take away nineteen. And that should be put in twenty-five piles. That doesn't work.

Here Lucas showed why the strategy was invalid, that one in the number 26 represents a group of 19, which is construed as understanding the DP.

Counterexample was used to evaluate the calculation strategy by use of numerical examples. Hence, it reflected multiplicative reasoning by implicit use of the DP. Students gave examples of moves of one from one factor to the other would not yield the same product, as exemplified by Ida.

Ida It is not the same, if it is eight times nine or seven times ten.

Here, Ida showed an awareness that if she used the same strategy as suggested by the fictitious student in P2, the calculation would yield an incorrect result, since it transformed the problem. She transferred the strategy into easier numbers to make arguments of why the strategy did not work. There were also students who gave counterexamples to the suggested strategy in P1, which reflected knowledge of the DP, stating that 6 needs to be multiplied by 19 and then the two partial products can be added.

Check the answer was used to assess the result rather than the strategy, and drew on a calculation of the answers for both the suggested strategy and for 26·19; if the answers were not the same the strategy must be invalid. This reflected a result-oriented view on multiplication without argumentation as to why the results differ; hence, such an argument does not demonstrate understanding of the DP. It was used for P2 and P3 and is exemplified by Hanna.

Hanna I will calculate that [25·20] and then this [26·19] and see if it is the same.

Experience was when students knew that the strategy was invalid or "knew" that it was valid from their experience of calculations. This argument offered no evidence of understanding of the DP since there was no reasoning as to why the strategy does not work. Alice used it to justify the falseness of P3 and Wilma its truth.

Alice That does not work. [...] I thought it worked before, but it doesn't.
Wilma It works. That is how I calculate.

Additive reasoning reflects the students' incorrect additive reasoning when calculating. This type of reasoning occurred in relation to all three problems.

Matilda If you first take twenty-six, and split it, that's the same. You can take nineteen and then take [one] to first make a twenty, that is, you can take one from the six to the nineteen, so it becomes twenty times twenty, and then just add five. Then you will get the same answer, just that you split it in different [parts].

Here, Matilda described an additive way of handling big numbers to partition the numbers into parts that are easier to handle. She suggested that 26 is split into 20 and 6, and then add 1 from the six (splitting 6 into 5 and 1) to make 20, take 20·20. Then finally add 5, ((19+1)·(26-1-5)+5).

The category *other* consists of vague and unclear arguments as well as no answer. Felicia gives an example of a vague argument and Alva of unclear reasoning to P1.

Felicia Then the six isn't timesed [multiplied].

Alva It is hard to explain, but it is just wrong.

Some of the students who reasoned like Felicia meant to take 20·19 + 6·19, others meant 20·19·6, while others never explained further how the six should be multiplied. Alva's statement is an example from which it is impossible to draw any conclusions about the student's understanding of the DP, which is this study's aim.

When the categories of arguments were analysed further, and in relation to the DP, different types of reasoning were found. Four students investigated the suggested strategy in P2 on a meta-level; for example, under what premises their arguments were valid, which can be described as an *investigative reasoning* on a *meta-level* about multiplication. These students not only considered the structure of multiplication but also the generality of their claims. The arguments, which drew on 'equal groups' and 'counterexamples', were construed as *multiplicative reasoning by the DP* since arguments in both these categories reflected an implicit understanding of the DP as a theorem-in-action (Vergnaud, 2009). The difference between the two categories of argument was that in 'equal groups' all arguments were validated by contextual examples, e.g., Lucas' piles (see above), while the 'counterexamples' were validated by numerical examples without references to objects in groups. In contrast to the category 'check the answer', 'counterexample' was focussed on explaining why the strategy was invalid while 'check the answer' was focussed on calculating answers, and hence labelled as *procedural reasoning*. To use 'experience' reflects a *descriptive reasoning* by stating that the suggested strategy was invalid, but not why. The descriptions were focussed on the calculations as a procedure to get the right answer, implying that the student did not understand the DP. Finally, there were students who gave arguments *not showing multiplicative reasoning*, some by 'additive reasoning' and some categorised as "other". Vague arguments and unclear statements are not necessarily indicative of their not being able to use multiplicative reasoning; they might have had problems verbalising their understanding. All arguments are presented in Table 1.

Since many students gave multiple arguments for the same problem, the sum of arguments for P2 and P3 exceed the number of participating students. The category "other" is only presented when students did not provide any other argument, hence reflecting the number of students unable to give any clear argument to each problem.

The distribution of arguments for each problem varies. For P1 six students employed multiplicative reasoning when they explained why the suggested strategy was invalid and thirteen used arguments showing no multiplicative reasoning. For P2 the distribution of arguments spread over all categories except 'experience', and the 19 students used 33 arguments, demonstrating students' use of multiple arguments. This problem also engaged students in general justifications, which did not occur for the other problems. For P3 six students drew on 'experience', three correct and three incorrect, in the evaluation of the erroneous strategy. The incorrect evaluations drawing on experience are the only arguments, besides additive reasoning, which led students to make incorrect conclusions about the validity of strategies.

In the rich discussions where students reasoned about P2 it was possible to infer understanding of both the DP and the CP. The following utterance from Emil shows his distinguishing the multiplier from the multiplicand. The transcript also demonstrates that he was aware of the CP when speaking about calculating "the other way around", a common way for Swedish students to talk about the CP.

Emil — But if you take less there [pointing at 19] then it has to be fewer times multiplied. Or it depends if you do it the other way around, so if I calculate 19·26, then it is anyway twenty-six times multiplied...

Type of reasoning	Category of arguments	P1	P2	P3
Investigative reasoning on meta-level	General justification	0	4	0
Multiplicative reasoning by the DP	Equal groups	2	6	7
	Counterexample	4	8	0
Procedural reasoning	Check the answer	0	9	8
Descriptive reasoning	Experience	0	0	3+3
Not showing multiplicative reasoning	Additive reasoning	1	4	4
	Other/no answer	12	2	3

Table 1: Number of students using different arguments for each problem

When students reasoned about equal groups they distinguished the multiplier from the multiplicand. Some of them interpreted 26·19 with 19 as the multiplier, others interpreted 26 as the multiplier. In some pairs this different interpretation of a fixed factor as the multiplier caused some confusion. However, all students were aware of the CP being valid for multiplication and overcame confusion by stating, that it did not matter which factor was multiplier, as exemplified by Johanna and Ida.

> Johanna Ida, it is ten times nineteen. Not ten times twenty-six.
>
> Ida What? You did it like this before, and then I thought twenty-six times ... but it doesn't matter what way around you do it.

During the discussions about all three problems some students offered other suggestions as to how to calculate 26·19. These suggestions clarified how they understand the DP, as with Hugo's statement where he gives a suggestion how to proceed with the strategy in P2 to get a correct answer.

> Hugo She has multiplied twenty times, and then she must take away what stands for one time, that is twenty-five. She has to take away twenty-five. [...] Then she gets that one times nineteen, so she has plus nineteen.

Here, Hugo demonstrates his understanding of the DP as he proposes compensating for the erroneous strategy of taking 25·20 instead of 26·19 by subtracting 25 and adding 19 to the product of 25·20; 26·19 = (26 - 1)·(19+1) - (1·25) + (1·19).

In summary, by engaging in the evaluation of incorrect strategies for two-digit multiplication, students with an implicit understanding of the DP demonstrated their understanding, mainly by reasoning about multiplication as equal groups. In equal groups the multiplier is distinguished from the multiplicand and this representation helped students to offer valid justifications about the incorrect strategies and to suggest other valid strategies employing the DP, but it also contributed to miscommunication connected to the CP. The arguments to explain and justify strategies demonstrated different types of reasoning involving both the DP and the CP as building blocks for understanding of multiplication. Students showing additive reasoning did not show knowledge about the arithmetical properties.

DISCUSSION AND CONCLUSIONS

The different arguments that students gave for the invalidity of the three strategies reflected different degrees of understanding the DP. When students cannot explain why or how a multiplication strategy works or not works it might be due to difficulties in expressing what they mean. It might also reflect shallow understanding of multiplication or explanatory difficulties due to perceptions of self-evidence. From my readings of students' explanations to P1, I infer that it was too easy for the majority of students to explain why you need to multiply the six as well. Still, one student, Matilda, who showed additive reasoning to all three problems, was convinced that P1 was a valid strategy, which she had trouble reconciling with the fact that the answer was wrong.

> Matilda It should work, but it doesn't. It might work if you take 20·19 and then multiply by 6. (After checking the calculation.)

Even though students like Matilda can be exposed as additive reasoners, P1 was not very productive since most students' answers and arguments were vague. This is in contrast to the other two problems, especially P2. The suggested strategy in P2, to move one from one factor to the other, caused long and elaborate discussions among most of the pairs. One reason might be that this strategy was new to most students. The novelty, and the analogous strategy for addition, might have evoked students' curiosity to investigate and engage in discussion about the strategy on a more general level than the other problems. In contrast to novelty, six students drew on experience to P3, the common mistake to only multiply tens by tens and ones by ones (Lo et al., 2008). Experience might have decreased the interest to engage in discussions about the strategy; students just knew that it "worked" or did not work.

Students who represented multiplication as equal groups in order to make sense of the DP and calculation strategies were successful, see for example Lucas' explanation why the suggested strategy in P2 did not work. The representation of equal groups as piles of objects served as a thinking tool to sort out the multiplication. To use the representation of equal groups as a thinking tool was demonstrated both for invalid strategies in the problems and for valid strategies employing the DP that the students offered as an alternative calculation. These Swedish middle school students seemed to prefer thinking about multiplication as equal groups just as the younger students from other studies (Lampert, 1986; Squire et al., 2004) and prospective teachers (Lo et al., 2008). However, the successful representation of multiplication as equal groups in respect to the DP proved to have a drawback concerning the CP. Even though students knew the validity of the CP for multiplication, there were instances where their view of one of the factors as the multiplier hindered their understanding of their peer's reasoning. This may be due to the fact that they represented the expression 26·19 differently, either as 26 groups of 19 or as 19 groups of 26. The students' explicit statements about the CP being valid can be construed as if the students did not take the CP as something self-evident when they were engaged in discussions drawing on equal groups. Interestingly, there were no utterances at all where students drew on rectangular array to make sense of calculation strategies or the CP.

The results of this study suggest that if we want students to learn and understand the DP we might better introduce the DP by equal groups and discuss the limits of its validity as well as how it can be used. On the other hand, the rectangular array, also an important representation of multiplication, highlights the CP by making it self-evident that $a \cdot b = b \cdot a$ (Carpenter et al., 2003) and can also be used to illustrate the DP (Carpenter et al., 2003; Young-Loveridge, 2005). If the underlying reason for illustrating the abstract properties of multiplication by contextual and visual representations is to build mental representations that can enhance understanding of the concepts (Yackel, 2001), it would be of interest to introduce multiple representations of multiplication. The findings from this study also suggest that more effort might be needed to incorporate representation of multiplication by rectangular arrays (and areas) in the instruction as complimentary representation to the equal groups, not as a substitute. Further research might give suggestions to how instruction can enhance the possibilities for students to build solid and useful mental representations of multiplication and its properties.

Investigating fourth graders' conceptual understanding of computational estimation using indirect estimation questions

Sabrina Lübke

TU Dortmund University, Faculty of Mathematics, Dortmund, Germany, sabrina.luebke@math.tu-dortmund.de

This paper presents selected findings from a qualitative study that has the main goal to investigate the procedures and concepts of fourth grade pupils solving computational estimations problems within the context of spending money. It gives theoretical background with respect to understanding computational estimation, and it points out a hitherto unmentioned concept underlying computational estimation – the interrelation of an estimate and the exact calculation – which is closely related to task characteristics. Therefore, the data analysis and the discussion focus on the role of this concept as well as of the role of task characteristics.

Keywords: Computational estimation, elementary arithmetic, conceptual understanding, problem types, approximate numbers.

INTRODUCTION

The necessity of computational estimation in the mathematics curriculum has been discussed for years, especially since the 1980s. Theoretical reflections and prior research have shown that it is an important skill in everyday life as well as in mathematics because it is strongly interwoven with number sense and flexibility in mathematical thinking (e.g. Sowder, 1992; Verschaffel, Greer, & De Corte, 2007). A considerable number of research about computational estimation exists, mainly focussing on estimation strategies used by secondary pupils and adults in America and Asia (e.g., Alajmi, 2009; B. Reys, R. Reys, & Peñafiel, 1991; R. Reys, B. Reys, Nohda et al., 1991; R. Reys, Rybolt, Bestgen, & Wyatt, 1982), and on the adaptivity of strategy choices (e.g., Lemaire & Lecacheur, 2002; Lemaire, Lecacheur, & Farioli, 2000). Depending on the specific problems and its underlying mathematical structures as well as on individual preferences there are different strategies that can be used to make an estimate (see Table 1). At the same time empirical studies gave evidence that rounding is the predominant one being used to solve computational estimation tasks, as soon as it is brought up in the classroom (cf. R. Reys et al., 1991; R. Reys et al., 1982) and whether or not it leads to the correct answer. According to this it is assumed that this strategy is often used without understanding (e.g. Schoen, Blume, & Hoover, 1990). These findings are mainly based on quantitative studies. Thus, it is only little known about pupils' thinking, and about their concepts of computational estimation. Therefore, this paper deals with the concepts underlying computational estimation by means of a qualitative study with fourth grade pupils.

THEORETICAL FRAMEWORK

What is computational estimation?

To clarify the underlying concepts of computational estimation, the term itself will be defined first, since there are several, sometimes inconsistently used terms and definitions. In the English language, probably one of the most widely used expressions is *estimation*. On the one hand, this term refers to activities like *measurement* and *numerosity estimation:* In these cases some information is missing, and therefore an exact calculation is not possible and consequently assumptions about a quantity have to be made. On the other hand, estimation refers to *computational estimation,* which is the focus of this paper. In this case all quantities, respectively numbers, are known, but an exact calculation is not necessary due to the context. Thus, an exact calculation is consciously 'refused' in favour of a *simplification* (cf. Breidenbach 1969). This idea of simplifying a calculation to make it easier is finally one of the main goals of computational estima-

139 + 119 + 124 ≈	
Rounding	100 + 100 + 100 = 300
Translation	e.g. 3 · 130 = 390
Compensation (Adjustment while or after an estimate)	100 + 100 + 100 = 300, it has to be more because of rounding down, ≈ 370

Table 1: Examples of computational estimation strategies (cf. R. Reys et al., 1982)

tion (cf. LeFevre, Greenham, & Waheed, 1993; Star & Rittle-Johnson, 2009).

Concepts of computational estimation

Although most of the previous research deals with strategy execution, there are some studies that are concerned with the concepts of computational estimation as well (e.g., Cochran & Dugger, 2013; LeFevre et al., 1993; Sowder & Wheeler, 1989; Star, Lee, Chang, Glasser, & Rittle-Johnson, 2007). Sowder & Wheeler (1989) differentiated five components involved in computational estimation with *conceptual components* as one of them (p. 132). According to this, there are three concepts pupils have to understand in order to make an appropriate estimate (Cochran & Dugger, 2013; Sowder & Wheeler, 1989):

— **Role of Approximate Numbers**: Recognition that the process of computational estimation requires computing with approximate numbers, and that an estimate is an approximation.

— **Multiple Processes/Multiple Outcomes**: Acceptance of several possible processes for obtaining an estimate, and of more than one possible value as an estimate.

— **Appropriateness:** Recognition that appropriateness depends on the context and the desired accuracy.

An interview study focusing on these concepts (Sowder & Wheeler, 1989) found that pupils (grades 3, 5, 7 and 9) hardly seem to recognize these concepts. For instance, many pupils preferred a compute-then-round method in place of a simplification of the problem, and hence, did not seem to recognize the role of approximate numbers in the sense of Sowder and Wheeler (1989).

In addition to the conceptual components provided by Sowder and Wheeler (1989), Star and Rittle-Johnson (2009) operationalize conceptual knowledge of computational estimation by tasks that focus on the *impact of estimation strategies on distance from the correct answer*. In accordance with this, van den Heuvel-Panhuizen (2001) points out a peculiarity for so-called indirect estimation questions. These are types of estimation problems like "Quickly decide if the total of 186, 495 and 197 points is more or less than 1000" (van den Heuvel-Panhuizen, 2001, 184). For this sort of question the answer is not a number, but a decision. Since an exact calculation is not necessary, a simplification is sufficient. Therefore, an estimate is an adequate, but not a sufficient solution strategy:

> However, in order to answer the estimation question with some degree of certainty, some reasoning is still necessary. With the problem about the total number of points, students must be able to perceive that rounding up three times (besides the fact that the sum of the rounded off numbers is only 900) allows them to be certain that the total must be under 1000 (van den Heuvel-Panhuizen, 2001, 184).

This quotation points out two aspects: It is not only important to take into account the impact of estimations strategies in an operational way, as emphasized by Star and Rittle-Johnson (2009), but it is another relevant concept of computational estimation to perceive that an estimate is directly intertwined with the original problem. In other words, an estimate is a model for an exact calculation. This means, pupils must understand that there is an interrelation of an estimate and the exact calculation and an estimate finally has to be interpreted (adjusted) to lead to a correct answer of an indirect estimation question.

Combining the concepts pointed out by Sowder and Wheeler (1989) on the one hand, and Star and Rittle-Johnson (2009), and van den Heuvel-Panhuizen (2001) on the other hand, the concepts of computational estimation can be summarized as follows:

— Role of Approximate Numbers

— Multiple Processes/Outcomes

- Appropriateness
- Interrelation of an estimate and exact calculation (operational and conceptual)

Not investigated before, the last concept became one of the four foci of a study on the concepts and procedures of grade four pupils solving direct and indirect estimation questions (cf. Hunke, 2012) and leads to the following question:

To what extent do pupils respect the concept of the interrelation of an estimate and exact calculation when they solve indirect estimation questions ("Is it enough money?")?

Since this aspect is closely related to the necessity of interpreting an estimate, the findings in this paper will be discussed along the following questions (Q)

Q1: How do children arrive at the answer to an indirect estimation question when they start with an estimate? Do they interpret their estimates?

Q2: If the situation should arise – How do they carry out such an interpretation?

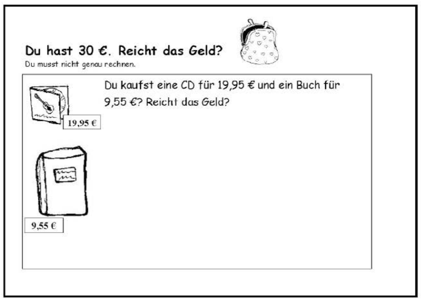
Q3: What are possible reasons for not interpreting estimates?

METHOD

Since the estimation process is quite complex it would be difficult to get insights into pupils' concepts and thinking only by analysing written documents and outcomes of a task (cf. Heirdsfield, 2002; Schoen et al., 1987). Carpenter, Coburn and Reys (1976, 299) pointed out that "to obtain a valid measure of a student's ability to estimate it is probably necessary to observe that student estimating". Thus, all in all 42 fourth grade pupils from four different primary schools in the state of North Rhine-Westphalia (Germany) were interviewed. To gain a broad and balanced overview of strategies and concepts pupils showing low, average and high performance in mathematics were chosen for the interviews. This ranking was made according to the teachers' evaluation of the pupils. However, the pupils' background was not deeper taken into account for analysis.

Two different sets of problems were used in the interviews, following the idea of van den Heuvel-Panhuizen (2001) to differentiate between direct and indirect estimation questions. As pointed out earlier, especially the indirect estimation questions require the concept of *interrelation of an estimate and exact calculation* to be answered successfully. One problem set only consisted of direct estimation questions ("*Approximately how much does it cost?*"), where a number as a result was necessary. The other set only consisted of indirect estimation questions ("*Do you have enough money?*"), where a mathematically based decision had to be made (see Figure 1). With regard to the aforementioned research questions, only data gained by solving the indirect estimation questions are taken into account for this paper.

The settings contained six addition and six multiplication problems. Whole numbers as well as decimals were used. To get an insight in the concepts of computational estimation, some of the problems contained numbers that make an interpretation necessary when a conventional rounding strategy is used first (e.g., the problem in Figure 1). Since there also were also other research foci not discussed in this paper, the numbers in some of the other problems were rather chosen to operationalize other aspects of computational estimation (Hunke, 2012, 117ff.). Nonetheless, all these problems were taken into account for the following analysis.



You have got € 30. Do you have enough money?
An exact calculation is not necessary.

You buy a CD for € 19.95 and a book for € 9.55. Do you have enough money?

Figure 1: Indirect estimation question (addition) (cf. van den Heuvel-Panhuizen, 2001)

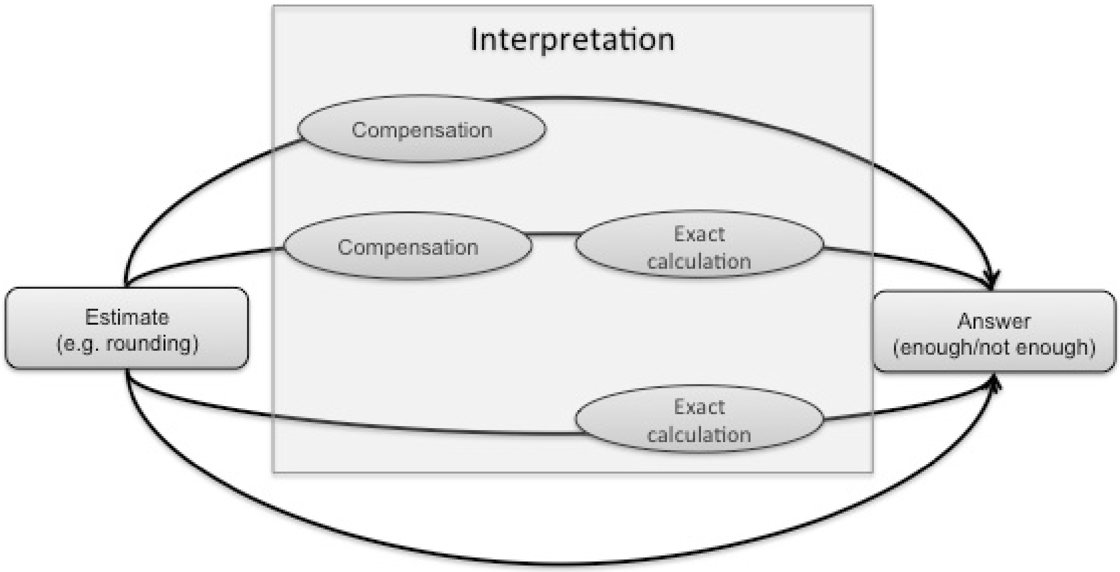


Figure 2: Four approaches of finding an answer to an indirect estimation question

All interviews were video recorded and transcribed for data analysis. Afterwards the data were coded along the four research foci. Therefore, categories were developed according to the theoretical framework, the research questions as well as to the data itself (cf. Schmidt, 1997).

FINDINGS

Data analysis on behalf of question 1 (Q1) led to four considerably different approaches (categories) how children deal with their estimates gained by rounding, to arrive at the answer to the "Do you have enough money?"-problems [1]. Each approach is represented by one arrow in Figure 2. It shows that an interpretation of the estimate, which would indicate a certain amount of conceptual knowledge, is not naturally included in the children's approaches.

Q2: *How do the children carry out such an interpretation?*

The children who use one of the upper three approaches all show a certain amount of conceptual understanding, because, to some extent, they recognize the interrelation of their estimate and exact calculation as they conduct some sort of interpretation. The following excerpt of the interview with Franziska illustrates the second approach 'estimate – compensation – exact calculation – answer' used by her for finding an answer to the addition problems illustrated in Figure 1. Franziska starts with an estimate and then argues as follows:

> *"You have got € 30. You buy a CD for € 19.95 and a book for € 9.55. Do you have enough money?"*

Franziska: That would be 30 Euro. *Since I rounded up here and here, well, I don't believe that it makes 30 all together.* Give me a second, now I calculate it like this (*writes down and executes an exact calculation, see Figure 3*). Yes, because here, I rounded up and rounded up, it's actually more, and thus 30 Euro.

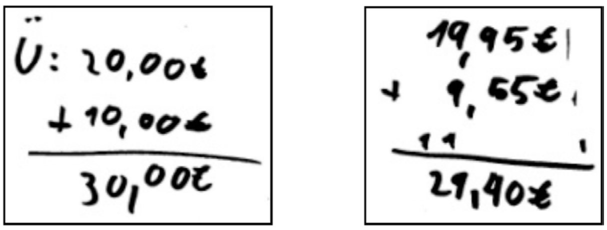

Figure 3: Franziska's estimate and subsequent exact calculation

Franziska is conscious of the fact that the estimate is 'only' a model for an exact calculation, which for this certain problem has to be interpreted. She carries out this interpretation with a compensation strategy first ("Since I rounded up here and here"). But it seems that Franziska does not feel comfortable with this because she checks her arguing by an additional exact calculation. At least, this example shows that Franziska already has an understanding of the concept of the interrelation of an estimate and the corresponding exact calculation from an operational as well as from a conceptual perspective. On the contrary, some children had difficulty in carrying out a compensation strategy although they were conscious about the need of it (cf. Hunke, 2012). Nonetheless, Franziska has to gain more confidence in her number sense, because for this certain problem a further exact calculation was not necessary.

Q3: *What are possible reasons for not interpreting estimates?*

Next to those three approaches, that to some extent reflect conceptual knowledge, it is the fourth of the aforementioned approaches that seems to be especially interesting, since it represents those children who do not take into account the interrelation of an estimate and the exact calculation. In fact, some pupils directly generate their answers from their estimates, which is exemplified by Jessica's and Anna's reasoning:

As well as Franziska, Jessica easily finds an estimate for the problem "*Larissa has got € 25. She wants to buy seven wooden ornamental letters to put on her bedroom door. Each letter costs € 3.55. Has she got enough money?*":

Jessica: [...] I prefer taking € 4 ... multiplied by 7, makes 28! Thus, it's not enough money, she hasn't saved enough. € 3 are missing.

4€ · 7 = 28

Figure 4

She rounds up the price from € 3.55 to € 4 that leads to an estimate above the budget. Jessica then directly generates her answer to the problem on basis of her estimate (approach 4) instead of taking into account her rounding. This is evident by her statement "€ 3 are missing". Thus, Jessica finally gets an incorrect answer to the problem. In fact, due to the process of rounding up, the exact result must be smaller than € 28 and thus some fine-tuning is still necessary to find out if eventually there is enough money. This demonstrates that for Jessica an estimate seems to be an autonomous form of calculation with no relation to the original task. Consequently, it has to be supposed that she does not yet have a comprehensive understanding of the concepts of computational estimation.

More or less the same can be stated for Anna. In addition, her reasoning leads to a further problem which emphasizes the importance of the concept of computational estimation concerning the interrelation of an estimate and the exact calculation. Anna solves all the problems with an exact calculation at first. She only makes estimates when the interviewer explicitly encourages her to do so. For some problems this leads to two competing results as in the following case: *"You have got € 30. You buy a CD for € 15.55, a woolly hat for € 5.99 and a scarf for € 8,98. Do you have enough money?"*

At first, Anna chooses the written algorithm to get to the exact result of € 29.42, and according to that she arrives at the answer that she has got enough money. After that, the interviewer asks her to solve the problem with an estimate as well. Consequently, she gets to the estimate 16 + 9 + 6 = 31, and comes to the conclusion that "it doesn't work with an estimate, actually":

Interviewer: So, what is the answer, finally?

Anna: There is enough money, because 58 Cent are left, but you cannot buy anything expensive in addition to that.

Interviewer: And what about the estimate?

Anna: Yes, well...(speaks quietly) 15 plus 9, 25. It's 31 with estimation. *That doesn't work.*

Here, the assumption comes up that, although Anna is able to execute an estimate, she regards it as an autonomous calculation form which leads to another conclusion to the question than the exact calculation, and therefore, to Anna's mind, estimation is not possible here. Thus, Anna's approach is also categorized as approach number 4 – she tries to generate her answer to the question directly on the basis of her estimate. This can be a hint that Anna does not have a comprehensive understanding of the concepts of computational estimation. In Anna's case this might as well be the reason for preferring exact calculations. For her, estimation does not seem to make sense, and thus she resigns it.

CONCLUSION

This paper supports previous findings that computational estimation is a complex task for which a comprehensive understanding is needed. Theoretical analysis of the concepts of computational estimation led to a hitherto unmentioned and therefore unexamined concept of computational estimation, namely the concept of the interrelation between an estimate and the exact calculation.

The empirical snapshot underlined the theoretical considerations that this concept is a very important aspect of understanding computational estimation. Of course, these results cannot be generalized because of the small scope of the study. Nonetheless, for the case of indirect estimation questions it could be pointed out that although the subjects of this study were generally able to carry out an estimate they did not necessarily understand what an estimate really is. This especially was apparent in those approaches where the children directly generated an answer to the question "Do you have enough money?" from their estimates. While this approach is sufficient for direct estimation questions ("Approximately how much...?"), it is not generalizable for every type of estimation problem.

In consequence, indirect estimation questions turned out to be a useful tool to make this certain concept of computational estimation visible. At the same time the findings give useful indications for teaching computational estimation. If we want to teach computational estimation with understanding, we need to provide tasks that allow pupils to develop the aforementioned concepts. Indirect estimation questions as used in this study seem to be adequate for this because they give the opportunity to discuss the interrelation of the estimate and the exact calculation from an operational as well as from a conceptual perspective.

Although estimation questions like "How much does it cost approximately?" (direct estimation question) and "Do you have enough money?" (indirect estimation question) have been typical estimation tasks in textbooks in the German primary classroom before, their respective potential does not yet seem to be utilized. According to van den Heuvel-Panhuizen (2001) a learning-teaching trajectory is suggested that starts with indirect estimation questions. Not only can these questions evoke other strategies than rounding (Hunke, 2012; van den Heuvel-Panhuizen, 2001), but they can also be used to discuss the concepts of approximation and interrelation, *before* the children learn any estimation strategy that might be executed without understanding. Thus, further research is needed. Design experiments therefore seem to be especially desirable. Pursuing such an experimental approach, further research questions could be "Which design principles are needed for fostering children's understanding of computational estimation? How can direct and indirect estimation questions be used systematically in the primary classroom? Which numbers are especially suitable to make this certain concept obvious? How can children be encouraged to evoke more number sensed based strategies for computational estimation problems?". Finally it is particularly necessary to support teachers to become more sensitive for this very important topic, especially what it means to teach estimation with understanding.

ENDNOTE

1. More than one half of the indirect estimation questions have been solved with an estimation strategy, mainly rounding (Hunke, 2012).

The impact of a teaching intervention on sixth grade students' fraction understanding and their performance in seven abilities that constitute fraction understanding

Aristoklis A. Nicolaou[1] and Demetra Pitta-Pantazi[2]

1 Ministry of Education of Cyprus, Strovolos and University of Nicosia, Egkomi, Cyprus, educati@cytanet.com.cy

2 University of Cyprus, Strovolos, Cyprus

In a previous study, we found that students' abilities in fraction recognition, definitions and explanations, argumentations and justifications, relative magnitude of fractions, representations, connections and reflection constitute fraction understanding of sixth grade students. In the present study, we examine the impact of an intervention comprising of lessons for developing the seven abilities on students' fraction understanding and their performance in the seven abilities. The sample comprised of 343 sixth grade students. Repeated measures analysis showed that the students of the experimental group outperformed those of the control group in their level of fraction understanding and their ability in fraction recognition, definitions and explanations, argumentations and justifications, connections and reflection.

Keywords: Fraction understanding, repeated measures analysis, sixth grade, students' abilities, teaching intervention.

INTRODUCTION

Fraction complexities and students' difficulties have led a number of researchers in the past to study fraction understanding carrying out research programs and teaching experiments (e.g. Cramer, Post, & delMas, 2002). In the present study, we examine the impact of a teaching intervention which is based upon a different perspective compared to the studies already carried out. More specifically, in a previous study conducted by the authors (Nicolaou & Pitta-Pantazi, 2011), we confirmed a theoretical model with seven abilities that constitute fraction understanding at elementary school. The seven abilities were: (a) fraction recognition, (b) definitions and mathematical explanations for fractions, (c) argumentations and justifications about fractions, (d) relative magnitude of fractions, (e) representations of fractions, (f) connections of fractions with decimals, percentages and division, and (g) reflection during the solution of fraction problems. Five of these abilities, definitions and mathematical explanations, argumentations and justifications, representations, connections and reflection correspond to the mathematical processes suggested by NCTM (2000) that are important for understanding mathematical concepts. We consider that apart from the various issues related to fraction understanding that were already investigated, students' ability to engage in processes such as reflection during the solution of fraction problems, explanations for fractions, argumentations and justifications about fractions, representations of fractions and connections of fractions with decimals, percentages and division are essential for fraction understanding. Additionally, we included fraction recognition and the relative magnitude of fractions in the abilities required for fraction understanding at elementary school (the reasons for this decision are provided in the next section "Theoretical Background").

In the present study, we examine the impact of a teaching intervention comprising of lessons for developing the seven abilities on sixth grade students' fraction understanding and their performance in the seven abilities. The aim was twofold: (a) To examine the impact of the intervention on sixth grade students' fraction understanding, and (b) To examine the impact of the intervention on students' performance in each of the seven abilities.

THEORETICAL BACKGROUND

The seven abilities

According to NCTM (2000), mathematical processes are very important for understanding mathematical concepts. Based on this rationale, we considered that students' abilities in these processes are also important for fraction understanding at elementary school. We also included two more abilities as explained below. In this section we will briefly refer to these seven abilities (for more details see Nicolaou & Pitta-Pantazi, 2011).

Reflection during the solution of fraction problems refers to students' ability to reason their thinking and their answer while solving fraction problems, to support the reasonableness of their answer and verify a given answer. In order to solve fraction problems, students should be able to use the various fraction sub-constructs; they should be able to think of fractions embedded in mathematical problems corresponding to these sub-constructs and utilize them accordingly to solve the problem. Moreover, students should be able to carry out operations with fractions. Argumentations and justifications about fractions refer to a kind of "informal proof" at elementary school. For the purpose of the present study, argumentations and justifications refer to students' ability to judge statements about fractions as true or false, justifying at the same time their choice. Definitions and mathematical explanations for fractions refer to students' ability to define in their own words what a fraction is and also to explain in various ways (verbally, by using drawings, examples etc.) other issues concerning fractions (e.g., fraction equivalence, comparison, density). Connections refer to students' ability to connect fractions to other forms of rational numbers (decimals and percentages) and division. Representations of fractions refer to students' ability to translate to visual, verbal and symbolic representations and their ability to construct drawings for fractions.

In order to propose a model that would provide a sufficient description of fraction understanding, we also included fraction recognition and relative magnitude of fractions in the abilities required for fraction understanding. Fraction recognition refers to students' ability to recognize structural characteristics of fractions and detect similarities and differences between fractions. It also includes students' ability to categorize fractions on the basis of a common characteristic. The relative magnitude of fractions refers to students' ability to compare and order fractions and is crucial for fraction understanding, since in the case students are not able to compare and order fractions, then they probably do not understand the meaning of fractions.

METHODOLOGY

The rationale of the intervention – Its principles

The intervention comprised of activities which aimed at developing the seven abilities. The design of the intervention was based on some principles. According to the first principle, the activities and the problems should be interesting, arise from everyday life and attract students' interest (Elbers, 2003). The second principle referred to the sequence of the activities from the easiest to the more difficult ones. The third principle was about the way students worked; either individually or in small groups favoring discussion and exchange of ideas (Elbers, 2003; Martino & Maher, 1999; Terwel, Van Oers, van Dijk, & van den Eeden, 2009). After working individually or in small groups, students discussed their ideas in the whole classroom and this procedure helped them to share their views and interact (Elbers, 2003; Martino & Maher, 1999; Terwel et al., 2009). Additionally, in every activity students had to explain their thinking and provide adequate reasoning for their decisions. The fourth principle referred to the modification of the lesson plans according to the strengths and weaknesses of the students and their previous knowledge of fractions. The fifth principle referred to the role of the teacher as a facilitator of learning. While students worked individually or in small groups, the teacher moved around the classroom, provided support and feedback. During the whole class discussion and exchange of ideas, the teacher was expected to guide the discussion and pose questions that would stimulate further inquiry (Martino & Maher, 1999).

Participants, instruments and procedure of the study

Participants in the present study, which was quantitative in nature, were 343 sixth grade students (age range 10.8–11.8 years old). A test comprising 37 tasks for measuring the seven abilities was developed. The tasks of the test were content and face validated by four experienced primary school teachers and two

Fraction recognition	One of the following fractions differs from the others. Find that fraction and circle it. $\frac{2}{7}$ $\frac{3}{2}$ $\frac{14}{49}$ $\frac{10}{35}$ $\frac{4}{14}$
Definitions and mathematical explanations for fractions	Imagine that your teacher asked you to explain to one of your classmates what a fraction is. Use as many different ways you can.
Argumentations and justifications about fractions	If I double both the numerator and the denominator of a fraction, then the formed fraction has twice value compared to the initial one. T F Justify your answer:
Relative magnitude of fractions	Order the fractions $\frac{1}{2}, \frac{4}{3}, \frac{2}{3}, \frac{1}{4}$ starting from the smallest one.
Representations of fractions	Marinos ates $\frac{1}{2}$ of a cake and Marinas $\frac{3}{8}$ of the same cake. Construct a drawing to show what part each child ate and what part the two children ate together.
Connections of fractions with decimals, percentages and division	Convert the following fractions to decimals. a) $\frac{1}{4}=$ b) $\frac{2}{5}=$ c) $\frac{3}{10}=$ d) $\frac{1}{20}=$
Reflection during the solution of fraction problems	In order to prepare a cake, I need $\frac{1}{10}$ L milk. If I have $\frac{4}{15}$ L milk, then how many cakes can I prepare? **You should definitely reason about your answer.**

Table 1: Tasks used to measure each ability

university tutors of mathematics education before their administration. Tasks 1–3 were used to measure fraction recognition, tasks 4–7 definitions and mathematical explanations for fractions, tasks 8–12 argumentations and justifications about fractions, tasks 13–15 and 32–37 were about reflection during the solution of fraction problems, tasks 16a-16c and 17 were about the relative magnitude of fractions, tasks 18–27 measured representations, while tasks 28–31 examined students' ability to link fractions to decimals, percentages and division. Examples of tasks used to measure each one of the abilities are presented in Table 1.

The first measurement was conducted at the beginning of the school year in the first two weeks of October. After the first measurement, the participants were split into experimental and control group. The experimental group comprised of eight classes (144 students), while the control group comprised of eleven classes (199 students).

The intervention comprised of nine lessons, four of which had a duration of 80 minutes, two 60 minutes, while the other three 40 minutes. The total time devoted was 14x40 minutes. The time devoted to the development of each of the seven abilities was about the same (2–3 40 minute periods) with the exception of the relative magnitude of fractions, which was devoted less time (about 40 minutes). The reason for this is that similar activities for developing this kind of ability are included in school textbooks. It should also be stressed that some lessons aimed at developing more than one ability and comprised of activities that served towards this goal.

The implementation of the intervention started at the end of October after the first administration of the test for measuring the seven abilities (pre-test). Its duration was about nine weeks until the end of January before the second administration of the test (post-test). The teachers that participated in the study were asked to teach one lesson every week. The students of the control group during this time were taught according to the Cyprus National Mathematics Curriculum which included topics such as recognizing representations of fractions, some activities of explaining what a fraction is, recognizing fractions as the division of the numerator by the denominator, equivalent fractions, fraction comparison and ordering, improper fractions and mixed numbers, decimals and percentages and their conversion to fractions. It must be noted that the total time devoted to fraction teaching was about the same for the two groups.

After the completion of the intervention, all students (including those of the experimental group) were taught according to the Cyprus National Mathematics Curriculum until the end of the sixth grade. They practiced simplifying and comparing fractions, adding and subtracting fractions with the same or different denominator, adding and subtracting mixed numbers, solving fraction problems, fraction multiplication and division, solving problems of mixed numbers and multiplication and division of mixed numbers. About three months after the second measurement, a third measurement took place (retention-test) for examining the duration of the impact of the intervention.

The lessons

The activities designed for implementing the goals of the intervention shared a scenario that was challenging, attractive and pleasant for students. The scenario referred to the trip of the "Mathematician" to the land of fractions. The trip comprised of various activities and the participants were called to answer questions and solve some problems. The scenario was designed in order to please students and motive them to engage in the activities with enthusiasm.

The first lesson with duration 80 minutes aimed at developing students' ability in "defining" what a fraction is, recognizing fractions in various representational systems, placing fractions on number line and linking the concept of fractions to the division numerator ÷ denominator. The goal of the second 80 minutes lesson was the development of students' ability to connect fractions to the other two forms of rational numbers, decimals and percentages and was complementary to the first lesson. During the lesson, the teacher raised questions: "What are decimals?", "What are percentages?" that would lead to the definition of decimals and percentages. Students were also asked to convert fractions to decimals and percentages and the reverse. Emphasis was placed on understanding the conversion and not just applying the rules. Students also worked on textbook activities. The third 40 minutes lesson cultivated students' ability to construct visual representations of fractions and acquire a feeling of the relative magnitude of fractions. Students worked in pairs and were encouraged to construct various representations. Students also worked on textbook activities that referred to fraction comparison and ordering by utilizing visual representations. The fourth lesson with duration 80 minutes referred to the development of students' ability to convert verbal and symbolic representations to visual ones and vice versa. The fourth lesson was complementary to the first and third lessons regarding the development of students' abilities in representations. In some activities, problems of fractions were presented to students and they had to write the equation and construct drawing/drawings in order to solve them (translation from verbal to symbolic and visual representations). Other activities asked students to translate from symbolic to visual and verbal representations. In these activities, the equation was given and students had to write a problem that could be solved by this equation or construct a drawing. Finally, students were called to write problems on the basis of visual representations (from visual to verbal representation). Lessons 5 and 6, with duration 60 minutes each, aimed at developing students' ability in reflection during the solution of fraction problems. Five carefully selected problems were presented to students and they had to solve them and were encouraged to reason their thinking, explain the strategy they used, express their confidence about their solution, examine whether the path they followed was correct or not and what they did correct and what wrong. Furthermore, they were called to think about the reasonableness of their answer and verify their answer. The seventh and eighth lessons with duration 40 minutes each aimed at developing students' abilities in fraction recognition, mathematical explanations for fractions, justifications about fractions and reflection. The two lessons included activities requiring students to detect fraction similarities, fraction differences and write fractions that share a common property. The ninth 80 minutes lesson aimed at developing students' abilities in argumentations and justifications about fractions and reflection.

Statistical analyses

To answer the two research questions about the impact of the teaching intervention on students' fraction understanding and their performance in the seven abilities, the z-scores that emerged from the Confirmatory Factor Analysis utilized in a previous study carried out by the authors (Nicolaou & Pitta-Pantazi, 2011) were used. Descriptive statistics (means and standard errors of estimate) for students' fraction understanding and the seven abilities were first found for the control and the experimental group respectively. Afterwards, Repeated Measures Analysis was used with dependent variable the score for fraction understanding and then for each of the seven abilities separately and independent variables the kind of condition (control or experimental) and the time of the measurement (pre-test, post-test, retention-test). The independent samples t-test was also used to test for the equality of the two groups in the pre-test.

RESULTS

Table 2 shows means and standard errors of estimate of fraction understanding for the experimental and the control group for each of the three measurements.

Table 2 illustrates that before the intervention, the two groups of students were equal with respect to their level of fraction understanding. This was also confirmed by the application of t-test (t=.182, p=.856>0.05). In the period of the implementation of the intervention, both groups improved, but the improvement of the experimental group was greater. In the period three months after the intervention the two groups continued to improve and the difference found in the post-test was maintained in the retention test. Repeated Measures Analysis showed that the means of fraction understanding differed significantly between the three measurements (Pillai's $F_{(2,340)}$=.516, p<0.01), and additionally, there was a statistically significant interaction of fraction understanding with the kind of the condition (Pillai's $F_{(2,340)}$=.029, p<0.01). Therefore, the differences found between the two groups of students could be attributed to the implementation of the intervention which gave the experimental group superiority over the control group.

Descriptive statistics for students' performance in each of the seven abilities are shown in Table 3.

From Table 3, we observe that the experimental and the control group had about equal means for all the seven abilities at the pre-test. This was also confirmed by the application of the t-test, which showed the equality of the two groups of students before the conduction of the intervention (for fraction recognition t=-0.603, p>0.05; for definitions and mathematical explanations t=0.170, p>0.05; for argumentations and justifications t=0.600, p>0.05; for relative magnitude of fractions t=-0.203, p>0.05; for representations t=0.901, p>0.05; for connections t=0.827, p>0.05; for reflection t=-0.641, p>0.05). Regarding the evolution of students' abilities, the experimental group showed continuous improvement during the period of the three measurements in the relative magnitude of fractions, representations, connections and reflection, whereas this was not the case for fraction recognition, definitions and mathematical explanations and argumentations and justifications where there was improvement from the pre-test to the post-test and then a decline in the period three months after the intervention. Concerning the control group, students' ability in the relative magnitude of fractions and reflection showed continuous improvement in the period of the three measurements. For representations, a very small improvement was observed during the period from the pre-test to the post-test, but this improvement was much greater in the period from the post-test to the retention test. Students' ability in fraction recognition and connections had an increase during the period from the pre-test to the post-test and then a decline in the period from the post-test to the retention-test. For definitions and mathematical explanations and argumentations and justifications there was improvement in the period between the pre-test and the post-test and then stabilization. The improvement of the students of the control group in some of the abilities can be attributed to maturity and teaching. Nevertheless, both at the post-test and at the retention-test the experimental group outperformed the control group in all the abilities with the exception of the relative magnitude of fractions where the two groups were about equal. The application of Repeated Measures Analysis revealed that the means for all the seven abilities differed significantly between the three measurements. Additionally, for five abilities: fraction recognition, definitions and mathematical explanations, argumentations and justifications, con-

nections and reflection there was an interaction with the condition (experimental or control) (the results are presented in Table 4). Therefore, the higher means of the experimental group at the post-test and retention-test can be attributed to the implementation of the intervention, which according to the results of the Repeated Measures Analysis was effective in improving students' abilities in fraction recognition, definitions and mathematical explanations, argumentations and justifications, connections and reflection.

DISCUSSION

The results of the present study revealed that the intervention was effective in developing sixth-grade students' fraction understanding and their abilities

	Between the three measurements	Interaction with the condition
Ability	Pillai's $F_{(2,340)}$	Pillai's $F_{(2,340)}$

Table 4: Results of Repeated Measures Analysis for each of the seven abilities

in fraction recognition, definitions and mathematical explanations for fractions, argumentations and justifications about fractions, connections with decimals, percentages and division and reflection during the solution of fraction problems. Therefore, the content of the intervention and the principles followed were effective in improving students' fraction understanding and their performance in five out of the seven abilities.

The conduction of the retention test added value to the findings of the present study, as it permitted the extraction of conclusions about the duration of the effects of the intervention. The conduction of three measurements also provided some evidence for the evolution of each of the seven abilities for the students of the control classes that did not receive the intervention.

For two of the abilities, the relative magnitude of fractions and representations of fractions, the intervention did not have significant effects. Concerning the relative magnitude of fractions, the results might be attributed to the fact that the curriculum provided much emphasis in developing this kind of ability. For representations, the results can also be due to the moderate emphasis given by the curriculum towards developing students' ability in representations of fractions. However, in the case of representations it must be stressed that the experimental group was superior to the control group both in the post and the retention test, but this superiority was not statistically significant.

The contribution of the present study in the area is situated in that the intervention focused on the abilities that are essential for fraction understanding at elementary school, while the focus of other studies was different (for example, Lamon (2012) examined fraction understanding addressing fraction sub-constructs). The present study also has implications for teaching fractions with understanding as teachers can utilize the content of the intervention for developing students' fraction understanding and their performance in the five abilities applying at the same time its principles.

Processes of mathematical reasoning of equations in primary mathematics lessons

Marcus Nührenbörger[1] and Ralph Schwarzkopf[2]

1 Technische Universität Dortmund, Dortmund, Germany

2 Carl von Ossietzky Universität Oldenburg, Oldenburg, Germany, ralph.schwarzkopf@uni-oldenburg.de

Learning of mathematics in primary classes should not be reduced to learning algorithms and routines or procedures. As we see the learning of mathematics as a process of interpreting mathematical structures and generalizations, it is more important to foster children`s thinking and learning of meaningful relations between objects and operations in the context of equations. In this sense children have to learn algebraic relations in primary classes without using algebraic signs. In this paper the results of a design study and a video-based qualitative analysis of teaching/learning situations in the field of reasoning of equations are discussed.

Keywords: Argumentation, equation, algebraic thinking.

INTRODUCTION

This paper is about the well-known problems around the equal-sign in mathematics learning processes: Many pupils understand the equal sign as a clear action-symbol, e.g. the left side of the sign has to be interpreted as a computing-demand, whereas on the right side there can only be found a single number, i.e. the solution of the computing-task (Seo & Ginsburg, 2003; Kieran, 2011; Russel, 2011; Steinweg, 2013). Those pupils don´t accept equations like "8 + 5 = 10 +3" or "7+9 = 2 · 8" because they offend against the clear rule to have the computing term on the left and the result on the right side of the equal sign. For most situations in primary level, this "task-result-interpretation" (Winter, 1982) of equations may be sufficient. But, having in mind the algebra of secondary level curricula, someday the learners will have to overcome this restricted view on equations.

> It's more important, I think, to give them many opportunities to use symbols in many situations than simply to tell them, let´s say: this is the equals sign and what´s one side of the equals sign should be the same as what´s the other side of the equals sign (Seo & Ginsburg, 2003, p. 169).

To realise such *learning opportunities* we need rich learning environments that make algebraic structures accessible to children in primary schools. But, this is not enough. In the following, we give an example to illustrate that the rich learning environment alone does not lead to thinking about equalities in a structural way. Afterwards, we will discuss the necessity of argumentation-processes to motivate *fundamental learning processes*, i.e. to support the children on their way to an algebraic view on equalities. At least, we will give an example from our design study of how to initiate such *collective argumentations*.

An example of a fourth grade class

The example took place in a learning unit that was on the structure of "*Rechendreiecke*" (for an example see Figure 1), a substantial learning environment based on the well-known "arithmogons" (Wittmann, 2001): Every two numbers in the inner fields of the triangle are added, and the sum is noted in the appropriate field outside of the figure.

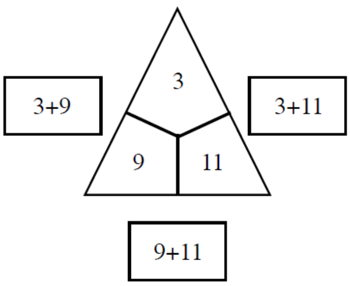

Figure 1

At the beginning of the unit the teacher gave the children some ordinary tasks in computing, i.e. the numbers for the inner fields were given and the children had to calculate the sums for the fields outside of the triangle. After some of these standard-exercises the children made the first discovery on the essential structures of the triangles: The sum of the outer numbers is twice the sum of the numbers in the inner fields, because every inner number appears in two outer fields.

In the present lesson, the teacher´s goal was to discuss the most difficult tasks within this learning environment: She wanted the children to find the inner numbers for a triangle with given numbers in the outer fields. So, she wrote an example for this kind of task on the blackboard (Figure 2), and asked the whole class for first ideas about how to solve this problem. The teacher clearly expected that the children would use the discovery mentioned above to find out the inner numbers: Firstly, they could calculate *the sum* of the inner numbers (by halving the sum of the given outer numbers). Then, they could find a fitting partition of this sum for the inner numbers by trying a systematic way.

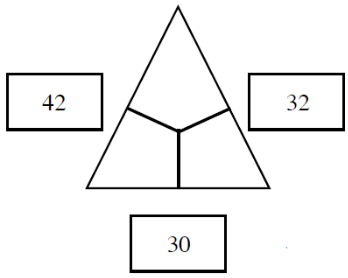

Figure 2

Having in mind this problem-solving approach, the teacher asked Robert for his idea:

Robert	I think that this is the same problem as we had with the number-walls, that 30 plus 32 take away 42 divided by two, the result must be noted in the bottom field (while talking, the pupil arrives at the blackboard).
Children	(make some noise to demonstrate their incomprehension)
Robert	Then we will have the ten there (notes 10 in the bottom field on the left) and twenty there (notes 20 in the bottom field on the right, then notes 12 in the field on the top, Figure 3)

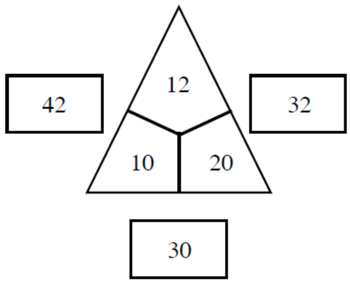

Figure 3

Teacher	Okay, now we have a ten here and a twenty over there (points to the numbers in the figure on the blackboard). How can we go on? The idea of Robert is not bad!
Clarissa	We could change the places of the twenty and the ten. Because, I think it would fit better. Then one would note twenty-two at the top and we had the result. (Clarissa modifies the numbers, Figure 4)

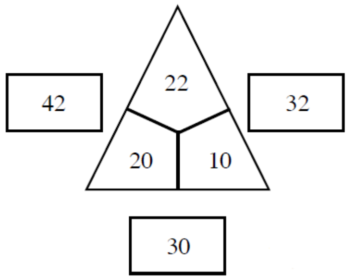

Figure 4

After this episode, the teacher and the pupils seemed to be satisfied, having found the fitting inner numbers. Neither the pupils nor the teacher not even Robert himself had the need to analyse whether it is coincidence or not that Clarissa only had to change the places of Robert's numbers in order to find the right solution of the triangle. Hence, even though the class found a solution for the special task, the underlying mathematical structure of the general problem remained covered. In other words: The *learning opportunity* given by the idea of Robert did not unfold its structural potential, we name it a "missed substantial learning opportunity".

Briefly, two questions remain, resulted from our observation of this episode:

1) Why is Robert's idea so hard to understand?

2) Why is there obviously no need to analyse the proposal of Robert, and no need to question whether the idea may lead to a general way of problem solving?

Analysis: The mathematical core of the missed learning opportunity

Even if Robert´s proposal does not lead to the correct solution, the underlying idea is correct: Given the inner numbers *a, b, c,* Robert firstly builds the sum of two outer numbers (i.e. $a+b+b+c$). Afterwards, he takes away the third outer number ($a+c$), the result is the double of one of the inner numbers (here $2b$).

Although we do not want to shift the mathematics curriculum of the secondary level into the primary school, from our point of view, it should be possible to discuss arithmetical structures like the one above in a fourth grades class. For example, one could organise the learning process within a reflective exercise (s. Figure 5), forcing the children to calculate with the outer numbers in the way Robert does: "Build the sum of two outer numbers and take away the third one – what do you observe?" Having in mind that every outer number is built by the sum of two inner numbers, the children might be able to explain the result of their calculations, and then to use this new knowledge as an effective solving strategy for problems like the one above.

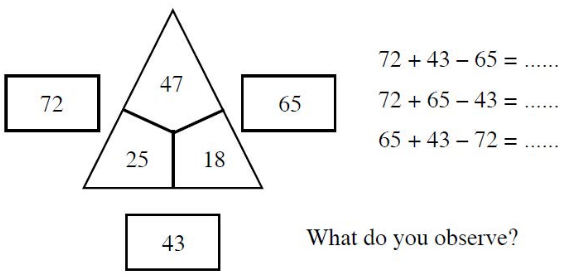

Figure 5

The main difficulty on the way to find an explanation like this is the necessary flexibility in interpreting the inner and outer numbers: Sometimes, they are computing numbers, sometimes they are the result of a computation and the problem-solver has to decide which number would be used to calculate and which one must be understood as a computing-result.

From our point of view, we should help the children to construct a flexible understanding of equations already in primary level. But, again, we do not want to shift the mathematics curriculum of the secondary level into the primary school. Hence, we propose to promote the development of a content-related, flexible *understanding of equality* rather than teaching the children *how to handle equations* in an adequate form to prepare algebraic notations. According to Steinbring (2005), the children in primary school should work on a flexible concept of mathematical equality mainly by constructing several adequate reference contexts rather than learning how to use the standard mathematical signs within the solution of equations.

THE PRESENT PROJECT

Within our project we started a variety of different teaching-learning experiments, like whole class instruction, group working and peer interviews. The experiments were planned on the basis of already existing substantial learning environments, mainly taken from the project "mathe 2000" (Wittmann, 2001). Our goal is to strengthen the *content-related concept* of equality. Hence, the equal *sign* and its algebraic correct and formal rules to use do not play the leading role within the learning environments. In some of them (like arithmogons, number walls, etc.; Wittmann, 2001), this special sign does not even appear in the tasks. But nevertheless, the learning environments focus on equality. For example, the children have to find different number walls with equal numbers in the top stones.

Our main research interest is to understand the micro-processes of teaching and learning mathematics rather than to measure the success of a learning environment. Hence, our analysis of the teaching-learning-experiments follows the interpretative paradigm, mainly using approaches of symbolic interactionism and ethnomethodology (Bauersfeld, Krummheuer, & Voigt, 1998; Voigt, 1994; Yackel & Cobb, 1996), epistemological theories (Steinbring, 2005) and theories of argumentation (Schwarzkopf, 2003). In the following sections we discuss some aspects of the first results of the study.

Theoretical embedding: Different types of learning processes

What does it mean to modify a restricted "task-result" interpretation of the equal-sign to a more sophisticated, flexible and structurally sustainable concept of equality? Following Steinbring (2005), the construction of an adequate equality-concept moves between two epistemological poles:

On the one hand, there is an *empirical, situated description* of mathematical knowledge like finding the result for a computing task in the sense of Clarissa´s offer for the solution of the problem above. This kind of knowledge is easy to handle in communication, one simply has to offer some empirical facts, and everybody will know what they mean. But, in conclusion, the pupils can only learn new facts; the associated learning opportunities will not help them to construct a better structural understanding of the mathematical background.

On the other hand, the understanding of Robert's idea for example, requires a *relational generality* of mathematical knowledge. Learning opportunities that concentrate on this kind of knowledge have to offer the need for the children to create a new interpretation of the thematic mathematics. At the same time one has to consider that the pupils cannot create interpretations that are completely detached from their experienced points of view.

These fundamental learning processes (cf. Miller, 1986, 2002) can only be realised in situations of *collective argumentations*, i.e. the children must be confronted with a problem that makes it somehow impossible for them to go on by routine and they first have to solve that problem in an argumentative way (Miller, 1986; Schwarzkopf, 2003). But, according to Miller, argumentation is a very stressful kind of interaction, and, normally, people try hard to solve their problems in a non-argumentative way.

Even within mathematics classrooms, where argumentation is one of the learning goals, there are many opportunities to avoid a content related argumentation – at least one can always ask the teacher as an expert in mathematics. Remember the example above: There is no need for an argumentation around the idea of Robert because Clarissa found an easier way to solve the problem by changing numbers, and presenting directly the correct solution. In the sense of Steinbring (2005, p. 194–213), the offers of Clarissa and Robert stand for the two poles of communication between which the interactive constructions of knowledge move: Whereas Clarissa´s gives a simple "mediation of facts" (correct calculations), an adequate understanding of Robert´s idea needs a "construction of a new interpretation" that is obviously not accessible to the communication partners.

Hence, collective argumentations do not emerge in mathematics lessons in a somehow natural way. On the contrary, the teacher has to *initiate* the concerning processes in both, a careful and persistent way (Schwarzkopf, 2000). For this, it is important to think about social requirements and mathematical learning goals that are necessary to initiate substantial learning opportunities by cooperative argumentation.

To enforce the emergence of substantial learning opportunities, we develop tasks that initiate mathematical needs for collective argumentation. Our intention is to confront the children with a "productive irritation" (Nührenbörger & Schwarzkopf, 2013), concerning their social experiences in classroom discussions. The tasks or problems, for example, provide phenomena that were not expected by the children so that they have to reflect on the given structures and see the need to re- interpret the experienced mathematics behind the problem.

This approach bases on Piaget´s (1985) work on cognitive conflicts. Roughly speaking, Piaget points out that a child develops new ideas when it is confronted with facts or beliefs that contradict their expectations, depending on their individual experiences. If the concerning cognitive schemas resist the child´s possibilities of assimilation, there is a need for the child to generate a cognitive consensus, i.e. a learning-process emerges.

To initiate productive learning opportunities in this sense, one of the main difficulties is that an observation of a pattern or a surprising discovery is not enough to create the need of argumentation – we gave an example at the beginning of this paper. Moreover, it is necessary that the observation becomes an amazing phenomenon for the pupils. For example, the children discover a pattern in a series of tasks. Then, they are confronted with another task that does not exactly fit to the previously solved series and they are asked to make a prognosis: Will the result of the next task fit to the pattern or not? By this we try to force the children to create an expectation on the result of the next task. The initiation of a "productive irritation" is successful, when this expectation fails while computing the next result – by this, there is an interactive need to find explanations for the failure of the prognosis. In this sense, a productive irritation can widen the implicit working, often sense-restricting "sociomathematical norms" (Yackel & Cobb, 1996) that influence the interpretation of arithmetical terms in routinized (cf. Voigt 1994) classroom discussions.

Initiating productive irritations: Arguing for amazing equalities

In the following part we give an example for a short learning unit with the goal to initiate an argumentation, initiated by a productive irritation within a primary class (3rd or 4th class). The content comes from the well-known substantial learning environment "number-walls" (see Figure 6), where you have to note the sum of the numbers in every stone from the two stones under it. Typically, children discover different types of terms to describe the top stone of the wall (e.g. as a result of a calculation or as a relation between the bottom stones: $a+b + b+c = a+2b+c$).

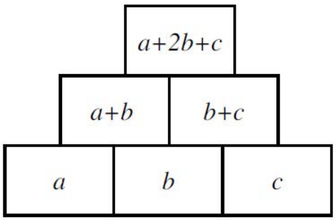

Figure 6

In the first part of the present learning unit, the children calculate a series of number-walls and discover a pattern, that is very familiar to them: Increasing the number in the right bottom-stone and decreasing the number in the left bottom-stone by the same difference will leave the number at the top of the wall constant (keeping the same number in the middle of the bottom, of course) in this example 650 (Figure 7).

The children can calculate the number of the top as well as they can argue with the relations between the stones of a number wall. To point out the equalities between the number walls the children can use so called "term walls" (see Figure 8), noting calculations instead of their results in the stones. These term-walls might build bridges for the children to change their interpretations of the numbers as results (e.g. 650 = 460 + 190 and 650 = 450 + 200) and to see them as computing numbers (650 = 380 + 2 × 80 + 110 = = 370 × 2x80+ 120).

However, having calculated some of these tasks, the children are confronted with another number-wall that does not exactly fit to the previously discovered pattern (e.g., the one in Figure 9), and they are asked about their expectations on the result: Will the number at the top of the wall change or not?

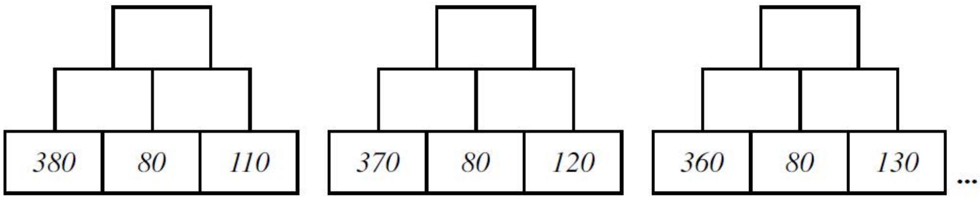

Figure 7

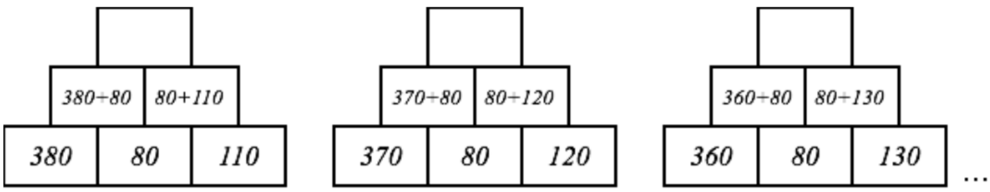

Figure 8a

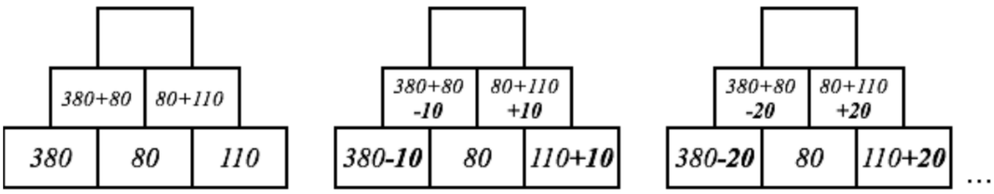

Figure 8b

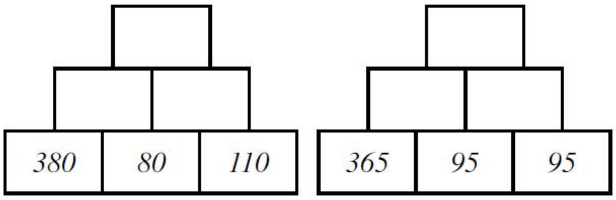

Figure 9

The following episode takes place in an interview-situation, where a teacher-student works together with two children on the above given number walls. The children have already discovered that the top numbers of the number-walls in Figure 7 are all the same, namely 650. This pattern seemed to be clear for the children, having in mind that from wall to wall one of the bottom numbers increases and one of the others decreases by the same difference. Afterwards, the teacher showed the children some number walls like the one in Figure 9, asking for a prognosis about the number of the top-stone. As expected, both of the children gave the prognosis that the top stone must change, because two of the bottom-numbers increase by fifteen and only one of them decreases by fifteen.

Teacher	Do you think that in this top stone (pointing to the right number-wall in Figure 9) there will be the 650 again?
Moritz	no.
Luisa	no.
Teacher	Why do you say no?
Moritz	Well, here are fifteen more than there (points to 380 and 365), and here are fifteen more than there (points to 110 and 95 in the right bottom stone), but here are fifteen more than there (points to 95 in the middle bottom stone and 80), and fifteen plus fifteen are together thirty and not fifteen (.), exactly.

Moritz reasons by comparing the changes of the two increasing bottom numbers with the decreasing number. In this way, he activates his experiences with the constancy-law of additions that was successfully used in the first part of the unit. The teacher moderates the interaction, so that also Luisa has to reason for her prognosis:

Teacher	Luisa, do you have the same opinion?
Luisa	Yes, the result here above is the same.
Teacher	How do you mean it?
Luisa	Well, if you add the bottom stones (points to 365, 80, 110) then they must have the same result as there (points to 380, 95, 95) for getting the same result on the top, and this is another sum.

Luisa points out a hypothesis for a general rule: Two number walls with the same numbers in the top stones must be equal in the sum of the bottom numbers.

Even if the two given arguments are different in detail, from an epistemological point of view, both of them can be characterised as an *empirical, situated description of knowing* (Steinbring, 2005; Schwarzkopf, 2003): The comparisons of the (unknown) top numbers are based on empirical observations of the given examples without leading to a structural deeper understanding of the mathematical structures.

After the children have verified their hypothesis and found out that their observation offended against their expectation, they rethink the arithmetical structures between the stones of the number walls and find new arguments:

Luisa	Mmm, they are the same because this (points to the left and right bottom stone, Figure 10) is coming to the other stones, and this (points two times to the middle bottom stone) meets twice. So we have to calculate them together.

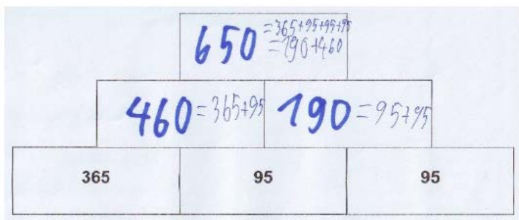

Figure 10

Moritz	Mmm, because in the middle we have 460 is equal 365 plus 95 (.) that is 460 (.), and because there are not four bottom stones you have to calculate once again 95 plus 95 is equal 190 (.). You have to take once again the 95.
Teacher	Ok, and why do we get in both number walls the same number 650 in the top?
Moritz	Because you need the 95 for both sides. However, for example, here you have to

> take 15 more and here exactly the same (points to both number walls).

In their arguments, both children become aware of the special function of the number in the middle bottom stone. On the first view, Luisa argues in a somehow dynamic, still empirical way – as if the numbers would crawl through the stones to the top. But regarding her offer in detail, the argument already shows qualities of a more theoretical approach: The middle stone "meets twice", although the number exists only once. This discovery builds the bridge from the empirical view to the structural understanding of number walls: The meaning of the numbers result of their position in the wall. Moritz modulates this approach (Krummheuer, 1992) of Luisa to a more static view, and by this he strengthens the theoretical character of the argumentation: The number in the middle bottom stone is not a concrete, single object, but it is part of two calculations. His remark "there are not four bottom stones" builds the bridge between the empirical understanding of the numbers as objects (that crawl through the wall) and the numbers as part of calculations that depend only on their position in the wall: An empirical version of the number wall would have four bottom stones (see Figure 11), providing every number as often as it will be needed in the wall.

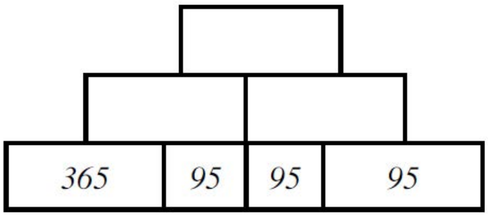

Figure 11

Finally, Moritz is able to interpret the new view on the number walls on his hypothesis of the beginning of the episode: Changing the numbers in the bottom stones means changing the operators in the calculation terms.

The main aspect within this argumentation seems to be that the numbers of the task have changed their computational functions: Previously, the pupils interpreted the number wall in the sense of a task-result-view on equations: At the bottom there are three numbers, and at the top there is one result. Within the argumentation for the unexpected equality, they changed this view to a more flexible, theoretical one (Figure 12): No longer the numbers, but the computing-terms are the main objects of the number-wall (Steinweg, 2013). In this sense, the children have to construct this as a common object a new term concerning twice the decrease of 15 and the increase of 15: $(380 + 80) + (80 + 110) = (380 - 15 + 80 + 15) + (80 + 15 + 110 - 15) =$ $= (365 + 95) + (95 + 95)$.

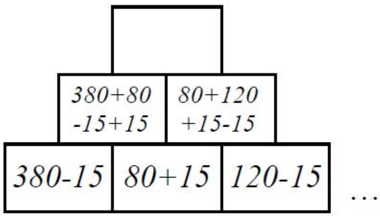

Figure 12

In conclusion, the pupils construct a new interpretation of the arithmetical relations which is related to their old knowledge. According to Steinbring (2005), the children construct a *relational generality* of mathematical knowledge.

FINAL REMARKS

By initiating substantial learning opportunities we try to promote the development of a flexible and structural sustainable concept of mathematical equality. In our work we mean by "understanding equalities in primary classes" that the children operate with the structures of computing-terms rather than only focussing on pure numbers as if they were concrete objects. To understand equality between two terms means to find one theoretical interpretation that fits for two different looking terms (Winter, 1982). In this paper, we discussed a somehow reflective approach to the promotion of accompanying activities, concerning the initiation of collective argumentation through productive irritations.

The rules for the order of operations: The case of an inservice teacher

Ioannis Papadopoulos

Aristotle University of Thessaloniki, School of Education, Thessaloniki, Greece, ypapadop@eled.auth.gr

In this paper a two-stage project is presented concerning the rules for the order of operations. During the first stage the mal-rules used by an experienced teacher as he evaluated arithmetical expressions were recorded and a session for repairing these misinterpretations followed. During the second stage the influence of the teacher's teaching on his sixth graders was examined. The findings showed that the initial understanding of the teacher was so persistent that almost all his students and in order to evaluate the same arithmetical expressions used exactly the same mal-rules.

Keywords: Mal-rules, order of operations.

INTRODUCTION

The major issue in mathematics teaching and learning is whether students really know mathematics or whether they just memorize rules or conventions. The rules for the order of operations that are introduced during the fifth and sixth grades constitute a representative example. Even though, one can argue that the precedence rules are a matter of procedural knowledge. Lampert (1986) claims that there are contexts that order of operations matters, and according to Merlin (2008) the order of precedence is not simply the sort of convention adopted without careful consideration; rather, it reflects something essential and deep about the operations themselves. Students are taught that symbols of inclusion (i.e., ( ), [ ]) can be used to show which operation is to be performed first in an expression. If there are more than three operations then there would be so many parentheses and brackets that the expression would look extremely complex. Therefore, in order to avoid this, mathematicians have agreed on an order for performing the operations and the parentheses are used only to change this order (Foerster, 1994). The rules for the order of operations are:

i. Brackets first

ii. Evaluate expressions with exponents

iii. Carry out multiplications or divisions from left to right

iv. Carry out additions or subtractions from left to right.

For young students these rules might appear random and therefore meaningless. So, according to Wu (2007) the situation is like this: students are encouraged to memorize things without understanding their use or meaning and teachers are also becoming part of the game as they know that exam points can be surely achieved by this useless memorization. This way of teaching order of operations results in some overgeneralizations that are used equally by primary school students (Linchevski & Herscovics, 1994), middle school students (Blando, Kelly, Schneider, & Sleeman, 1989), university students (Pappanastos, Hall, & Honan, 2002), and prospective elementary teachers (Glidden, 2008). However, there is no research on the teaching practice of in-service teachers in this topic. This leaves out in-service teachers. Therefore, in this study we try to find out how such misconceptions of an experienced in-service primary school teacher may influence the way his students conceive the topic of the order of operations.

BRIEF LITERATURE REVIEW

Perhaps, the whole story starts during the early years of schooling when teachers use problems of the type 5 + 2 x 3 + 10 − 5 = ?. In these problems each operation is followed by "and then" (i.e., 5 plus 2 and then what you found times 3 and then that answer plus 10, etc.). Indeed, very often this kind of problems is considered as a proper one since the students are encouraged to think and carry out mental operations. However, this may – unintentionally- contribute to students' difficulties related to the order of operations convention (Schrock & Morrow, 1993). They disregard the order of operations practice and therefore learn that operations are simply worked from left to right (Kieran, 1989). Linchevski and Livneh (1999), working with 53 sixth graders, found that possibly students have generalized incorrectly the rule for the order of operations and believe that addition takes precedence over subtraction and multiplication over division. This is not unrelated to the fact that in many textbooks the order of operations is given via the known mnemonic BOMDAS (Brackets first then "Of", Multiplication, Division, Addition and Subtraction) (Herscovics & Linchevski, 1994). PEMDAS (Please Excuse My Dear Aunt Sally, which stands for Parentheses, Exponents, Multiplication and Division (from left to right), Addition and Subtraction (from left to right)) is another example of students' reliance on mnemonics. Pappanastos, Hals, and Honan (2002) surveyed over 300 business school students at two universities and the results showed that (a) they recalled the above mentioned acronym, and (b) one third of the respondents applied incorrectly the order of operations. Rambhia (2002) states that as a result of PEMDAS focused teaching many students are convinced that multiplication has to be done before division and that addition is more important than subtraction. Thus, PEMDAS and similar mnemonic devices either hide or assist the learning of operations. But what is especially interesting in the case of these mnemonics is that their use is a symptom of a lack of attention to structure. Finally, Glidden (2008) who investigated how well 381 prospective elementary teachers solved four arithmetic problems that required using the order of operations found that fewer than half of them answered more than two questions correctly.

All these findings are important since (a) teachers must know the correct order of operations to teach the concept correctly, and (b) light might be shed on whether students do in fact understand the order of operations completely or merely interpret the mnemonics literally (Pappanastos et al., 2002). However, despite the importance of these findings there is an aspect that is not represented in the body of the research literature. The above mentioned presented studies concern how very young students overgeneralize the order of operations (Linchevski & Herscovics, 1994), and then how older students tend to perform the operations sequentially from left to right (Kieran, 1979), and then how college students use mnemonics devices to remember order of operations since they do not understand the proper order of precedence that should applied to mathematical operations (Pappanastos et al., 2002), and then how prospective elementary school teachers give incorrect answers attributable to misunderstanding the order of operations (Glidden, 2008). All this incorrectly learned information perhaps continues to handicap learning into their next math courses and beyond for several years. So, what if an in-service teacher did not manage to "repair" this incorrect knowledge acquired years ago? How this influences the way he teaches the specific concept to his young students? How easily these errors are transferred as an incorrect knowledge to them? Actually, these are the research questions of this paper.

THE SETTING OF THE STUDY

This is a two-stage study. During the first stage a collection of tasks was designed to uncover errors with precedence rules. The collection of the tasks was administered to an in-service primary school teacher before teaching the unit of order of operations to his 6th graders. Four of the tasks are presented in Table 1.

Item 1:	$14 : 2 \cdot 14 - 12 =$
Item 2:	$18 + 19 + 14 \cdot (11 + 22) =$
Item 3:	$9 + 23 + (11 - 3) \cdot (4 : 2) =$
Item 4:	$7 \cdot (6 \cdot 6 + 14) \cdot 5 + 6 =$

Table 1: Tasks of the study

The answers of the teacher were examined and the incorrect answers were coded on the basis of the work of Blando and colleagues (1989). In their work, errors are mentioned as *mal-rules* which stand for violations of legal mathematics rules. Their theoretical model relies on *repair theory* which states that errors occur when a student is faced with a difficult or unfamiliar feature of a task. In this case the student may react by modifying a known procedure and applying it (incorrectly) to the task. Blando and his colleagues (1989) described the students' incorrect solutions in term of mal-rules. In relation to Precedence Errors they listed six mal-rules using acronyms (see examples in Table 2).

PAM	Add before multiplying	Example: 4 + 2 x 3→ 6 x 3
PAD	Add before dividing	Example: 10 / 2 + 3→10 / 5
PSM	Subtract before multiplying	Example: 9 – 2 x 3→7 x 3
PSD	Subtract before dividing	Example: 8 – 6 / 2→2 / 2
PAS	Add before subtracting	Example: 6 – 4 + 3→6 – 7
PIP	Ignore Parenthesis	Example: 8 - (2 + 4)→6 + 4

Table 2: List of mal-rules for precedence errors (from Blando et al. (1989))

Thus, in our study, the teacher's errors were coded according to the above mentioned list.

In Item-1 the solution given by the teacher was:

$14 : 2 \cdot 14 - 12 = (14 : 2) \cdot (14 - 12) = 7 \cdot 2 = 14$

The general format of this task is $a : b \cdot c - d$, the correct rule is $[(a : b) \cdot c] - d$ and one of the possible mal-rules is $(a : b) \cdot (c - d)$. This could be regarded as "subtract before multiplying" (PSM) mal-rule. The teacher correctly made the division 14 : 2. But then he ignored the multiplication and chose to subtract 14 - 12 before multiplying.

In Item-2 the solution of the teacher was:

$18 + 19 + 14 \cdot (11 + 22) = (18 + 19 + 14) \cdot (11 + 22) =$
$51 \cdot 33 = 1683$

The general format of the task is $a + b + c \cdot (d + e)$. The correct solution is $a + b + [c \cdot (d + e)]$ and the mal-rule applied by the teacher was $(a + b + c) \cdot (d + e)$, which means "add before multiplying" (i.e., PAM). The teacher correctly evaluated the part inside the parentheses but then he violated the precedence rule and carried out addition prior to multiplication.

In Item-3 the answer given by the teacher was:

$9 + 23 + (11 - 3) \cdot (4 : 2) = [(9 + 23) + (11 - 3)] \cdot (4 : 2) =$
$(32 + 8) \cdot 2 = 40 \cdot 2 = 80$

Even though the general format seems to be more complex than the previous one, the core idea of the teacher's error was the same. He did not ignore the parentheses (11-3=8, 4:2=2), however, he added before multiplying (PAM) instead of following the correct rule (i.e., $9 + 23 + [(11 - 3) \cdot (4 : 2)]$).

Finally, in Item-4, the PAM mal-rule was again prevalent:

$7 \cdot (6 \cdot 6 + 14) \cdot 5 + 6 = [7 \cdot (6 \cdot 6 + 14)] \cdot (5 + 6) =$
$[7 \cdot (36 + 14)] \cdot 11 = 7 \cdot 50 \cdot 11 = = 350 \cdot 11 = 3850$

The correct solution was $[7 \cdot (36 + 14) \cdot 5] + 6 = (7 \cdot 50 \cdot 5) + 6 = 1750 + 6 = 1756$. For one more time what actually the teacher did was to add (5 + 6 = 11) before multiplying (PAM). Once more he respected the parentheses but then he incorrectly evaluated the expression 5+6 before multiplying. These answers signalled the need for an intervention session aiming to let the teacher become aware of his errors. Research has suggested that interventions focused on developing teachers' subject-matter knowledge can positively impact teachers' knowledge (Swafford et al.. 1997) and makes them able to improve their ability to make sense of and evaluate students' thinking strategies in a variety of mathematical context (Tyminski et al., 2014)

The session was decided to take place at school and lasted about 90 minutes. During the session a lot of examples were discussed offering the opportunity for the teacher to internalize (a) the order of operations as an introduction to the necessity for structure and rules, and (b) the need to have a unique answer in tasks and also to have rules required to achieve it. For each example it was clarified that there was a unique answer. The application of various mal-rules result to different outcomes but only one answer is the correct and certain rules are required to achieve it. When multiple operations are included in an expression, different numerical results are obtained according to the precedence given to some operations over others. Visual representations were used to illustrate the notion of operation precedence. More specifically, the *tree diagrams* were used (Kirshner & Awtry, 2004). Their central feature is an iterative procedure for analysing the syntactic structure of a mathematical expression, and representing it as a partially ordered hierarchical structure. In a tree diagram the operation that is more precedent appears lower on the tree than an operation less precedent. In this tree notation it is easy to see the independence of

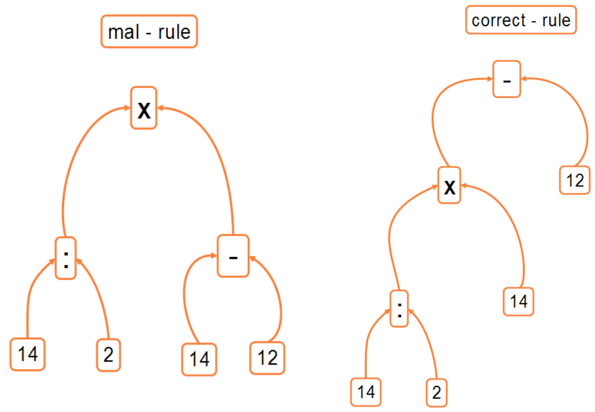

Figure 1: Tree diagrams for Item-1

the operations in the separateness of the tree's main "branches". In Figure 1 two tree diagrams illustrating the precedence decision for Item-1 are presented.

Following Ernest (1987), the teacher's errors might be attributed to a failure to discern the hierarchical syntactical structure or orders of precedence within mathematical expressions. So the tree model was used exactly to exhibit this structure explicitly to the teacher. He was 'trained' to analyse expressions into written tree forms.

It is worth mentioning that the teacher was an experienced one in the sense that he had been teaching for at least 25 years. This means that during this period he was carrying this incorrect perspective about the order of operations which may influence the learning of his students. Consequently, the question is: To what extend an intervention can sufficiently help the teacher to correct his stable errors relevant to order of operations?

This is why the teacher was left to teach the specific unit to his students which lasted for about a week. The second stage of the study took place almost a month after completing the unit and at that moment the teacher was not aware of our intention to come back again and work with his 6th graders. This decision was made on purpose since it was important to let the teacher work on his own terms and not under the feeling that he has to be cautious due to our future return into his classroom. We requested permission to work with the students on this topic. He gladly agreed and confessed that in the meantime he was wondering about the possible impact of this experience on him and/or on his students.

So, the students were invited to cope with the same collection of the tasks that was initially administered to their teacher. Twenty two 6th graders participated. The study took place a month after the beginning of the school year. The students had been taught comparison between natural and decimal numbers as well as the four operations among these numbers. Their worksheets were collected and their incorrect answers were coded according to two criteria: (a) whether their incorrect answers corresponded to the mal-rule list of Blando and colleagues (1989), and (b) whether their answers reflected their teacher's incorrect ones.

RESULTS AND DISCUSSION

The students' answers were classified into three categories:

(i) Incorrect answers that were identical to their teacher's ones (i.e., the ones during the first stage of the study).

(ii) Answers that were correct, and

(iii) Answers that did not fit to any of these two categories (i.e., the students did not answer the item at all or the students answered but there was not a clear way of showing their thinking for the computations).

	Incorrect answers identical to the teacher's ones (students followed mal-rules)	Correct solutions (correct application of the rules for the order of operation)	Other
Item-1 (PSM)	6 (27.27%)	12 (54.54%)	4 (18.19%)
Item-2 (PAM)	**19 (86.36%)**	3 (13.64%)	-
Item-3 (PAM)	**18 (81.81%)**	3 (13.64%)	1 (4.55%)
Item-4 (PAM)	**12 (54.54%)**	4 (18.19%)	6 (27.27%)

Table 3: Summarized view of the student's answers

A summarized view of the students' answers is presented below in Table 3.

It is interesting that many students used symbols of inclusion that facilitated their erroneous way of evaluating the arithmetical expressions. Even though they followed mal-rules for the order of operations they respected the symbols of inclusion they used. Some examples of the students' usage of inclusion symbols that supported their incorrect generalization for the order of operations can be seen in Figure 2.

It is evident that almost the whole class reacted exactly in the same way their teacher did a month before. The percentages for Items 2–4 are extremely high. More than half the students repeated the mal-rule of their teacher for Item-4 (12/22), all but three students for Item-2 (19/22), and all but four students for Item-3 (18/22). It seems that this did not happen for Item-1 since only 6 students out of 22 repeated the mal-rule of "subtract before multiplying" (PSM). A potential explanation for this might be that the students were accustomed to work sequentially from left to right. During their early grades the students were given exercises which disregarded the order of operations and therefore many of them learned incorrectly that operations are simply worked from left to right. The fact is that in Item-1 following the operations from left to right happened to be the same as following the rules for the order of operations and this possibly explains the small percentage of the PSM mal-rule.

The results were also equally surprising for the teacher since he realized how similarly incorrect were his own errors to his students' ones. So, the question is: Given that during the intervening session the rules for the order of operations were examined and became clear, then what would be a possible explanation for having almost all the students repeating their teacher's initial errors?

Before presenting our thesis it has to be acknowledged that teachers' content knowledge in the subject area does not suffice for good learning. However, it is also true that the knowledge of mathematics obviously influences the teachers' teaching of mathematics and subsequently they cannot help children learn things they themselves do not understand. This could explain the impact of the specific teacher in his students' performance for the time period before this study. The difference now was that the teacher was led to face his weak mathematical background concerning order of operations and moreover he participated in a session that made him to see why the rules he applied were mal-rules as well as to get practice on a series of tasks that challenged him to apply now the correct rules for the precedence of operations. He declared that he understood the violation of the rules for the order of operations he used to follow. However, the findings of the study did show that the teaching that took place after the session was dominated by his persistent misinterpretation on the order of operations. This contradiction may be explained by accepting that the session that took place was not sufficient to confront the teacher's erroneous long-time way of teaching. Thus, a stronger intervention might be needed to establish a more compact knowledge on order of operations accompanied with guidance concerning instructional strategies for the unit. Moreover, it can be said that learners generalize in a way that they are initially taught and this can lead to the construction of schemata at an early stage that have a strong inherent robustness (Waren, 2003). Linchevski and Livneh (2002) claim that occasionally these old schemata become tacit models of comprehension and this could mean that –as in our case- despite the intervening session, initial understanding persists.

$[(14 : 2)(14 - 12)] = 7 \cdot 2 = 14$

$[(9 + 23) + (11 - 3)] \cdot (4 : 2)\ (32 + 8) \cdot 2 = 40 \cdot 2 = \underline{80}$

$(18 + 19 + 14) \cdot (11 + 22) = 51 \cdot 33 = 1683$

$[7 \cdot (6 \cdot 6 + 14) \cdot 5] + 6 = [7 \cdot (36 + 14) \cdot 5] + 6 = [(7 \cdot 50) + 5] + 6 = (350 + 5) + 6$
$355 + 6 = \underline{361}$

Figure 2: Students' usage of inclusion symbols

CONCLUSIONS

The deep content knowledge of mathematics is – among others- necessary for teaching successfully mathematics. Until a few years ago, the subject matter knowledge of teachers was largely taken for granted in teacher education. But recent research focused on the ways in which teachers and prospective teachers understand the subjects they teach, reveals that they often have misconceptions or gaps in knowledge (Ball & McDiarmid, 1990). In the same paper Ball and McDiarmid also argue that as teachers are themselves products of elementary and secondary schools in which pupils rarely develop deep understanding of the subject matter they encounter, we should not be surprised by teachers' inadequate subject matter preparation. This was clearly presented in our study. An experienced teacher, teaching more than 25 years, introduced a specific mathematical topic (i.e., order of operations) based on certain mal-rules that probably influenced the quality of learning of his students.

It also seems that these misinterpretations of the correct rules for the order of operations made it difficult for the teacher to have control over his own teaching under the light of the new information. Despite a session that aimed to support the teacher to confront the situation the findings showed that he continued to be based on the same mal-rules. It seems that the session was not really efficient. This is verified by the fact that his students showed similar behaviour to his towards the same collection of tasks. Their responses followed the same incorrect formats that were used by their teacher. This is very helpful to depict clearly the situation in our country. And the situation is like this:

The mathematical content knowledge of primary school teachers takes place only during their university courses. Later on, for pre-service and in-service teachers there are training programs but all of them are focused on the new curriculum, on the new teaching methods, on the usage of technology in mathematics classrooms, etc. Implicitly, all these training programs take for granted that these people know mathematics and this is why they give emphasis to pedagogical aspects of mathematics teaching. So, in this paper we tried to show that this is a rather false image of the real situation. Even though the work of only one teacher was presented and this could be considered as a case study (and therefore we could not generalize) we still believe that this is evidence that cannot be ignored. Part of the training programs must give emphasis on the subject matter knowledge of the persons who are responsible for teaching mathematics in young students and influence by their teaching the mathematical thinking of their students.

Cracking percent problems in different formats: The role of texts and visual models for students with low and high language proficiency

Birte Pöhler, Susanne Prediger and Henrike Weinert

Technische Universität Dortmund, Dortmund, Germany, birte.poehler@math.uni-dortmund.de

Students with low academic language proficiency are often considered to meet specific comprehension challenges with word problems. But how do conceptual and reading challenges interfere in these situations? We approach this question by investigating how performance depends on the problem format for different problem types. A test with N=250 students investigates cracking percent problems in pure, text, and visual format. The results show that text formats are most difficult for elementary problem types, whereas (con-)text can enhance the accessibility for more complex problem types. Item difficulties differ similarly for students with high and low language proficiency, hence reading challenges seem as crucial as conceptual challenges. A deeper analysis shows specific linguistic challenges with the expressions reduced to and reduced by.

Keywords: Percentages, word problems, visual models, language proficiency.

BACKGROUND

Word problems in mathematics tests – reading challenges or conceptual challenges for students with low language proficiency?

Secondary students' academic language proficiency is a crucial factor for their performance in mathematics tests, as has been found in various empirical studies (Abedi, 2006; OECD, 2007; Prediger et al., 2013). Especially in the context of high stakes testing in the US, language biases in mathematical word problems have been investigated for students with low language proficiency (in brief: low LP) (Abedi, 2006). Many researchers emphasize that students with low LP have specific *reading comprehension difficulties with word problems* (e.g., Duarte et al., 2011, for an overview) whereas test items with less text are often assumed to be "language fairer".

However, at least for the German high stakes test ZP10 NRW, this assumption turned out to apply only partially (Prediger et al., 2014): In nearly all items, language proficient students outperformed their less language proficient peers. But the items in which the former had even more difficulties than expected due to their general performance (the items with significant DIF-values) could *not* be characterized by reading challenges, but by conceptual or process-oriented challenges. We tentatively concluded that reading might not be the main obstacle for students with low LP to crack problems, but their restricted conceptual understanding accumulated in ten years of schooling with language disadvantages. However, the phenomenon requires a deeper investigation.

In many different mathematical topics and for students of all levels of language proficiency, word problems have proved to be more difficult than pure items (e.g., Kouba et al., 1988). For students with low LP, these text formats seem to pose specific challenges (cf. Duarte et al., 2011) that require further exploration. However, some studies (especially in primary schools) have shown that using contexts in problems can also support students' performance since a context can enhance the accessibility of the problem and the underlying mathematical concepts (van den Heuvel-Panhuizen, 2005).

Whereas the role of text and context is discussed incoherently in mathematics education research throughout age levels, there is a consensus on the role of visual models as having the potential to facilitate the accessibility of a test item (shown, for example, in Walkington et al., 2013). One could even assume that students with low LP do equally well as their more language proficient peers in visually presented items if there were no problems in conceptual understanding, only in text comprehension.

These different considerations motivated our research interest on comparing difficulties in *different problem formats*. We treated it for the exemplary mathematical topic of percentages with the following research questions:

— How do students perform in parallel test items on percentages with text format, visual format and pure format?

— How does the role of texts and visual models in test items on percentages differ for students with high versus low language proficiency?

Cracking percent problems as identifying different problem types

The mathematical topic percentages was chosen because it is important in many everyday contexts, and percent problems in assessments bear various difficulties for students (Parker & Leinhardt, 1995; Prediger et al., 2013). Compared to other areas of arithmetic and proportions, relatively few recent studies exist that explore students' competencies and difficulties, (historical exceptions are named in Parker & Leinhardt, 1995; recent exceptions are Dole et al., 1997; Jitendra & Star, 2012 and Walkington et al., 2013).

Typical for percent problems is that students' mathematizing process is shaped by one core step, *identifying the problem type* (Dole et al., 1997). Classically, *three elementary problem types* are distinguished (ibid., with different names): 'Find the amount (if rate and base are given)', 'Find the rate (if amount and base are given)', and 'Find the base (if amount and rate are given)'. Empirical studies show different success rates for different problem types, often 'Find the amount' is easier than the two others (e.g., Kouba et al., 1988, p. 17), and this type being overgeneralized to 'Find the base'.

Beyond these three elementary problem types, *more complex problem types* pose even bigger challenges for students, for example 'percentage growth', 'percentage comparison' or 'Find the base after reduction (if discount and reduced amount are given)' (Parker & Leinhardt, 1995, p. 439). These complex problem types bear reading challenges as well as conceptual challenges and are therefore interesting to compare to elementary types in this study.

Existing empirical studies have compared students' performances on percent problems mainly with respect *to problem types* (Kouba et al., 1988; Dole et al., 1997). In contrast, the comparison of *problem formats* have been less considered (an exception is Walkington et al., 2013). Furthermore, little is known on difficulties with percent problems of students with varying language proficiency. Especially the more complex problem types seem to pose additional comprehension challenges that are worth being considered in more detail. These indications and the limited state of research on percent problems suggest the following additional research question:

— How successful do students of low / high language proficiency identify different percentage problem types? What supports them for more complex problem types?

RESEARCH DESIGN

The study presented in this paper was conducted as a mixed methods study with a paper and pencil test on percent problems for N=250 students (age 13 to 15) in two countries, Germany and German-speaking Switzerland, and complementary interviews. Here, we mainly focus on the tests.

Test design

Language proficiency. Students' language proficiency was assessed by a C-Test in German, an economical and reliable measure of a complex construct of general language proficiency of first- and second-language learners (Grotjahn et al., 2002). By its specific construction in a gap text receptive and productive skills in lexical and grammatical areas are addressed.

Three problem types for percent problems. Students' varying performances for percent problems were measured by a paper-and pencil test with 15 items, systematically constructed in three selected problem types 'Find the amount', 'Find the base' and 'Find the base after reduction' (Table 1 shows the 14 items, some taken from Hafner, 2012, which are relevant for this paper). The problem type 'Find the rate' was omitted as it is the easiest to distinguish from the others by merely considering the involved units.

Table 1: Item sets in three different formats for three problem types (translated) with frequencies of correct identification and mathematization in the whole sample

Three problem formats for percent problems. Each problem type was presented in three formats: For the *pure format*, exercises were given together with the technical terms (hence the decision of problem type is already explicit, see Table 1). The *visual format* roused the bar model, an established visual model for percentages (van den Heuvel-Panhuizen, 2003), here contextualized in download bars, a familiar everyday context for teenagers (Prediger, 2013). Three or two items for each problem type were constructed in *text formats* with varying language difficulties.

Sampling and subsampling

The sample consisted of 15 classes in 7 schools, in sum N = 250 students (age 13 - 15). In order to investigate robustness of the findings to national curricular specificities, the test was conducted in two countries, Germany (in the metropolitan Ruhr region) and Switzerland (in the German-speaking region of Lake Constance). Due to differences in the school systems (streaming in Germany since Grade 5 versus a more comprehensive Swiss system), the selected Swiss schools have a higher general achievement level. For investigating differences in students' achievements with varied language proficiency (LP), the sample was split into three groups with high, medium and low LP (the medium group is not considered here); the cut-offs being set by the standardized test norms.

Complementary clinical interviews

In order to deepen the insights into students' difficulties and to gain explanations for difficulties, the quantitative data were triangulated by a small interview study in which students solved the problems in a thinking aloud format. So far, we analyzed interviews with forty students, in sum 594 minutes of video, which were completely transcribed. Due to space restrictions, we only briefly refer to the results of these analyses for selectively strengthen possible explanations even if there is only limited space for transcripts.

Data analysis and hypothesis

For the written tests, an evaluation of success in problem type identification and mathematization for each item was binary-coded in order to allow hypothesis-testing on achievements for different formats etc. with t-tests (Davison, 2003). More precisely, the following hypotheses were tested through attempting to falsify the corresponding null hypotheses:

(H1) Problems in text format are more difficult than in pure format due to comprehension difficulties for word problems (Kouba et al., 1988).

(H1*) Problems in text format are easier than in pure format since contexts can enhance students' accessibility of the problem (as shown for elementary arithmetic problems by van den Heuvel-Panhuizen, 2005).

(H2) Problems in visual format are easier than in text and pure format since visual models can enhance the accessibility of the problem (Walkington et al., 2013).

(H3) Students with low language proficiency have difficulties with *other* problem formats than students with high language proficiency; especially they have specific difficulties with problems in text format.

For testing hypothesis (H3), the data were treated in a Rasch-Model for identifying differential item functioning with respect to the students' language proficiency (Fischer & Molenaar, 1995). Additionally, a categorization of students' written solutions allowed deeper insights into students' challenges and resources, shown here for two similar items (in Section Reduce to versus reduce by: An example for linguistic challanges).

Language-driven subsampling **Regional subsampling**	Whole sample	Subsample with low LP	Subsample with high LP
Whole sample	N = 250	n = 60	n = 84
German Subsample	n = 98	n = 25	n = 33
Swiss Subsample	n = 152	n = 35	n = 51

Table 2: Sample and subsamples

Problem type Problem format	Find amount			Find base			Find base after reduction		
	Pure	Visual	Text	Pure	Visual	Text	Pure	Visual	Text
Whole sample	78 %	67 %	46 %	67 %	67 %	53 %	44 %	59 %	41 %

Swiss subsample	82 %	72 %	53 %	78 %	80 %	61 %	63 %	73 %	53 %

Table 3: Frequencies of correct identification / mathematization in two regional subsamples

RESULTS

First results and their discussion

For each problem format, Table 3 shows the frequencies of successful problem type identification and mathematizations (here interpreted as finding adequate expressions but not necessarily successful calculations of the result). Frequencies are given for the whole sample and split for the German and Swiss subsample.

These empirical results show that *hypothesis (H1)* must be restricted to well known problem types: Problems in text format are significantly more difficult than in pure format only for the basic problem types "Find the amount" and "Find the base" ($p<0.0009$). In contrast, the ranking of difficulty differs for the more complex and less acquainted problem type "Find the base after reduction" (no significance for higher difficulty with $p=0.175$). In the German subsample, this problem type is marginally easier in text format than in pure format ($p=0.097$), hence hypothesis (H1*) tend to apply. The interviews strengthen our interpretation that the context of shopping discount can enhance the accessibility, and this role of context can compensate potential comprehension problems posed by the text format in this less known problem type (at least for the subsample of high language proficiency, see below). This is illustrated by the written comment of a student (see Figure 1) referring to Item Dress (printed in Table 1).

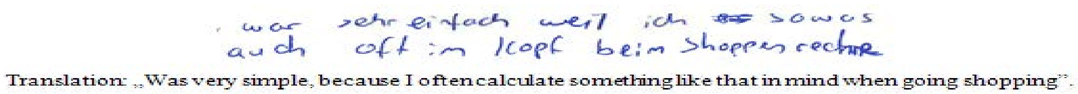

Figure 1: Statement of a student referring to Item Dress

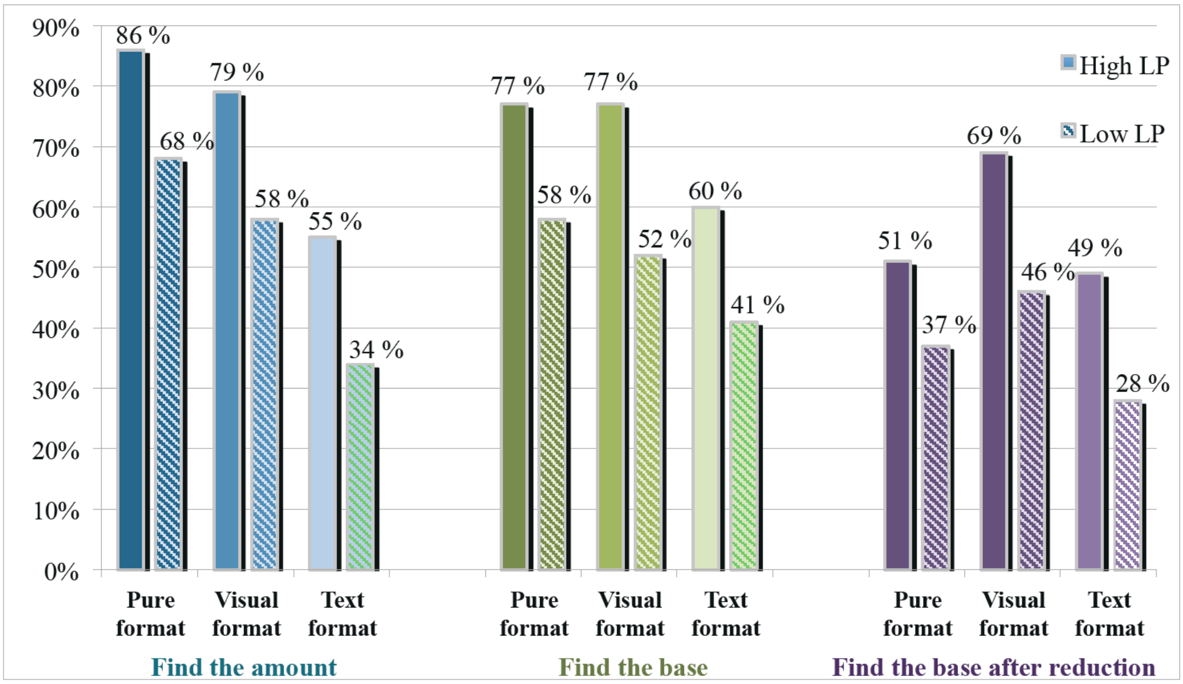

Figure 2: Frequencies of correct mathematization in subsamples with different language proficiency

In contrast, the Swiss subsample, which was more acquainted with the problem type, could solve the pure format more frequently than the text format.

Hypothesis (H2) on the role of the visual format is confirmed for all problem types for the text format: In both subsamples, problems with the visual bar model were solved significantly more frequently than in text format (p <0.0009). In contrast, the visual format is easier than the pure format only for the less known problem type "Find the base after reduction" in both subsamples (p<0.021). Also the interviews show that the visual bar model can enhance students' access to the problem when the key concepts do not suggest routine solutions.

Except for one deviance (text format for less known problem type "Find base after reduction"), the general pattern of difficulties between problem formats seem to be parallel in the German and Swiss subsamples. Unexpectedly, the mentioned differences are even significant in the separate subsamples (except for (H2) in the German subsample).

As Figure 2 shows, the described tendencies seem to apply for students with low as well as with high language proficiency in similar ways: the difference between pure format and text format is very similar for "Find the amount" (31 percent points for high LP and 34 percent points for low LP; of course with a higher rate) and "Find the base" (17 percent points for both samples).

These rather heuristic comparisons are confirmed by statistically more elaborate methods: The estimated item-difficulties in the Rasch-model had no differences for both subsamples, low LP and high LP. Significant differential item functioning was only found with respect to students' mathematics achievement, but *not* between the language proficiency subsamples. Hence, LP does not seem to determine specific difficulties. As a consequence, *hypothesis (H3)* can partly be falsified: Students with low language proficiency perform lower in all items, but their weaker achievement in the text formats is not per se an evidence for reading challenges being most dominant. In contrast, the differences between the formats of the problems proceeds in a related way for students with low LP as for students with high LP. The visual format which might be assumed to be relatively less difficult for students with low LP shows similar differences to the pure format for "Find the amount" (7 percent points for high LP and 10 percent points for low LP) and "Find the base" (0 percent points for high LP and 6 percent points for low LP). These comparisons of formats allow us to conclude that not the language alone, but the conceptual understanding (needed when the item format does not betray the problem type) is the highest difficulty for students with low LP.

This conclusion is strengthened by the analysis of the interviews, from which we show only one singular example, Tom's way of solving the Item Cross trainer (cf. Table 1). The student with low LP makes evident his conceptual understanding when subtracting the number indicating the percentage from the price (#2). He even validates and corrects his solution (#6 / 8), but still with no understanding that Euros and percent cannot be combined directly.

2	Tom:	Well, first, the client buys a crosstrainer in a sport shop. Yes, she pays 450 € for the equipment. That is the price which – how much it costs. She receives a discount of 10 % because she is a member. And now, we should calculate the normal price…. of the cross trainer. And I received: 440. And I have calculated 450 minus 10 %.
…	…	…
6	Tom:	But actually, the normal price should be [reads the text again] should be higher.
…	…	…
8	Tom:	Yes, now I have 460.

Like Tom, many students with low LP succeed in understanding the situation in the text but have too limited conceptual understanding to mathematize correctly. As a consequence, not only problems in text format are difficult for them, but all problems in which the mathematization is not pre-given by technical terms (like in pure format).

Reduce to versus reduce by: An example for linguistic challenges

Even if conceptual challenges are most crucial for students with low LP, there exist also linguistic challenges. We give an example from the deeper analysis of two similarly formulated items, both in text format:

Students' identifications of the problem types "Find the base" (Item Jeans) versus "Find the base after reduction" (Item Dress)	Frequency in *whole sample* (N=250)	Frequency in *subsample low LP* (n=60)	Frequency in *subsample high LP* (n=84)	Significance of differences low-high LP
recognizing a difference	40 %	36 %	49 %	p=0.049
(*both* problem types correctly identified)	14 %	7 %	21 %	p=0.004
(*one* problem type correctly identified)	6 %	7 %	4 %	n.s.
(*no* problem type correctly identified)	20 %	22 %	24 %	n.s.
recognizing no difference	59 %	65 %	52 %	p=0.049
(*one* problem type correctly identified)	39 %	35%	37 %	n.s.
(*no* problem type correctly identified)	6 %	12 %	5%	n.s.
(*both* items not treated)	14 %	18 %	10 %	n.s.

Table 4: Identifying the difference between Item Jeans ("reduced to") and Item Dress ("reduced by")

Item Jeans (Find the base): 40 € for jeans, were *reduced to* 80 %. What did they cost before?

Item Dress (Find base after red.): 30 € for dress, was *reduced by* 40 %. What did it cost before?

The prepositions in the expressions "reduce to" versus "reduce by" determine the problem type, and the typical challenge to recognize this difference (as discussed by Parker & Leinhardt, 1995, p. 439). Table 4 shows students' mathematizations for both items.

Only 40 % of the students have identified different problem types and have hence recognized a difference between the two items, 36 % of the students with high LP and 49 % of those with low LP (the difference being significant with p =0.049). In contrast, 59 % have not recognized the difference while treating the items (65 % with low LP and 52 % with high LP again a significant difference with p =0.049).

However, the fact that only 14 % identified both problem types correctly show that al-though there is a significant linguistic challenge that requires attention in classrooms, the conceptual challenges are still virulent. This can again be illustrated by Tom's way of solving the Item Jeans (cf. Table 1):

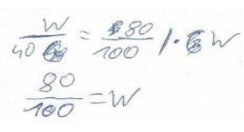

Figure 3

1 Tom: [after reading and calculating]: Yes okay, okay the amount is to be found, short W.

CONCLUSION AND OUTLOOK

The results of the presented test with N=250 students confirm that the same problem formats can provide different challenges: students have most difficulties in cracking percent problems in text format compared to those in pure or visual format. Whereas for elementary problem types, items in pure format are solved better than those in visual format, the visual model seems to enhance the accessibility for more complex, more unknown problem types. A methodological limitation of the study is that we did not account for the specific classroom curricula, which might influence students' varied abilities.

Although the language proficient students outperformed the students with low language proficiency in all items, the general pattern of differences in item difficulties is similar for both groups. This contradicts commonly held assumptions that disparities are bigger for text formats than for pure formats. It suggests that not exclusively the students' restricted reading proficiency is responsible for difficulties in tests, but also their lacking conceptual understanding in percentages (similar in grade 10, cf. Prediger et al. 2014).

In the future research, the findings will be extended by (1) an extended sample, (2) by deeper qualitative insights into students' difficulties by the interview study, and (3) by investigating whether these findings also apply to other problem formats.

Already the current state of the results is taken into account when designing a remediating course for enhancing students' conceptual understanding for percentages and dealing with word problems in this topic.

ACKNOWLEDGEMENT

We thank Esther Brunner for collecting data in Switzerland.

Cognitive flexibility and reasoning patterns in American and German elementary students when sorting addition and subtraction problems

Elisabeth Rathgeb-Schnierer[1] and Michael Green[2]

1 University of Education, Weingarten, Germany, rathgeb-schnierer@ph-weingarten.de

2 University of North Carolina Charlotte, Charlotte, USA

This study focuses on sorting and reasoning patterns in second and fourth grade elementary students. Based on a theoretical interpretation of flexibility in mental calculation we argue that sorting and reasoning for addition and subtraction problems provide information about students' cognitive flexibility. For the study reported here, a problem-oriented, guideline-based interview incorporating 12 two-digit addition and subtraction problems was conducted with American and German students. Following the theoretical background and design, this article gives an overview of results concerning reasoning patterns.

Keywords: Reasoning patterns for easy and hard problems, flexibility in mental addition and subtraction, cross cultural study.

SYNOPSIS OF THEORETICAL BACKGROUND

In recent decades math educators and researchers have taken an increasing interest in students' techniques for performing mental addition and subtraction. Similarly, math educators have emphasized the importance of developing flexibility in performing mental calculations (e.g., Anghileri, 2001; National Council of Teachers of Mathematics, 2000; Selter, 2000). In this context, mental calculation, in the sense of solving multi-digit arithmetic problems mentally without using paper and pencil procedures, has received increasing attention among researchers (e.g., Blőte, Klein, & Beishuizen, 2000; Heirdsfield & Cooper, 2004; Rathgeb-Schnierer, 2006; Threlfall, 2009).

Recent research on flexibility in mental addition and subtraction has revealed the following general patterns: (1) a negative impact on flexibility when addition and subtraction are learned by examples (Heirdsfield & Cooper, 2004); (2) students' mental strategies influenced by multiple factors (Blöte, Klein, & Beishuizen, 2000; Rathgeb-Schnierer, 2006; Torbeyns, De Smedt, Ghesquière, & Verschaffel, 2009), (3) some approaches more than others support the development of mental math flexibility in elementary students (Heinze, Marschick, & Lipowsky, 2009; Rathgeb-Schnierer, 2006), (4) greater mathematical competence among students who exhibit flexibility in mental calculation (Heirdsfield & Cooper, 2004; Threlfall, 2002), and (5) recognition of number patterns and relationships correlated with computational flexibility (Macintire & Forrester, 2003; Rathgeb-Schnierer, 2010; Threlfall, 2009).

At the same time, inconsistent perspectives appear in the research literature on mental calculation flexibility (Rathgeb-Schnierer & Green, 2013; Star & Newton, 2009). For example, nearly all definitions have the same basic idea of flexibility in mental calculation as an appropriate way of acting when faced with a problem, which is to say that flexible strategies are adapted dynamically to problem situations. Nevertheless, there exist in current research crucial differences concerning the meaning of what constitutes "appropriate" as well as the use of different methods to measure "flexibility" and "appropriate ways of acting" (Rechtsteiner-Merz, 2013). Many researchers define flexibility as the choice of the most appropriate solution to a problem (Star & Newton, 2009; Verschaffel, Luwel, Torbeyns, & Van Dooren, 2009). While Torbeyns and colleagues (2009) had the same notion, they enhanced their definition to incorporate both computational accuracy and timeliness: "strategy flexibility is conceived as selecting the strategy that brings the child most quickly to an accurate answer to the problem" (Torbeyns et al., 2009, p. 583). Even contrasting views of "flexibility" focus on mental outcomes, including elements of speed and accuracy.

The project described here refers to a notion of flexibility based on the model of process of calculation (Rathgeb-Schnierer, 2011; Rathgeb-Schnierer & Green, 2013) and current research results which underscore the crucial role of number patterns and relationships for flexibility in mental math (see above). Therefore, the following definition of flexibility has evolved: cognitive actions that match the combination of *strategic means* [1] (Rathgeb-Schnierer & Green, 2013) to the recognized number patterns and relationships of a given problem in the context of processing a problem solution. In this sense, our definition incorporates the capacity to use several strategies and adaptive thinking and is similar to Threlfall's "interaction between noticing and knowledge" (2002, p. 29):

> *When faced with a fresh problem, the child or adult who follows different solution paths depending on the numbers does not do so by thinking about what the alternatives are and trying to decide which one to do. Rather, he or she thinks about the numbers in the problem, noticing their characteristics and what numbers they are close to, and considering possibilities for partitioning or rounding them. (Threlfall, 2002, p. 41)*

Our work seeks to understand the mental processes that underlie problem solutions, the *cognitive elements* [2] that support the solution process. Therefore, we examine directly whether students recognize problem characteristics, number patterns, and relationships, and whether they use this knowledge for solving a problem (Rathgeb-Schnierer & Green, 2013). Our definition of flexibility differentiates between solution processes based on learned procedures (step-by-step mental calculations) and recognized problem characteristics, number patterns, and relationships. Hence, our project is aimed at identifying degrees of flexibility in students' mental arithmetic by identifying the cognitive elements that sustain the solution process (learned procedures or problem characteristics, number patterns, and relationships).

SYNOPSIS OF THE PROJECT

The project incorporated interview questions directed at students' recognition of problem characteristics, number patterns, and relationships. Students were encouraged to look at the given problems, sort them into either 'easy' or 'hard' categories, and give reasons for the sorting (details in Rathgeb-Schnierer & Green, 2013). In addition, we examined country and classroom-related differences.

Generally, our study was aimed at answering the following empirical questions: Do students recognize problem characteristics, number patterns, and relationships, and what reasoning do they exhibit about these elements? To what extent is cognitive flexibility in mental calculation related to sorting and reasoning patterns? Do students of different grade levels or countries exhibit differences or similarities (or both) in sorting and reasoning? In this paper, we focus predominantly on the first question.

Design

A qualitative study with guideline-based interviews was conducted with 78 second and fourth grade American (Charlotte, North Carolina) and German (Baden-Württemberg) students from ten different classrooms (three from 2nd grade and two from 4th grade in each country). These classrooms were chosen purposely by observing several math lessons and characterizing them by the degree of directness of instruction and openness of tasks. Typically, seven students per classroom were interviewed, and these were teacher selected as being either average or strong in arithmetic.

The qualitative, problem-oriented and guideline-based interview contained twelve two-digit addition and subtraction problems that were displayed on small cards. Each problem was purposely designed with at least one special numerical pattern or relationship feature: 31-29 (renaming required; range of numbers; 29 is close to thirty), 46-19 (renaming required; 19 is close to twenty), 63-25 (renaming required), 66-33 (no renaming required; double and half relation; double digits; inverse problem to 33+33), 88-34 (no renaming required; double and half relation of the ones), 95-15 (no renaming required; fives at the ones place), 33+33 (no regrouping required; double digits; double facts at the ones place; inverse problem to 66-33), 34+36 (regrouping required; double facts at the tens place; ones add up to ten), 47+28 (regrouping required), 56+29 (regrouping required; 29 close to thirty), 65+35 (regrouping required; fives at the ones place add up to ten), 73+26 (no regrouping required).

Students were interviewed one-on-one for 15 to 30 minutes, with video recording. Normally, each interview had two parts: (1) sorting problems into categories "easy" and "hard" and talking about the reasons for sorting, and (2) solving problems (if not already done during the sorting process). If it was indicated by the situation (for instance by utterance or action of the student), a third part was sometimes added to compare selected problems and direct student's attention to the characteristics of the problem 46-19 ("Is there way to make this problem easier?"). The cards were mixed and laid out on the table, and students were asked to sort cards one-by-one under "easy" or "hard" labels placed on opposite sides of the table. After a card was placed, students were asked, "Why is this problem easy/hard for you?"

Interviews were conducted by one researcher and took part in the last two months of the academic year (Germany 2010 and 2012, USA 2011). All interviews were transcribed in their original language for content-analysis.

Based on theory and student data, a coding system was developed. Two types of reasoning were applied to both easy and hard problems: reasoning by problem characteristics for easy (RCE) and hard (RCH) problems and reasoning by solution procedures for easy (RSE) and hard (RSH) problems. Reasoning by problem characteristics was coded when students referred for instance to features of numbers (e.g. similarity of tens and ones), numerical relations (e.g. double and half, analogies), and relations of tasks (e.g. invers problem). Reasoning by solution procedures was coded when students immediately started to describe a technique of mental, step-by-step computation (e.g., Selter, 2000; Threlfall, 2002).

All interviews were coded using event sampling, the individual sort for each of the 12 cards. An event was defined as one complete statement of reasoning that began with a student's first utterance after sorting a card and ended either when the student stopped talking or was interrupted by the interviewer. Multiple codes in the same category could be assigned to an individual event, but the assignment to one of the four core categories was exclusive. For example, a student's reasoning could either be coded as reasoning by characteristics (RCE/RCH) or reasoning by solution procedure (RSE/RSH), never to both; the deciding factor was always the very first statement. For validation, the entire data set was scored by two independent judges, and all disagreements were resolved through discussion.

RESULTS

Sixty-nine students were included in our analysis (eight interviews were dropped [3]): 28 fourth graders, 17 American students and 11 German students, as well as 41 second graders, 19 American students and 22 German students.

Reasoning (31-29)	Coding
This one is easy, cause both of the numbers are very close to each other, so – uhm, you can find out that there're only a couple numbers apart and so the answer would be two.	reasoning by problem characteristics – easy (core category) • relation of numbers (code) • range (sub-code)
This is an easy one, because I do 31 – 20 – uhm, and this is 11, and 11 – 9 equals 2.	reasoning by solution procedures – easy (core category) • compose and decompose (code) • jump method (sub-code)

Figure 1: An example of categorizing

	Sorting	Reasoning by Problem Characteristics	Reasoning by Solution Procedures	Other
Total	902 (100.0%)	492 (54.54%)	284 (31.48%)	127 (14.07%)
Easy	644 (71.39%)	351 (38.91%)	236 (26.16%)	58 (6.43%)
Hard	258 (28.60%)	141 (15.63%)	48 (5.32 %)	69 (7.64%)

Figure 2: Frequency of sorting and reasoning

General patterns in sorting and reasoning

In terms of sorting and reasoning, Figure 2 displays frequencies for easy and hard problems sorted by reasoning category.

In total, 902 reasons appeared in the sample, an average of 13.07 per student (minimum 8, maximum 17). More than two-thirds of the problems were judged as easy. Regarding the two types of reasoning, 54.54% belong to reasoning by problem characteristics, 31.48% to reasoning by solution procedure, and 14.07% to other reasons (which were excluded here from further data analyses). Regarding the category "reasoning by problem characteristic" the ratio for easy to hard is 2.48 to 1; within the category "reasoning by solution procedure" the ratio is 5.24 to 1.

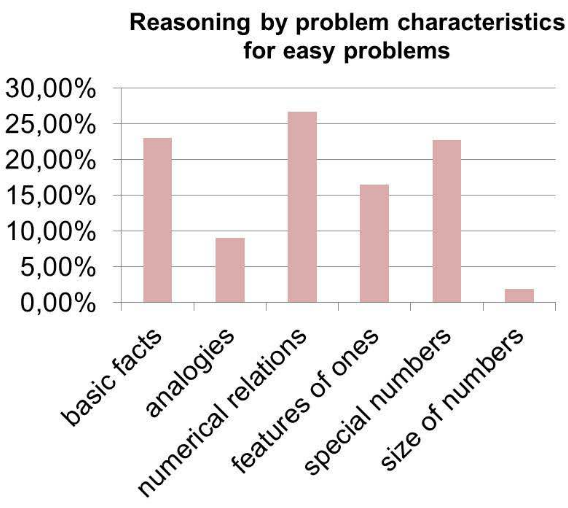
The percentage of each reasoning type related to all given arguments in each grade (separated by problem characteristics and solution procedures) is shown in Figure 3. Differences between grades occurred for both problem characteristics and solution procedures. Regarding the fourth graders, 69.53% of the arguments referred to problem characteristics and 30.47% to solution procedures. In contrast, second graders exhibited 10% fewer arguments belonging to problem characteristics and 10% more to solution procedures. Prior research by Selter (2000) had led us to expect fourth graders to argue more using solution procedures, since they are more familiar with the standard algorithms than second graders (in Germany the standard algorithms are introduced in third grade). Interestingly, our fourth graders exhibited less solution procedure reasoning than second graders, and they used nearly 50% more reasoning by problem characteristics than by solution procedures. This finding might be affiliated with the range of numbers used in the interview tasks and is probably explainable by the greater familiarity of fourth graders with two digit numbers.

In order to examine students' recognition of problem characteristics, number patterns, and relationships, we focused on the core categories "reasoning by problem characteristics." Figure 4 shows the percentage of the entire sample for each code in the two core categories "easy" and "hard." Distinct differences between easy and hard problems are readily apparent. With

	4th (n=28)	2nd (n=41)
Reasons - total	**340 100%**	**436 100%**
Characteristics - total	**234 68.82%**	**258 59.17%**
Characteristics - easy	165 48.52%	186 42.66%
Characteristics - hard	69 20.29%	72 16.51%

	4th (n=28)	2nd (n=41)
Reasons – total	**340 100%**	**436 100%**
Solution - total	**106 31.17%**	**178 40.82%**
Solution - easy	89 26.17%	147 33.71%
Solution - hard	14 5%	31 7.11%

Figure 3: Percentage of reasoning in each grade



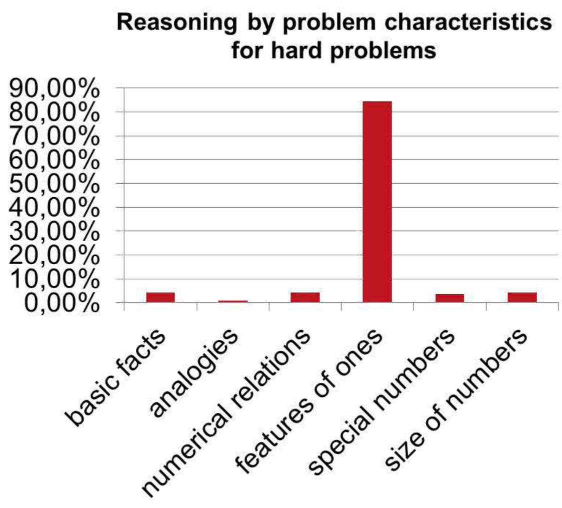


Figure 4: Reasoning by characteristics for easy and hard problems

reasoning for easy problems, students consistently referred to a variety of number patterns and problem characteristics. They pointed, for example, to basic facts [4] (23.36%), analogies between tens and ones (8.83%), numerical relations (27.06%, e.g. range of both numbers, double half, inverse problem), special features of numbers at the ones place (16.23%, e.g. two fives at the ones place or numbers that add up to ten), special numbers (22.50%, e.g. double digits or numbers close to the next ten), and also size of numbers (1.99%).

A completely different pattern was exhibited with reasoning by problem characteristics for hard problems. Students referred predominantly to "features of ones" (84.39%), referring directly to the numbers in the ones place. One typical characteristic for hard problems was the specific constellation of numbers in the ones place that leads to the need for renaming.

Student: So *((selects the card 46-19))* ok *((puts it in the "hard" column))* I'll put that one in the hard. So 46 plus, um, minus 19 *((points at the numbers on the card))* I think it's a little harder because first *((points at the tens on the card))* you can do four minus one which is three, and that one *((points at the 6 and the 9))* is kind of hard, because this one *((points at the 9))* is bigger than that one *((points at the 6))*.

Even if problems that required renaming were often considered as hard, we also found opposite judgments especially with those problems that include one number which is close to the next ten (predominantly numbers with a nine) for instance 31-29 (see Figure 2), 46-19 or 56+29. Whenever students discovered problem characteristics other than the requirement of renaming, they considered those problems to be easy.

Example for 56+29:

Student: This one is easy *((points to the problem 56+29))* because 29 is close to 30, I only have to add one.

Interviewer: That means you add one to 29?

Student: Here is 30 *((points to 29))*, and here 55 *((points to 56))*, um, and I do 30 plus 55.

Example for 46-19:

Student: *((points on 46-19))* One could easily subtract 20 *((points on the minuend))*.

Interviewer: Mhm.

Student: So, for 46 minus 20 you need no special trick, you know the answer immediately.

Interviewer: Yes.

Student: - this is 26, and then you need (..) to (..) – moment (..) to add one.

Interviewer: Why do you need to add one? Is this correct?

Student: Yes, because we have one more subtracted, that means we have subtracted one number more.

Summarizing, our data analyses suggest that addition and subtraction problems that require renaming are not regarded by students to be hard in general. In fact, in our sample, students depicted a more differentiated assessment of problems that required renaming: They considered those problems to be easy when additional problem characteristics (e.g., 9 in ones place) were obvious.

Reasoning in different classrooms

Qualitative analyses suggest classroom-related tendencies concerning reasoning patterns. Figure 5 shows students' reasoning patterns from three different second grade classrooms. Each column represents the arguments of one student, and the size of the dots displays the quantity of arguments in the category. The math lessons in classrooms A (American) and C (German) showed the same high degree of open tasks and self-regulated learning, whereas in classroom B (German) predominantly direct instruction and closed tasks were observed.

Students from classroom A referred almost exclusively to problem characteristics to explain why a problem seems to be easy or hard. Students from classroom B showed a distinct preference for reasoning by solution procedures and exhibited a quite restricted range in their reasoning: Whenever reasoning based on solution procedures appeared, "composing and de-

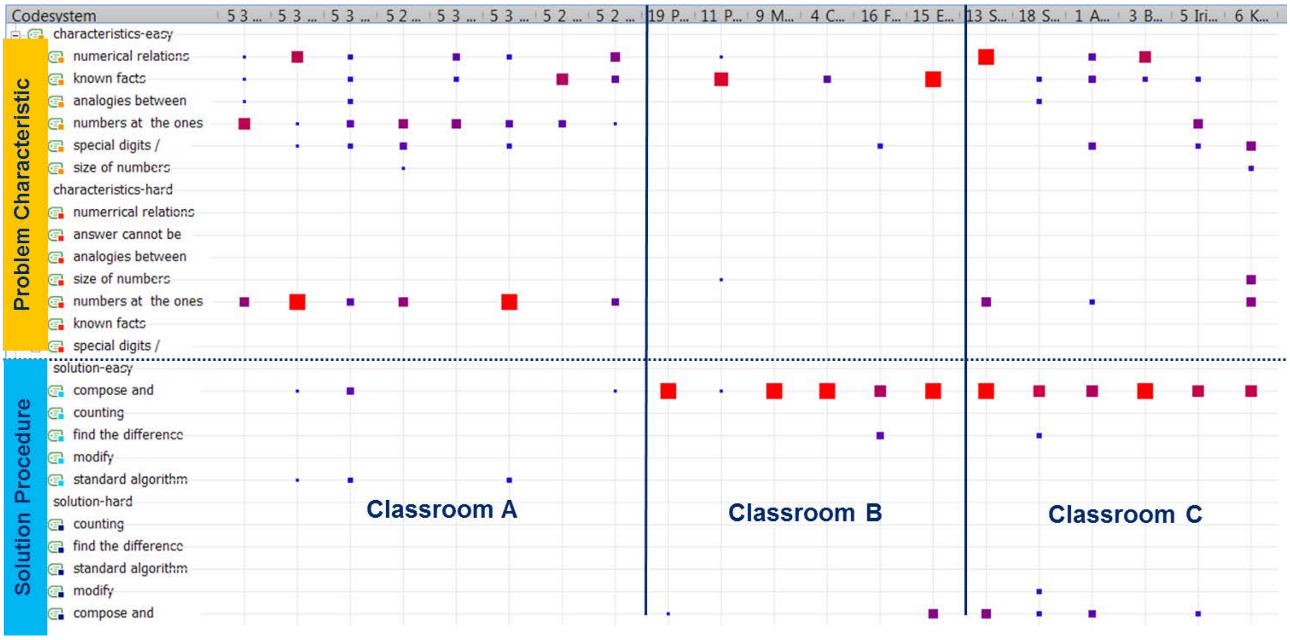

Figure 5: Reasoning patterns in classrooms

composing" strategies were exhibited. The few times reasoning based on problem characteristics emerged, students referred predominantly to "known facts" (basic facts). Classroom C students can be described as more comprehensive, since problem-based and procedure-based reasons coexist. In that sense, this group showed a great variety of problem related arguments and no variety at all in the section of procedure related arguments (note that solution procedures for both hard and easy problems were coded "compose and decompose"). This is an important pattern revealed throughout the whole data: Whenever students' reasoning referred to problem characteristic and number patterns, a great variety was noticeable. Therefore, we presume that those students act dynamically and can be considered as mentally flexible. On the other hand, whenever students depicted reasoning based on solution procedures, a quite restricted range of reasons was empirically observable. Hence, those students acted very statically and can be considered as mentally rigid.

CONCLUSION

In summary, we have reported a variety of patterns in students' reasoning for easy and hard problems that reflected the characteristics we built into the problems. There was obviously a greater variety of arguments for easy problems than for hard ones. Based on individual and classroom related reasoning patterns, we were able to identify three forms of reasoning: flexible (multiple reasons predominantly referring to characteristics), rigid (one reason referring to a solution procedure) and mixed (multiple reasons when referring to characteristics, one reason when referring to a solution procedure). Data analyses suggested that students who exhibited reasoning by characteristics were more cognitively flexible than students who didn't. Our next step will be to identify whether the recognized characteristics (that were visible in students' reasoning) function to sustain the solution process, and therefore can be considered as cognitive elements.

ENDNOTES

1. Strategic means are neither holistic strategies nor cognitive menus that complete a solution path; they are distinct devices that can be combined in flexible ways to modify complex problems to make them easier. Strategic means include decomposing and composing, modifying a problem, deriving the solution from a known problem, and using decade analogies.

2. Students' solution processes are based on specific experiences that we designate with the term "cognitive elements." Such cognitive elements that sustain a solution process can be learned *procedures* (such as computing algorithms) or *number characteristics* (such as number patterns and relationships).

3. Eight interviews were dropped from the analysis for inaudibility, early termination or irreversible deviation from the interview guideline.

4. The code "basic facts" was purposely assigned to the core category "reasoning by problem characteristics." In our opinion, referring to basic facts is not a sign of procedure, but an indicator of the recognition that parts of the problem belong to basic facts. In this context, we only assigned an argument to the code "basic facts" when students expressed clearly and consciously that part of a problem or a whole problem is known by heart. The naming of a result by itself was not assigned to the code "basic facts."

A network of notions, concepts and processes for fractions and rational numbers as an interpretation of Didactical Phenomenology

Rubí Real and Olimpia Figueras

Centro de Investigación y de Estudios Avanzados del IPN, Departamento de Matemática Educativa, Ciudad de México, México, creal@cinvestav.mx; figuerao@cinvestav.mx

One of the main purposes of the research project that is being carried out in Mexico consists on building, from Filloy's point of view, a Local Theoretical Model (LTM) for fractions and rational numbers. For this purpose, four components of the LTM have to be constructed: models of formal competence, teaching models, models for the cognitive processes and models of communication. In this paper, a network of notions, concepts and processes for fractions and rational numbers that constitutes a fundamental part of the models of formal competence is described. This network was structured taking into account five mathematical processes grounded on Freudenthal's specimen of Didactical Phenomenology of fractions.

Keywords: Fractions, rational numbers, mathematical processes, teaching models.

INTRODUCTION

In the sixties, prestigious university educators discussed two approaches for the teaching of fractions in basic education. One group argued that decimal numbers could replace common fractions while the other one asserted that fractions should be taught, but only those that are more frequently used in everyday life (Rappaport, 1962). Those different positions generated discussions about the teaching and learning of fractions. Rappaport (1962) argued that fractions should be taught, since it is a necessary mathematical concept in order to understand rates and ratios. Usiskin (1979) claimed that a fraction is a representation of many numbers, and identified different uses of fractions involved in situations of splitting up, rates, proportions, mathematical formulae and equations.

Kieren's research (1976 & 1988) showed the complexity of the rational number concept. He stated that in order to construct a permanent knowledge of rational numbers, a person has to understand several constructs: measure, quotient, operator and ratio. For Kieren, part-whole relationship serves as a basis for connecting those constructs, which supports a construction of more formal knowledge that includes equivalence, and additive and multiplicative structures of a quotient field.

Lesh, Landau and Hamilton (1980) pointed out that the concept of rational number is a group of sub-constructs and integrated processes related to a wide range of basic concepts, appearing in a variety of problem situations.

Aware of the constructs identified by Kieren (1976); Behr, Lesh, Post and Silver (1983) proposed a model by grouping them in view of their relationships and links to equivalence, operations and problem solving. They also considered that the part-whole relationship is a fundamental meaning in order to understand the other meanings.

Although the part-whole relationship is an important meaning of fractions, Freudenthal (1983, p. 144) argued that the teaching based only on this relationship is restricted not only phenomenologically, but also mathematically, for it yields only proper fractions.

The research findings influenced worldwide educational reforms in the 90s, in order to improve the teaching and learning of fractions and rational numbers. In Mexico, in 1993, three different fraction meanings (quotient, measure and ratio) were included explicitly in the study programmes for primary and secondary school. However, nowadays secondary school students go on obtaining low scores on questions about fractions in national tests. For instance, a comparative study (data from 2005 to 2008 provided by the *Instituto Nacional para la Evaluación de la Educación* [INEE], 2012) showed that the correct answers obtained by third grade secondary school students in the Excale test, applied in Mexico, were lower than 40%.

For many years – at least since 1962, as mentioned above– it has been thought that knowledge of fraction concept is important in understanding other mathematical concepts. Siegler and colleagues (2012) found that "elementary school students' knowledge of fractions and division uniquely predicts students' knowledge of algebra and overall mathematics achievement in high school" (p. 691). Siegler and collaborators' findings imply that almost 60% of Mexican students would have a poor performance in mathematics in high school. Therefore, the teaching and learning of fractions and rational numbers pose still a problematic area for mathematics education.

As a consequence, it was decided to design a research project so as to characterise the structure and organization of the current teaching model of fractions; to analyse the interpretation made by authors of textbooks of the study programmes, and to characterise the effectiveness of the overall design and the understanding of those authors. This information will provide knowledge for designing an alternative teaching model of fractions for secondary school, and carrying out its experimentation in the classroom.

In this paper the most important result of the building up of the models of formal competence of the LTM for fractions and rational numbers is described. This outcome is a network of notions, concepts and processes for fractions and rational numbers, which is used as a methodological tool for analysing and designing teaching models.

THEORETICAL FRAMEWORK

Filloy's Local Theoretical Models theory (see Filloy, Rojano, & Puig, 2008) is used as a theoretical and methodological framework to organize the research bearing in mind its four components: 1) models of formal competence, 2) teaching models, 3) models for the cognitive processes, and 4) models of communication. Models of formal competence are related to fractions and rational numbers as mathematical objects; the teaching models and models of communication are associated to those mathematical objects as teaching objects, and models for the cognitive processes deal with fractions and rational numbers as learning objects.

METHODOLOGY

To construct the LTM, a specific methodology has been defined for each component. The models of formal competence were built mainly considering Freudenthal's Didactical Phenomenology of fractions (1983). The teaching models comprise analyses of the Mexican current study programme for secondary school and mathematics textbooks used by students. The models for the cognitive processes and communication include: 1) Kieren's explicative model (1988) which provides a global overview of individual construction of rational numbers knowledge; 2) a review of the results found in empirical studies carried out among secondary school students; 3) an analysis of other theoretical perspectives; 4) a characterisation of Mathematical System of Signs (MSS) (Filloy et al., 2008) of fractions and rational numbers, and 5) an analysis of items designed to assess these kinds of knowledge.

MODELS OF FORMAL COMPETENCE

This component of the LTM is related to mathematical knowledge, emphasising the structure and properties of fractions and rational numbers as mathematical objects. It is an important component due to: 1) the observer of educational experimentation should be capable to interpret the messages and texts generated by students and their teacher in the classroom. Therefore, the researcher needs more abstract MSS that encompasses all the MSSs used in the observed processes (Filloy et al., 2008, p. 36); 2) the design of a teaching model requires the knowledge of the characteristics of a competent user of fractions and rational numbers, and 3) the task designer must have examples of diverse situations in which these numbers are used readily available.

For the authors of this paper, the fulfilment of those requirements is possible through analysis of Didactical Phenomenology of fractions done by Freudenthal (1983). In these types of analyses, those phenomena organized by fraction and rational number concepts are described; consequently they provide diverse examples of how those numbers are used in various situations. In the processes of identifying different phenomena, the characteristics of the necessary competencies for using fractions and rational numbers for solving problems emerge.

Freudenthal starts the characterisation of phenomena from the first ideas of fractions embedded in everyday language through to the complex concepts included in the mathematical theory of rational numbers.

The specimen of Didactical Phenomenology of fractions was reinterpreted by the authors, identifying classes of phenomena: description and comparison of quantities, magnitude values or objects, division of substances measured by magnitudes, distribution of quantities, measurement, and numbers as part of a numerical system. For each one of the first five classes, different notions and concepts of fractions and rational numbers were identified, organized, schematized and linked with five mathematical processes: describing, comparing, dividing, distributing and measuring. The sixth class refers to the mathematical constructions of rational numbers.

In the following sections of this paper a brief description of these processes/classes of phenomena associated with fractions and rational numbers is made.

Describing. In everyday language there are expressions in which fractions are used to describe: i) a quantity or magnitude value through another quantity or magnitude value, ii) a measure expressed by numbers, iii) cyclic or periodic processes, and iv) ratios. These expressions are related to the process of 'describing' (see Figure 1) and are linked with four kinds of phenomena in different contexts in which *the fraction is acting as a descriptor*.

Expressions such as: 'half of a way', 'three quarters of an hour' and 'one third of the world's population will suffer water shortages by 2015' are examples in which a description of a quantity or magnitude value through total distance of a way, of a number of minutes of an hour, and of the number of people that live in the world is made. Measures can be described using phrases as '½ litre of milk' or '¾ of a pound'. Different cyclic or periodic processes are described using fractions and mixed numbers, for example: 'a driver only could run ½ times the track due to a mechanical failure' and 'a Chinese competitor presented an almost perfect dive in which he rotated 2 ½ times'. Likewise, fractions are employed to describe ratios relating two quantities or magnitude values. For instance, '3 out of 5 parts' and 'six of every one hundred Mexican people speak an indigenous language'.

Comparing. Three types of phenomena associated to the process of 'comparing' in which *fractions represent comparers* were identified (see Figure 2). Fractions are

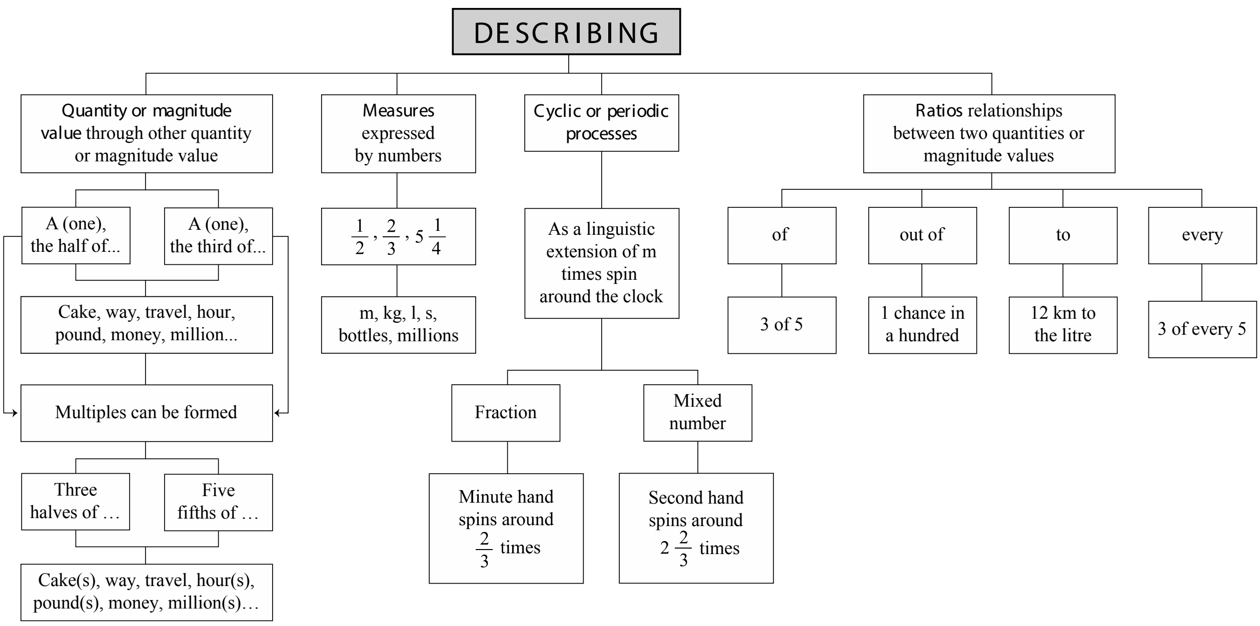

Figure 1: Schematic representation of the 'describing' process as part of the network

also used in everyday language to express the result of a comparison between two quantities or magnitude values; this comparison is related to a first abstraction level. In a comparison of the salary of two persons, one that earns 1 800 € and the other 1 200 € it is possible to say: 'one person earns 3/2 times than the other'.

In a second abstraction level, diverse aspects of the fraction were incorporated: fracturing operator, fracturing relation, ratio relation, ratio operator and transformer.

Two objects that are brought close together, or are in some other way considered, as though the smaller were part of the bigger, can be compared using the fracturing operator or fracturing relation. For example, if we compare the height of two bookcases, one has six shelves and the other has seven shelves, the fractions 6/7 and 7/6 represent these two possible comparisons.

Fraction as a ratio relation is the result of comparing two objects that are separated. This comparison can be made with respect to a number or a magnitude value of each object. To compare the height of two of the tallest towers in the world: the Tokyo Skytree and the Canton Tower, having in mind that one of them measures 634 m and the other 610 m, the fractions 634/610, 317/305, 610/634 and 305/317 are ratio relations that represent the comparisons of the towers' heights.

The aspect of fraction as ratio operator acts on a quantity or magnitude value, transforming it into another quantity or magnitude value. For example, to obtain the amount that each type of heir gets from an inheritance of 60 000 €, knowing that 2/3 are for the sons and 1/3 for the widow, the fractions 2/3 and 1/3 are ratio operators that transform 60 000 € in 40 000 € and 20 000 € respectively.

In its intermediate stage as transformer, the fraction performs on dimensions of objects by deforming or mapping to a scale a/b. To determine a scale of the transformation of an image whose size is 1280 x 960 pixels to another size of 1600 x 1200 pixels, the fraction 5/4 represents both a scale and a transformer.

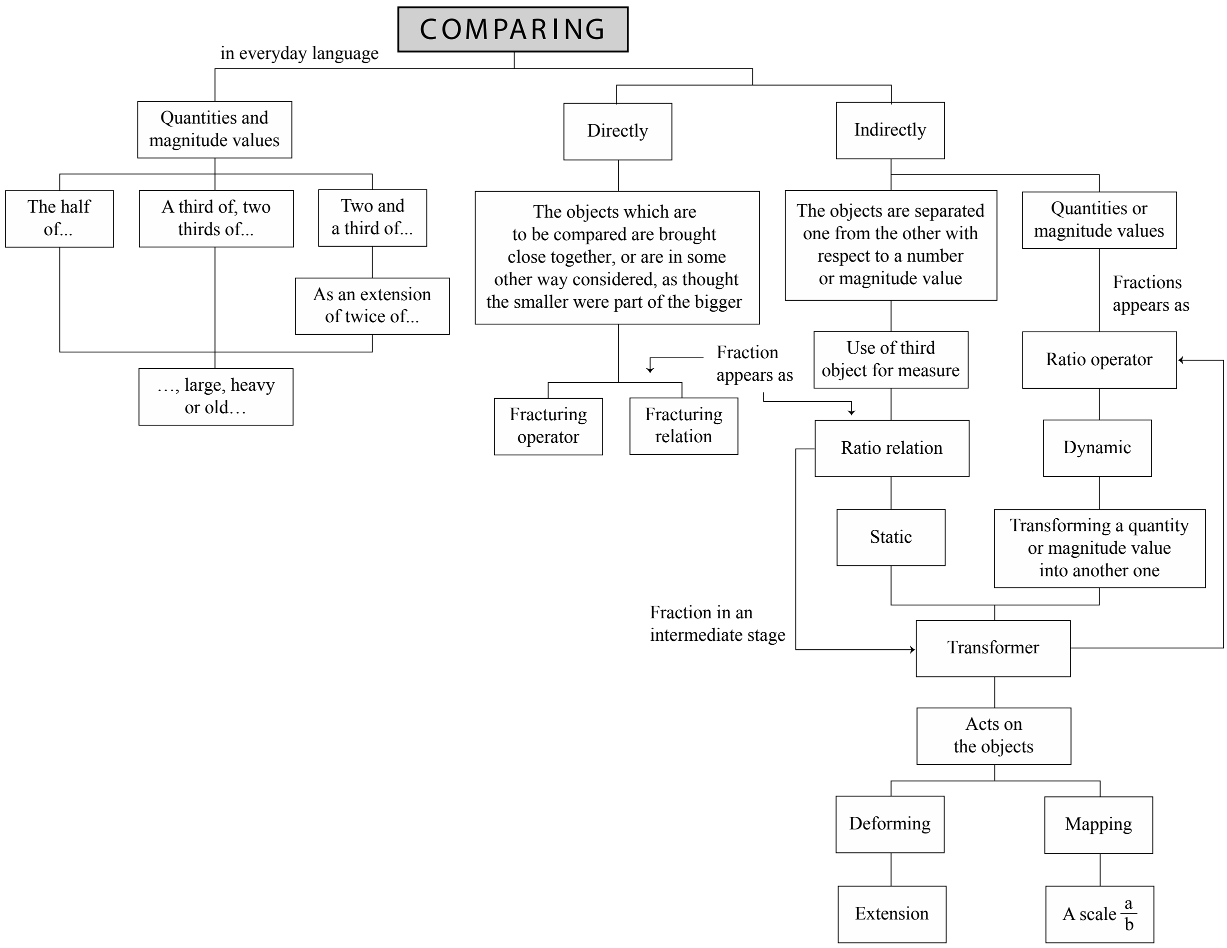

Figure 2: Schematic representation of the 'comparing' process as part of the network

Dividing. To divide substances measured by magnitudes, the whole is partitioned in equal parts, relating it to one or more of those parts (see Figure 3). In that way, *the fractions represent part-whole relationships and are acting as fracturers*. For instance, 18/27 parts of the roulette are black or 11/25 of the numbers of a bingo card are even numbers. The expression numerator/denominator represents the part-whole relationship.

There are different methods of fracturing in equal parts: in an irreversible, reversible or symbolic way. The estimating of equality of the parts can be made at sight, by feel or by others methods like the use of congruences or symmetries or employing different measuring instruments. Regarding the whole it can be discrete, continuous, definite, indefinite, structured or lacking structure. There are transitions among those types of wholes. The parts of the whole can be connected or disconnected.

Distributing. A distribution process of small or large quantities can be related to a finite set model and/or to a magnitude model (see Figure 4); *the fraction represents the result of this process*. On the one hand, when 10 leaf packs are distributed among 5 persons, each person gets 1/5 of the total of leaf packs (10 leaf packs ÷ 5 persons = 2 leaf packs per person = 1/5 of 10 leaf packs for each person). In this case, the process has finished and is associated with the finite set model.

On the other hand, if 3 sacks of rice whose mass is 50 kg each are distributed between 2 persons, each person would get 1 whole sack of rice and it would be necessary to distribute the remaining sack considering its mass, thus each person would get ½ of a sack more (50 kg ÷ 2 persons = 25 kg per person = ½ of a sack per person). In this case, the process is related to a magnitude model because the use of the mass unit has made possible the distribution.

When the magnitude model is introduced to distribute the remainder, it is necessary to constitute a magnitude in a system of quantities that include different requirements ranging from an equivalent relation to the division of an object in an arbitrary number of partial objects. The expression numerator/denominator represents, in this case, the quotient of a division; in other words, it is the result of the distribution process.

Measuring. Fractions also represent measures of magnitudes (see Figure 5). Magnitudes can be measured with unconventional units or using metric and non-metric systems. The metric system is related to decimal fractions. The non-metric systems are the an-

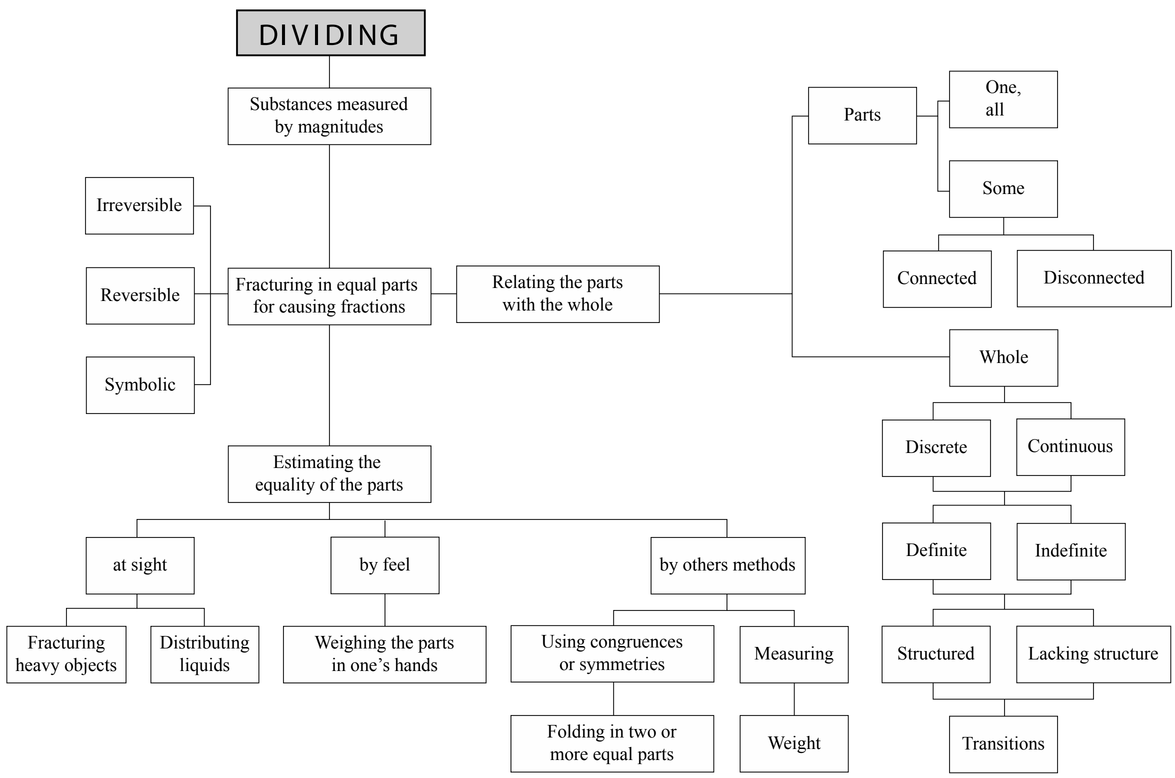

Figure 3: Schematic representation of the 'dividing' process as part of the network

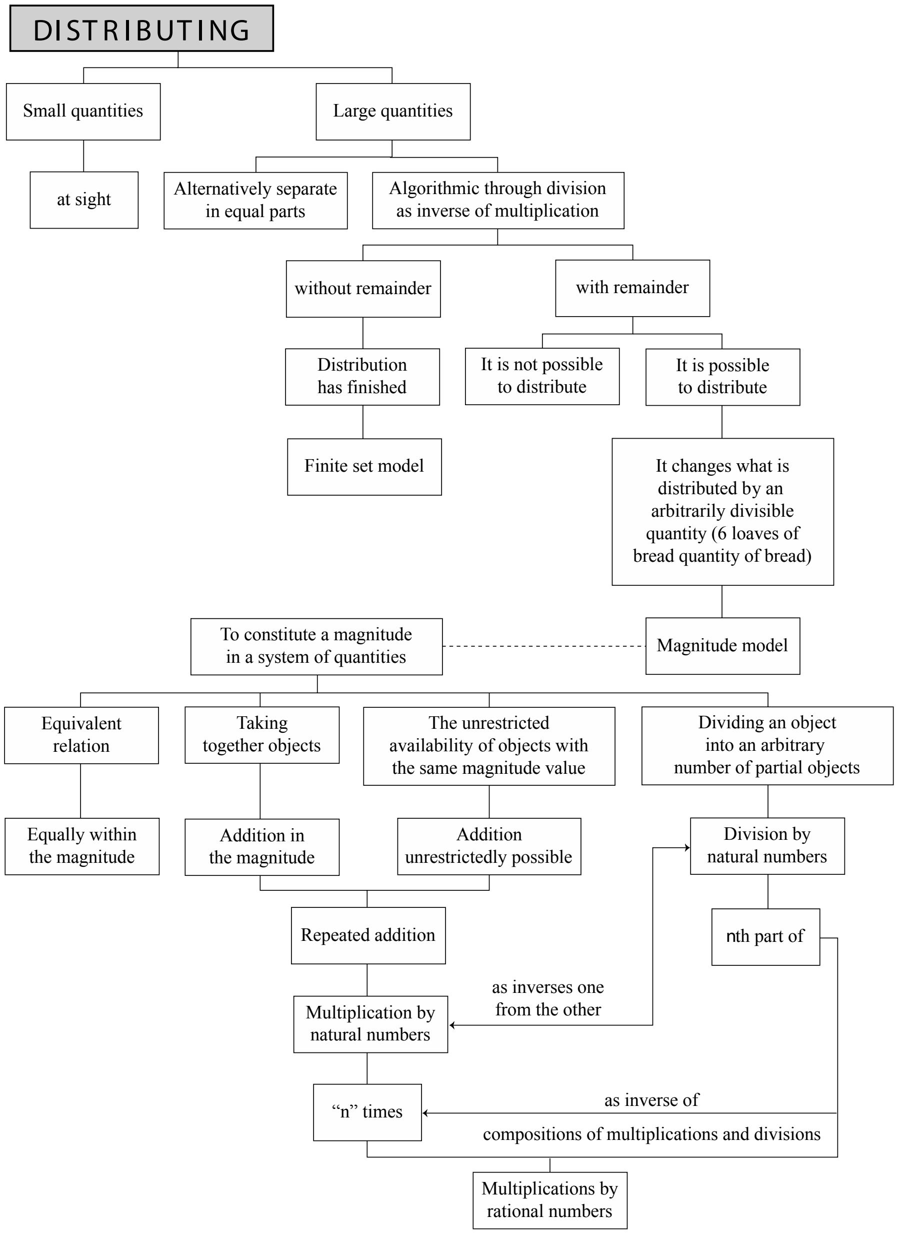

Figure 4: Schematic representation of the 'distributing' process as part of the network

cient systems of measurement and the English system; some of the former have various decimal relations; for example, in the Egyptian system 1 khet = 100 sq cubits.

Decimal fractions can be thought of as elements of ever finer nets. There are connections among these elements in the same net through addition, subtraction and comparison, or between elements from two different nets using multiplication.

To measure magnitudes it is also possible to use the number line, selecting an arbitrary length to represent a unit of measurement to be used for building different scales of length, time, temperature and mass measurements among other magnitudes. *The fraction represents the result of a measurement process and acts as a measurer*.

In the last part of the network of notions, concepts and processes, the phenomena that are associated with the rational numbers as a number system are included. Two ways of constructing this kind of numbers outlined by Freudenthal – an *a posteriori* axiomatic way (as equivalence classes of fractions) connected with the algebraic nature of these numbers, and an *a priori* genetic way (as a commutative semigroup) linked with the ratio operator – were considered as the sixth class of phenomena. These constructions of rational numbers correspond to a more abstract level. In the latter construction, an arbitrary length was selected

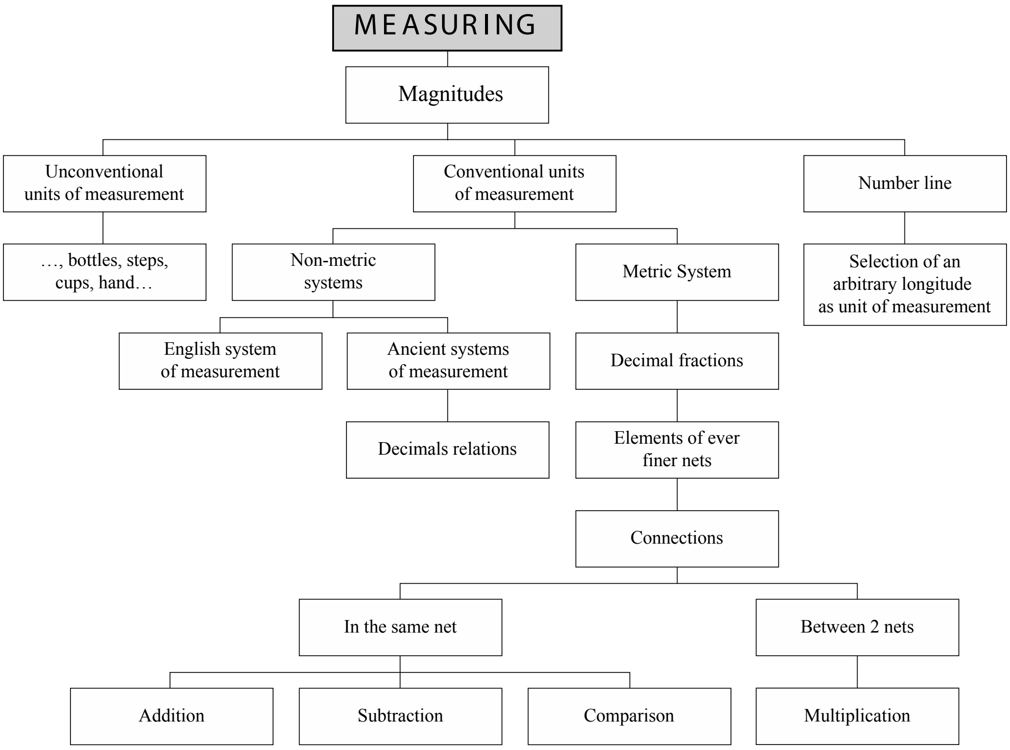

Figure 5: Schematic representation of the 'measuring' process as part of the network

in order to discover rational numbers as measures of a segment or points on the number line.

The network encompasses from the use of first ideas of fractions embedded in everyday language through to the mathematical constructions of rational numbers. Due to the extension of the network, it cannot be included in this paper, but the authors expect that readers could get a general idea from the above paragraphs.

THE USE OF NETWORK AS METHODOLOGICAL TOOL

In order to analyse a teaching model of fractions, the network was used as a methodological tool through examination of the activities included in mathematics textbooks, which were used by secondary school students in Valencia, Spain (Real, Figueras, & Gómez, 2013). The results of that analysis showed that the aspects of fractions in such teaching model are: descriptor, fracturer, ratio operator, and measurer (this last aspect appears in an implicit way). For representing a part-whole relationship the fraction as descriptor is used. The fraction as comparer is utilised for comparing two quantities or magnitude values. For transforming a quantity or magnitude value into another one, the fraction as ratio operator is employed. The fraction as a measurer is a means for solving some activities, but its use to compare different fractions in the number line is not included. In an overall view, some phenomena within the network are included in this teaching model of fractions, even though the authors state that it is based on problem solving.

FINAL REMARKS

All these mathematical processes related to different notions and concepts of fractions and rational numbers, included in the network, describe an overall perspective about teaching and learning of these mathematical objects. The network and its description constitute a potential theoretical element to analyse and to design an activity or a teaching model. Its use as a methodological tool has been proved through the analysis of two different teaching models: one from Spain (Real et al., 2013) mentioned above, and the other from Mexico (Real, 2014). Additionally its validation to design a teaching model for secondary school students in Mexico is being carried out.

Flexible mental calculation and "Zahlenblickschulung"

Charlotte Rechtsteiner-Merz[1, 2] and Elisabeth Rathgeb-Schnierer[1]

1 Pädagogische Hochschule Weingarten, Weingarten, Germany, rechtsteiner@ph-weingarten.de

2 Pädagogische Hochschule Freiburg, Institut für Mathematische Bildung Freiburg, Freiburg im Breisgau, Germany

The study focuses on the development of mental calculation of elementary students who show difficulties in learning math. In total, 20 children in 8 classes were observed during their first year at school. The math education of five classes was based on a special approach called "Zahlenblickschulung", whereas three classes experienced more regular lessons. The collected data allowed a development of a typology of flexibility in mental calculation. Additionally, it was possible to describe the development of each student. The data analysis shows that instruction with "Zahlenblickschulung" also supports less advanced students in developing flexibility in mental calculation. Another result indicates that the recognition of number patterns and numerical relationships is crucial for learning to calculate (beyond counting).

Keywords: Flexible mental calculation, less advanced students in mathematics, elementary arithmetic.

THEORETICAL FRAMEWORK

For over more than a decade, developing flexible mental calculation has been considered as an important goal in elementary school (Lorenz, 1997; Selter, 2009). Nevertheless, there is still no consensus on instructional approaches and support for less advanced students in learning calculation. The study described below focuses on the development of flexible mental calculation of less advanced students in mathematics. Thereby, we define less advanced children as those who have problems in learning mathematics and need a special support (Schipper, 2005).

Notions and related research results

Current literature offers different definitions of flexible mental calculation (Rathgeb-Schnierer & Green, 2013; Threlfall, 2009; Verschaffel, Luwel, Torbeyns, & van Dooren, 2009). Most of these definitions involve two common aspects: flexibility and adaptivity. Thereby, flexibility is commonly understood as the ability to switch between different tools of solution (Rathgeb-Schnierer & Green, 2013; Verschaffel et al., 2009), whereas adaptivity "puts more emphasis on selecting the most appropriate strategy" (Verschaffel et al., 2009, 337). What is meant by adaptivity is considered differently (Rechtsteiner-Merz, 2013; Verschaffel et al., 2009):

- adaptivity of solution methods and problem characteristics (Blöte, van der Burg, & Klein, 2001),
- adaptivity of solution methods and speed of obtaining a solution (Torbeyns, Verschaffel, & Ghesquière, 2005; Verschaffel et al., 2009),
- adaptivity of cognitive elements that underlie the solution process (Rathgeb-Schnierer & Green, 2013; Threlfall, 2002, 2009).

In this project, flexible mental calculation involves both aspects: flexibility as mentioned above and adaptivity. Referring to Rathgeb-Schnierer and Green (2013, 2015), this project is based on the assumption that the aspect of adaptivity in flexible mental calculation is related to the recognition of problem characteristics, number patterns and numerical relationships.

Number sense – structure sense – "Zahlenblick"

Our basic assumption of flexible mental calculation influences the notion of how to teach towards flexibility. If flexible mental calculation is related to problem characteristics, number patterns and numerical relationships, it is necessary to provide activities that encourage students to focus on these aspects. Therefore, the crucial aim is to develop "Zahlenblick" (Schütte, 2004; Rathgeb-Schnierer, 2006; Rechtsteiner-Merz, 2013). To describe the meaning of "Zahlenblick", it is necessary to regard the constructs number sense und structure sense.

The term number sense is connected with two different notions: as a result of experience based development or as an inherent skill.

> "With respect to its origins, some consider number sense to be part of our genetic endowment, whereas others regard it as an acquired skill set that develops with experience." (Berch, 2005, 333f.)

Regarding the construct structure sense, the notions are quite similar. Lükens' definition (2010) of early structure sense reminds us of an inherent competence, whereas Linchevski and Livneh (1999) point out the necessity of its development. "Zahlenblick" is considered a result of development and means the competence to recognize problem characteristics, number patterns and numerical relationships immediately, and to use them for solving problems (Schütte, 2004). Comparing number sense, structure sense and "Zahlenblick" it is obvious that the meaning of number and structure sense as acquired skills that can be developed by special activities is quite similar to our notion of "Zahlenblick". Since there are still discussions about the different definitions, we use the term "Zahlenblick" in the previously described sense of Schütte (see above). To support the development of "Zahlenblick", it is crucial to provide activities, which highlight problem characteristics, patterns and numerical relationships (Rechtsteiner-Merz, 2013; Schütte, 2004). Generally, these activities target the development of number concepts, understanding of operations and strategic means [1]. They encourage students to recognize number patterns, problem characteristics and relations between numbers and problems, and to sort and arrange problems by using structural relations. These activities include cognitively challenging questions to provoke students' thinking and reflection. By combining mathematical topics with challenging questions, an increase of metacognitive competences is intended (Rechtsteiner-Merz, 2013). This can be illustrated by an activity called "Problem-Family" (Figure 1): The students start with one problem, for instance 5+5=10. Then, they were asked to arrange lots of cards with related problems (e.g. 5+6, 6+6, 4+6 etc.) around the first one with the aim of making the relations visible. Subsequently, the students were encouraged to describe their arrangements, and give reasons for their decisions. This activity does not focus on solving problems, but on recognising problem features and relationships.

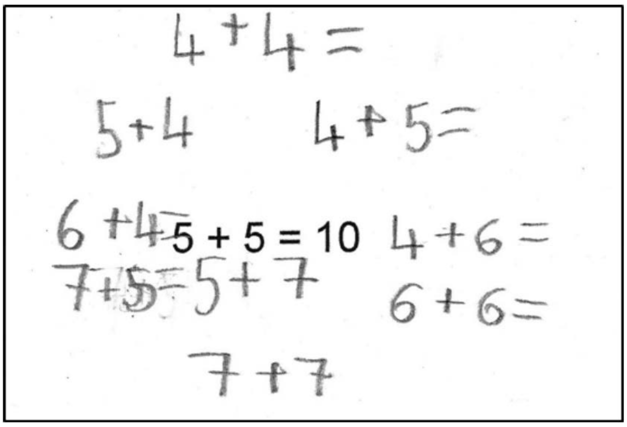

Figure 1: A "Problem-family" (Rechtsteiner-Merz, 2013, 113)

"Zahlenblickschulung" is not considered as an additional program. Rather, it can be understood as an essential principle of teaching arithmetic.

OVERVIEW OF THE PROJECT

Questions

Referring to prior research, we assume that

- "Zahlenblickschulung" is a good vehicle for developing flexible mental calculation (Rathgeb-Schnierer, 2006; Schütte, 2004) and

- not only middle and high achievers, but also less advanced students can develop flexible mental calculation (Torbeyns et al., 2005; Verschaffel et al., 2009).

These assumptions lead to the following research question: Are first graders with difficulties in learning math (numbers and operations) able to develop flexible mental calculation when educated with "Zahlenblickschulung"?

Design

Based on the theoretical notion of flexibility introduced above, a qualitative study that focuses on learning processes has been designed. The study included two parts: the instructional approach and the investigation of learning processes (Figure 1).

The investigation started with an extended period of observation to find students with problems in learn-

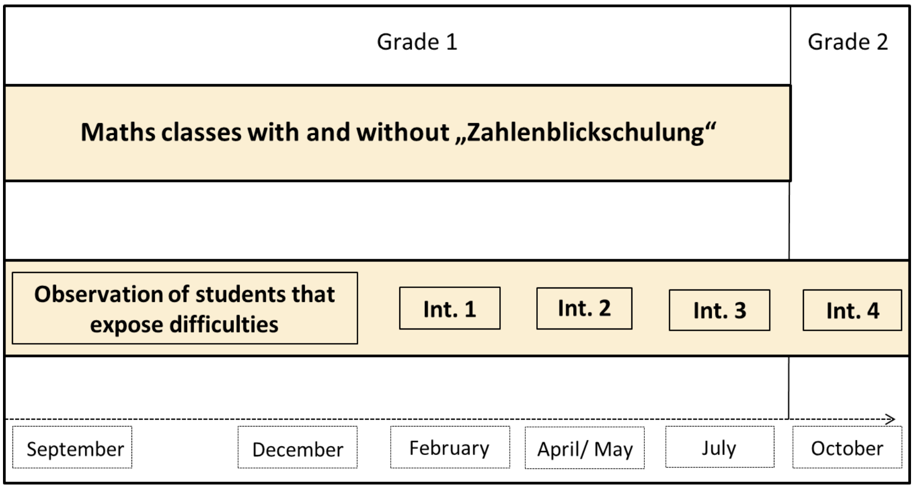

Figure 2: Design

ing numbers and operation. Therefore, two different not standardized tests were conducted with all students. Those who performed poorly were subsequently observed over a period of 6 to 8 weeks. As Schipper (2005) describes, approx. 20% of each class develops problems in learning mathematics. Based on this 20% benchmark, we decided to choose 20 students from eight different classes. Twelve students (five classes) experienced "Zahlenblickschulung" in one of four math lessons per week; eight students (three classes) had regular math classes.

From February until October 2008, each student was interviewed four times. The interviews were guideline-based, problem-orientated, and documented by videotape. Due to different moments in the academic year, each interview included different activities, except the one that was finally analysed. This special activity did not change and contained two parts: First, students were asked to sort addition problems and to talk about their reasons for sorting. Second, students were encouraged to solve the problems and to describe their solution procedures. The first three interviews included addition problems with single-digit numbers. In the last interview, several problems, up to 100, were added additionally.

Data analysis

For data analysis, interviews were transcribed. With the aim to reveal solution procedures and cognitive elements that sustain these procedures, two coding systems were designed based on the "Qualitative Inhaltsanalyse" of Mayring (2008): To classify the solution procedures, an a priori system was used. The analyses of sorting and reasoning were done with an inductively developed coding system (Rechtsteiner-Merz, 2013). Since there was a huge difference in the quality of students' reasoning, it was necessary to judge the value of arguments. Based on a theory called "Argumentationsanalyse" (analyses of arguments) (Fetzer, 2011; Toulmin, 1996) and the theory of proof (Almeida, 2001; Sowder & Harel, 1998), it was possible to judge different arguments according to the theory of flexible mental calculation (see above).

According to Kelle and Kluge (2010), types were constructed by interrelating three dimensions: (1) the amount of correct solutions, (2) the solution procedures, and (3) the reasoning for sorting and solving (Rechtsteiner-Merz, 2013). Therefore, it was necessary to build two feature spaces: First, the dimension "amount of correct solution" and the dimension "solution procedures" were combined. At this level, it was possible to construct pre-types which describe calculation in first grade. In the second step these pre-types were linked to the dimension "reasoning for sorting and solving". On this level, it was possible to develop a typology of flexible mental calculation in first grade (Figure 2).

RESULTS AND OUTLOOK

Finally, nine types could be derived from the data, four main types and five temporary types (Rechtsteiner-Merz, 2013) (Figure 3). The main types focus on a typical phase at the beginning of first grade (*counting strategies*) or on an intended phase at the end of first grade (*consistent use of procedural mastery*, *partly basic facts with relational expertise* or *basic facts extended with relational expertise*). The temporary types represent stages of developments when students learn calculating (beyond counting).

The arrangement of the types in Figure 3 must be understood as the combination of the two dimensions "counting subsumed by calculating" (horizontal dimension) and "reliance on numerical relationship in argumentation" (vertical dimension).

Subsequently, we describe the main types, followed by the temporary types: Students with *counting strategies* [2] solve each problem by counting, usually starting from the large number. Students with *consistent use of procedural mastery* are able to solve most of the problems up to twenty by calculating. Therefore, they always use the same solution procedure without noticing any problem characteristics. They argue for example "I do always like this" or "like always up to ten and then the rest". Students who exhibit *partly basic facts with relational expertise* use different strategic means by relying on problem characteristics. They are able to describe the solution process and give reasons for their strategic means in an elaborate way as the following example shows: "These problems are easy (*points to* 8+5 *and* 4+9), because here it's one less and here it's one more (*points to* 4 *and* 9)". Students who depict *basic facts extended with relational expertise* relay on basic facts with addition problems up to twenty. Additionally, they are able to solve problems with two digit numbers (higher than twenty) based on recognized characteristics and numerical relationships (even if this is not a topic in first grade). This type is special for first grade since all addition problems up to twenty can be memorized by heart.

Students who solve problems *predominantly by counting* are divided in two groups: those who *rely on procedures (temporary type 1)* and those who *rely sometimes on numerical relationships (temporary type 3)*. Students who belong to the *temporary type 1* predominantly practice counting as a rule. Sometimes, they suddenly use strategic means or number facts, although they cannot describe their approach or give a reason for it. Students who belong to the *temporary type 3* also use predominantly counting to solve addition problems, but sometimes they notice numerical relationships, and they are able to describe and reason their approach.

There are also students who solve problems *predominantly by calculating relying usually on procedures (temporary type 2)*. Based on procedures, they can solve many problems up to twenty. Exceptionally, they rely sometimes on numerical relationships when solving a problem or giving reasons for the sorting. On the other hand, there are students from the *temporary type 5* who solve problems *predominantly by*

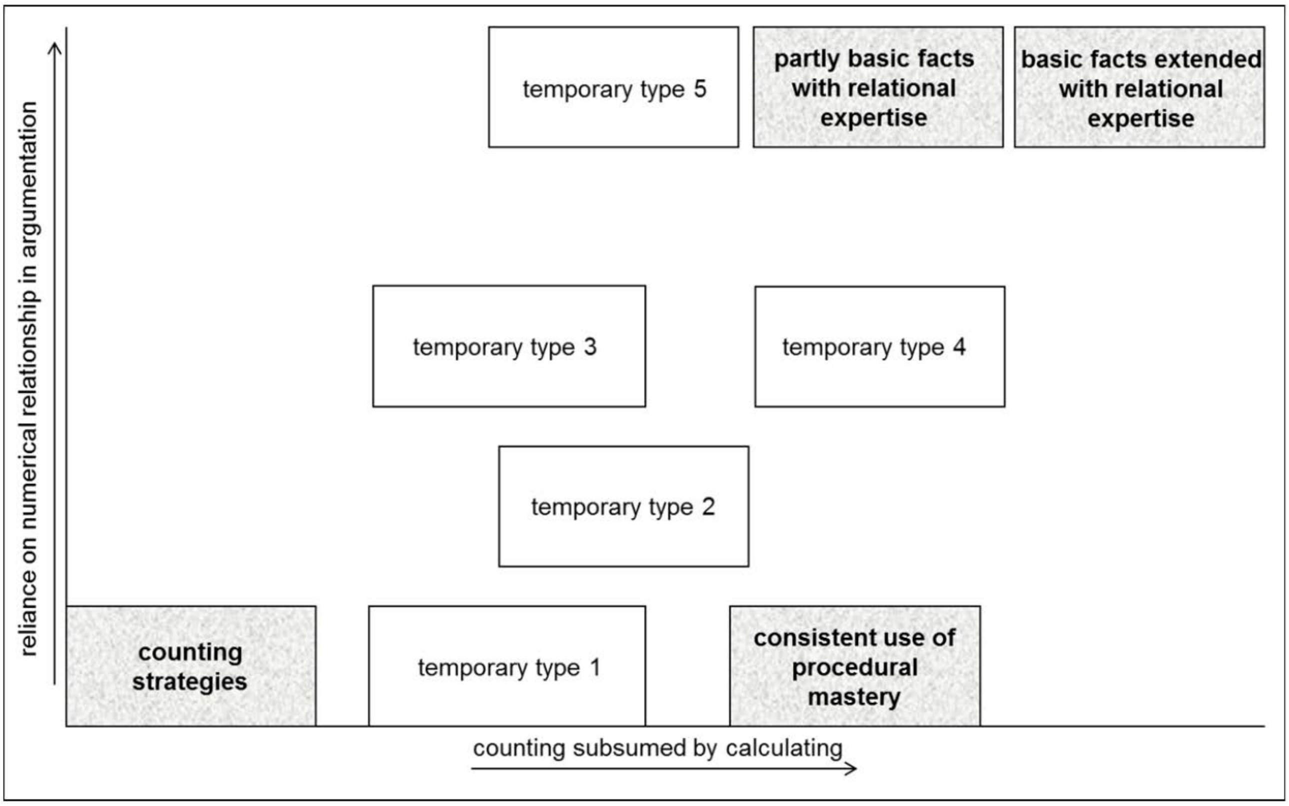

Figure 3: Typology of flexible mental calculation (Rechtsteiner-Merz, 2013)

calculating relying on numerical relationships. They are also able to solve a lot of problems up to twenty, but they recognize and use problem characteristics and numerical relationships.

Students who solve problems by *calculating relying sometimes on numerical relationships (temporary type 4)* are able to solve all the problems up to 20 by going beyond counting. Some solutions rely on procedures, others on numerical relationships. Whenever a solution is based on numerical relationships, it can be described and reasoned.

Finally, we give examples of students' development that were apparent in the timeframe from January in first grade to October in second grade.

Two students who used *counting strategies* at the beginning of second grade exhibited a *predominance of counting relying on procedures (temporary type 1)* in January. Finally, they showed a kind of regression, since their use of basic facts or strategic means were higher in the middle of first grade than at the beginning of second grade.

Four students who used *counting strategies* in January switched to the *temporary type 1* and solved problems by *predominantly counting relying on procedures* between April and July (end of first grade). After this change, no further development was obvious; it seems that they were trapped in counting.

Two students who reached the type *consistent use of procedural mastery* showed different ways of development. However, both exhibited relying on numerical relationships by calculating at least in one interview.

Five students who belong to the type *partly basic facts with relational expertise* at beginning of second grade started in January from *temporary type 1*, and solved problems *predominantly by counting relying on procedures*. They relied obviously on numerical relationships in April; some still by counting, others overcame counting. Lena, for example, solved the same number of problems predominantly by counting in January and April. But, there was a big difference in her reasoning: In January she did not recognize any problem characteristics, in April she used numerical relationships in solving and reasoning at least sometimes.

When comparing students' developments with and without math education based on "Zahlenblickschulung", some crucial differences can be described. Most students (only two exceptions) who did not experience "Zahlenblickschulung" stuck with their counting strategies based on procedures. Actually, those students did not show any progress in the second term of first grade. In contrast, all students who experienced "Zahlenblickschulung" (except Yannik) were able to overcome their counting strategies at least until the end of first grade. Additionally, all these students (except Amelie) used numerical relationships for solving problems, and they were able to reason sorting procedures in very elaborate ways.

Developed hypotheses: Conclusions

Focusing on students who have difficulties in learning addition, data analysis suggests the development of four central hypotheses:

- Relying on numerical relationships is an absolute condition for developing calculation strategies that go beyond counting.
- "Zahlenblickschulung" supports the development of conceptual knowledge.
- "Zahlenblickschulung" supports the development of flexible mental calculation.
- Activities in "Zahlenblickschulung" are a fundamental condition for developing calculation strategies and flexible mental calculation.

Subsequently, two hypotheses will be reported in detail:

Relying on numerical relationships is an absolute condition for developing calculation strategies that go beyond counting.

The knowledge of basic facts and strategic means seems to be insufficient for the development of a deep understanding of calculation that goes beyond counting. Therefore, the focus on numerical relationships and structures is essential. All students who overcame their counting strategies were able to "calculate without counting" at the beginning of second grade, and relied on numerical relationships at least in one stage of development. On the other hand, all students who were predominantly counting relying on procedures remained in this stage and could not progress. This *temporary type 1* seems to be like a dead-end road. Thus, the recognition and use of number patterns and numerical relations seems to be a crucial prerequisite for going beyond counting.

Activities in "Zahlenblickschulung" are a fundamental condition for developing calculation strategies and flexible mental calculation.

In order to develop flexible mental calculation in elementary school, Rathgeb-Schnierer (2006) and Schütte (2004) emphasized the necessity of "Zahlenblickschulung". Focusing on calculation competence of middle and high-achieving first graders, Torbeyns and colleagues (2005) showed that they are much more flexible than students who are considered as low-achieving peers. This observation indicates that middle- and high-achiever students develop a minimum of number patterns and numerical relationships for going beyond counting independently. However, students who have difficulties in learning arithmetic benefit from the "Zahlenblickschulung" approach; first to overcome counting, and second to develop an appropriate degree of flexibility in mental calculation.

The study reveals that less advanced first grade students are also able to develop competences in flexible mental calculation. Thereby, "Zahlenblickschulung" is an important and supportive vehicle. Especially for less advanced students, the recognition of number patterns and numerical relationships is the key for learning to calculate (beyond counting) and developing flexibility.

ENDNOTES

1. Strategic means are distinct devices to modify problems to them easier. They can be flexibly combined in a solution process, and include for instance composing and decomposing, modifying a problem, deriving the solution from a known fact, and using analogies (i.a., Rathgeb-Schnierer, 2006)

2. For calculating you can use different tools for solution: counting, basic facts, strategic means. Counting can be distinguished if it's with or without models and in there are counting-all or counting-on strategies used (Carpenter & Moser, 1982).

Foundational number sense: Summarising the development of an analytical framework

Judy Sayers and Paul Andrews

Stockholm University, Stockholm, Sweden, judy.sayers@mnd.su.se, paul.andrews@mnd.su.se

What number-related competences do grade one students need to ensure later success and avoid later failure? We address this question by summarising recent work on the development of an eight component framework, which we call foundational number sense (FoNS), in which those necessary learning outcomes are categorised. We then present summaries of three case studies undertaken to evaluate the robustness of the FoNS framework. Each case study, which focused on the teaching of a different mathematical topic, was undertaken in two different European grade one classrooms. Analyses confirm not only the sensitivity of the FoNS framework to both cultural and mathematical contexts but also its power as a tool for both cross cultural research and teacher education practices.

Keywords: Foundational Number Sense, grade one, teaching framework.

INTRODUCTION

The influence of a child's basic number understanding in later mathematical successes (Aubrey & Godfrey, 2003; Aunola et al., 2004) and failures (Geary, 2013; Gersten et al., 2012) is well known internationally. Consequently, it would seem sensible for researchers and teachers to be clear as to what such basic understandings entail. In this paper, focusing on the first year of schooling and from an international perspective, we do two things. Firstly, we summarise the competences research has shown will both avoid later difficulties and ensure later success in an eight component framework. Secondly, we summarise three recent case studies, each of which evaluates the framework's analytical efficacy by comparing specific topic-related practices of teachers from two different European countries.

DEVELOPING THE FRAMEWORK

In relation to the role of children's basic number understanding in their later mathematical development, the expression *number sense* dominates the literature. However, despite its ubiquity its definition has been elusive (Griffin, 2004). Indeed, despite its importance, "no two researchers have defined number sense in precisely the same fashion" (Gersten et al., 2005, p. 296). Our reading indicates that this has, in no small way, been due to psychologists and educators working with different conceptualisations (Berch, 2005), a problem exacerbated by psychologists employing different definitions according to whether they work in general cognition or learning disabilities. That said, our reading reveals three distinct but related perspectives on number sense, which we label *preverbal, applied* and *foundational*.

Preverbal number sense reflects those number insights innate to all humans and comprises an understanding of small quantities that allows for comparison (Ivrendi, 2011; Lipton & Spelke, 2005). For example, young babies can discern 1:2 but not 2:3 ratios (Feigenson et al., 2004). This, numerical discrimination is independent of formal instruction and develops as a consequence of human, and other species' evolution (Dehaene, 2001; Feigenson et al., 2004). *Applied number sense* concerns those number competences related to arithmetical flexibility that prepare learners for an adult world (McIntosh et al., 1992). *Foundational number sense* (FoNS) comprises those understandings that precede *applied*, typically arise during the first year of school and require instruction (Ivrendi, 2011; Jordan & Levine, 2009). Unlike preverbal number sense, it is a "construct that children acquire or attain, rather than simply possess" (Robinson et al. 2002, p. 85). Unlike applied number sense, it does facilitate a world beyond school but later arithmetical competence. FoNS is to the development of mathematical competence what phonic awareness is to reading (Gersten & Chard, 1999).

Below we summarise the key components of FoNS. Our intention was not to offer an extensive list of learning outcomes, as found in Berch (2005) or Howell and Kemp (2006), but a concise conceptualisation that would support a range of activities, including developments in curriculum, teacher education or assessment, as well as cross-cultural classroom analyses. To achieve these objectives we exploited the constant comparison analysis advocated by grounded theorists, a process we describe in full in Andrews and Sayers (2015).

In brief, research papers typically addressing grade one students' acquisition of number-related competence were identified. These were read and FoNS-related categories identified. With each new category, previous articles were re-examined for evidence of the new. This approach, drawing on literature from psychology, mathematics education, learning difficulties and generic education, placed, for example, *rote counting to five* and *rote counting to ten*, two narrow categories discussed by Howell and Kemp (2005), within the same broad category of systematic counting.

Number recognition: Children recognise number symbols and know their vocabulary and meaning. They can identify a particular number symbol from a collection of number symbols and name a number when shown that symbol;

Systematic counting: Children count systematically and understand ordinality and cardinality. They count to twenty and back, or count upwards and backwards from arbitrary starting points, knowing that each number occupies a fixed position in the sequence of all numbers.

Awareness of the relationship between number and quantity: Children understand not only the one-to-one correspondence between a number's name and the quantity it represents but also that the last number in a count represents the total number of objects.

Quantity discrimination: Children understand magnitude and can compare different magnitudes. They use language like bigger than or smaller than. They know that eight represents a quantity that is bigger than six but smaller than ten.

An understanding of different representations of number: Children understand that numbers can be represented differently, including the number line, different partitions, various manipulatives and fingers.

Estimation: Children can estimate, whether it be the size of a set or an object. Estimation involves moving between representations of number; for example, placing a number on an empty number line.

Simple arithmetic competence: Children perform simple arithmetical operations, which Jordan and Levine (2009) describe as the transformation of small sets through addition and subtraction.

Awareness of number patterns: Children extend and are able to identify a missing number in simple number sequences.

In sum, our systematic review identified eight distinct and not unrelated FoNS components. The fact that they are not unrelated is important as number sense "relies on many links among mathematical relationships, mathematical principles..., and mathematical procedures" (Gersten et al., 2005, p. 297). In other words, without the encouragement of such links children may be able to count but not understand that four is less than six.

EVALUATING THE FRAMEWORK'S EFFICACY

Having derived an eight component FoNS-related entitlement for grade one students, our purpose was to evaluate the framework's efficacy for identifying FoNS-related opportunities in different cultural contexts. Such a process facilitates both instrument refinement and an evaluation of its sensitivity to cultural nuances. In the following we summarise three recently reported case studies in which we evaluated the efficacy of the FoNS framework. The first examined the teaching of sequences in England and Hungary (Back et al., 2014), the second the development of students' conceptual subitising in Hungary and Sweden (Sayers et al., 2014) and the third focused on teachers' use of the number line in Poland and Russia (Andrews et al., 2015).

Each examined lesson, typically drawn from video-based teacher professional development programmes independent of not only the research presented here but also each other, involved a teacher construed against local criteria as effective. Thus, no lesson was captured with a FoNS-related analysis in mind. Two lessons were identified from those available for topic-based case studies. Such an approach, drawing on data intended for purposes other than a FoNS analysis, made these lessons ideal for evaluating the framework's capacity for identifying topic-related, but essentially incidental, FoNS-related occurrences. In all cases teachers had been video-recorded in ways that would optimise the capture of their actions and utterances. Each video, with transcripts, was repeatedly scrutinised for evidence of FoNS components by two researchers independently. These analyses were then compared and agreements reached with respect to which FoNS-related components were being encouraged at different times. Significantly, such an approach allowed lesson episodes to be multiply-coded according to which components were observed.

As data derived from different projects in five different countries, ethical procedures were managed according to local norms. In all countries permission from school principals and participating teachers was obtained by means of letters confirming the right of teachers to withdraw without notice or reason and anonymity. With respect to the Hungarian, Polish and Russian students, all parents, at the point at which their children entered their school, had signed to agree their child's participation in ethically conducted classroom based research. In England and Sweden, parental permission letters explained the projects and, alongside the promise of minimal classroom disruption, guaranteed the same protective principles as above.

RESULTS

In the following we do two things. Firstly, we summarise qualitatively the pilot studies introduced above. Space prevents detailed summaries but we believe that sufficient has been included to demonstrate the FoNS framework's sensitivity to both cultural and mathematical context. Secondly, acknowledging the limitations of case study, we present a simple, frequency-based, quantitative analysis to highlight not only how FoNS-related learning was managed but also interesting similarities and differences in the ways the various codes interact in the case study episodes. In so doing we show how the FoNS framework can facilitate the sorts of complex analyses discussed above in relation to our earlier European study of mathematics teaching.

The qualitative analyses

In the first study (Back et al., 2014) episodes focused on number sequences were analysed. In addition to examining the functionality of the FoNS framework an aim was to examine how teaching, focused explicitly on one FoNS component, would yield other components. The analyses, based on three episodes from each lesson sequence, indicated that Klara in Hungary addressed six of the eight FoNS components while Sarah in England addressed four. Both encouraged, throughout their respective episodes, students' recognition of number symbols, vocabulary and meaning. Both encouraged the awareness of number patterns and the identification of missing numbers and both exploited simple arithmetical operations, typically to facilitate finding the next values in a sequence. In respect of differences Klara addressed three categories, the relationship between numbers and quantities, comparisons of magnitude and different representations of number that Sarah did not, while Sarah was seen to address systematic counting when Klara did not.

However, while both teachers encouraged various FoNS components, Klara's teaching was more didactically complex, with an average of four components per episode, than Sarah's, with an average of barely two. Moreover, Klara's practice resonated with earlier research highlighting the cognitively demanding but coherent learning outcomes of Hungarian classrooms, while Sarah's reflected the relatively unsophisticated promotion of modest and less coherent goals of her English colleagues.

In the second study (Sayers et al., 2014), analyses focused on conceptual subitising in grade one lesson sequences taught by Klara, again, in Hungary, and Kerstin, in Sweden. Conceptual subitising, the ways in which individuals identify large quantities through identifying smaller quantities that comprise the whole, has been promoted as a key component of early number learning. In both cases, an average of five FoNS components were identified in each of the teacher's three analysed episodes, indicating that claims for the efficacy of teaching focused on conceptual subitising are not without warrant.

It was interesting that in neither case was conceptual subitising an explicit intention, nor were teachers expecting to address FoNS categories of learning. It is also interesting to note that despite substantial differences in the management of their lessons - Klara spent all her lesson orchestrating whole class activity with only occasional expectations of students working individually, while Kerstin spent the great majority of her time managing and supporting students working in pairs - the FoNS components addressed in their respective excerpts were remarkably similar.

Finally, the third pilot study (Andrews et al., 2015) examined episodes drawn from lesson sequences focused on the introduction and exploitation of the number line taught by Olga, in Russia, and Maria, in Poland. Here the analyses, as in the first case study, showed that such a didactical emphasis on one FoNS component does not necessarily restrict opportunities for other FoNS outcomes. For example, Olga's episodes addressed an average of almost five components, while Maria's almost four. Not surprisingly, bearing in mind the number line emphasis, all analysed episodes addressed number recognition and systematic counting, while all bar one showed evidence of children being asked to work with a different representation of number.

With respect to differences, whenever Olga asked her students to represent a number on the number line, she insisted on their pointing simultaneously to zero with their left hand and the desired number with their right. In this manner her teaching focused on the relationship between number and quantity. By way of contrast, Maria presented simultaneously three distinct number lines, each showing zero to eight but with different sized intervals. In so doing she highlighted the arbitrary size of the interval alongside the need for a consistent interval size. Both teachers also used the number line to facilitate simple arithmetical operations, including tasks involving several operations simultaneously. Finally, Maria used the number line in relation to number patterns, particularly even numbers and the identification of missing numbers. Interestingly, key differences were also found in Maria's frequent use of number line representations drawn from the real world, thermometers, measuring tapes, measuring jugs and so on, something that Olga did not do.

The quantitative analysis

It is important to remember that when teaching their respective classes, none of the case study teachers were focusing explicitly on FoNS-related learning opportunities. Moreover, despite the quality of instruction focused on it, neither Kerstin nor Klara were explicitly aware of conceptual subitising as a learning goal. In other words, all project teachers, in varying degrees and in varying ways, addressed a range of FoNS-related learning outcomes in incidental rather than planned ways. The extent to which these varying ways played out can be seen in Table 1. This shows a summary of the codes applied to each analysed episode. In addition, the mean number of codes calculated for each teacher's three episodes is included alongside the teacher's name. Finally, the table shows the total number of occurrences for each FoNS component.

At a very crude level, one could argue that the mean number of categories applied to a teacher's episodes could be construed as a measure of didactical complexity. For example, Sarah's number patterns-related practice, as reflected in a mean of 2.3 categories per episode, seemed considerably lower than that of her colleagues. In this respect, the next lowest mean, Maria's 3.7, was almost one and a half categories per episode more. Thus, Sara's practice seemed to lack the didactical complexity typically found in her colleagues' episodes. However, the more interesting differences, it could be argued, emerged at the level of the topic. Notwithstanding Sarah's low didactical complexity in relation to Klara when teaching number patterns, Olga's episodes, with respect to the number line, appeared more didactically complex than Maria's, particularly in the former's repeated opportunities for her students to explore the relationship between number and quantity. With respect to conceptual subitising such differences were minor, although it could be argued that Klara paid much more attention to systematic counting than did Kerstin. However, such conclusions remain tentative, although they allude to the sensitivity of the FoNS framework to culturally-located differences.

It is also interesting to note that the topics themselves seemed to invoke different levels of complexity. Admittedly, such distinctions are crude, but are supported by the fact that Klara was involved in both the highest and lowest topic means. As can be seen from the topic means in Table 1, episodes focused on number patterns invoked, in general terms, relatively few FoNS categories, while those focused on conceptual subitising the most. Indeed, the data suggest that some topics have a greater propensity for teachers to address a range of FoNS-related learning possibilities. However, such conclusions, while tentative, tend to confirm the sensitivity of the FoNS framework to topical differences.

Finally, with respect to this particular analysis, Table 1 highlights the relative paucity of opportunities for students to engage in quantity discrimination and the complete absence of encouragement to estimate. While it could be argued that such FoNS categories may not be suited to the three topics examined here, the fact that Klara managed to invoke quantity discrimination in two of her three number sequence-related episodes may suggest otherwise. Also, the complete lack of invitation to estimate may say something different about how teachers construe mathematics as a precise rather than imprecise discipline, not least because it is not difficult to imagine a teacher asking students to estimate, say, the twentieth member of a sequence or where a given number would be placed on an empty number line.

DISCUSSION

Our aim was to introduce and summarise recent work on the development of foundational number sense (FoNS). Our uncovering of three forms of number sense has gone a long way with respect to the problem of definition. Our atypical use of constant comparison has facilitated the development of an eight component FoNS framework that we have shown to be functional in different cultural contexts and with

			FoNS categories							
	Topic and mean	Episode	Number symbols, vocabulary and meaning	Systematic counting	Relationships between numbers and quantities	Quantity discrimination	Different representations of number	Estimation	Simple arithmetical operations	Number patterns and missing numbers
Sarah (2.3)	Number patterns (3.2)	1	X							X
		2	X						X	X
		3	X	X						
Klara (4.0)		1	X						X	X
		2	X		X	X	X		X	X
		3	X			X	X			
Olga (4.7)	Number line (4.2)	1	X	X	X		X			
		2	X	X	X		X		X	
		3	X	X	X		X		X	
Maria (3.7)		1	X	X			X			
		2	X	X			X			X
		3	X	X			X		X	
Kerstin (4.7)	Subitising (4.8)	1			X		X		X	X
		2	X	X	X		X		X	
		3	X		X		X		X	X
Klara (5.0)		1		X	X		X		X	X
		2		X	X		X		X	X
		3	X	X	X		X		X	
Totals			15	11	10	2	14	0	12	9

Table 1: Codes applied to each episode with summary statistics

different mathematical topics. Importantly, the case studies show that different teachers, while attending to similar core topic-related outcomes, also privilege different things. For example, Olga and Maria, in their number line-related teaching, encouraged several similar outcomes, although Olga focused attention on the relationship between number and quantity while Maria emphasised real world representations of the number line. In similar vein, when working on number patterns, Klara addressed almost twice as many FoNS-related outcomes as Sarah, confirming earlier research about the relative didactical complexity of Hungarian and English mathematics teaching. The analyses also show that the three topics failed to yield any episodes in which teachers encouraged their students to estimate, a key predictor of later arithmetical competence (Booth & Siegler, 2006), while only two, identified during Klara's teaching of number patterns, alluded to quantity discrimination, also a key predictor of later competence (Titeca et al., 2014).

In closing we speculate a little and suggest that the FoNS framework has the potential to inform the practices of teacher education for elementary teachers; its simple structure makes it a suitable starting point for students' professional learning, particularly from the perspective of practicum-related planning and teaching. It can also be used as a simple assessment tool for provoking post lesson discussion.

Additive adaptive thinking in 1st and 2nd grades pupils

Lurdes Serrazina and Margarida Rodrigues

Instituto Politécnico de Lisboa, UIDEF, Escola Superior de Educação, Lisboa, Portugal, lurdess@eselx.ipl.pt

This paper is part of the Project "Adaptive thinking and flexible computation: Critical issues". It discusses what is meant by adaptive thinking and presents the results of individual interviews with four pupils. The main goal of the study is to understand pupils' reasoning when solving numerical tasks involving additive situations, and identify features associated with adaptive thinking. The results show that, in the case of first grade pupils, the semantic aspects of the problem are involved in its resolution and the pupils' performance appears to be related to the development of number sense. The 2nd grade pupils seem to see the quantitative difference as an invariant numerical relationship.

Keywords: Adaptive thinking, numerical relationships, quantitative difference.

INTRODUCTION

This paper is part of the Project "Adaptive thinking and flexible computation: Critical issues" being developed by the Schools of Education of Lisbon, Setúbal and Portalegre that has two main focus: (a) to characterize the development of pupils' numerical thinking and flexibility in mental calculation from 5 to 12 years, and (b) to describe teachers' practices that facilitate that development.

In this paper we will discuss different perspectives on adaptive thinking and flexible calculation with regard to addition and subtraction in the literature, and present preliminary findings obtained by conducting individual clinical interviews with four pupils (two from first grade and two from second grade). We intend to understand pupils' reasoning when solving numerical tasks involving additive situations, and identify aspects related to adaptive thinking. Besides this goal, the interviews were also conducted to test tasks to later implement a teaching experiment.

THEORETHICAL FRAMEWORK

In the last decade, flexible calculation has been considered an ability that all pupils should develop in elementary school (Anghileri, 2001). Being proficient in mathematics implies the ability to use the knowledge in a flexible way and apply in an appropriate way what is learned in a situation to another (NCTM, 2000).

The flexible idea appears associated to mental calculation and arithmetic problem solving. There are different ways of solving an arithmetic problem mentally, usually mentioned as strategies. Strategic flexibility in mental calculation refers to the way as the problem is affected by circumstances to be solved (Threlfall, 2009). These circumstances may be related with specific features of the tasks or with individual characteristics or contextual variables. Threlfall (2009) refers to the mechanism behind calculation-strategy-flexibility as *zeroing-in*, still referring that it is not a fully conscious and rational process, involving partial exploratory calculations arising from noticing specific features of the numbers involved and their respective relationships. "The calculation-strategy is not selected and applied, it is arrived to" (Threlfall, 2009, p. 548). In a different perspective, Star and Newton (2009) define flexibility as knowing multiple solutions as well as the capacity and tendency to choose the most appropriated for a given problem and a particular objective of problem solving. These authors also stated that flexibility exists at a continuum; when the pupils gain flexibility they may first show a greater knowledge of multiple strategies, then particular preferences, and finally, the appropriate use of the preferred strategy. The 'appropriate' term refers to the more effective strategy: one which requires the least number of intermediate calculation steps to arrive at the result. Other authors (Baroody & Rosu, 2006; Rathgeb-Schnierer & Green, 2013) reported that flexibility in calculation is related to the fact that children discover patterns and relations, as they develop number sense, thus building a network of relationships. For example, pupils who recognize the commutative property of addition, given the need to calculate 3 + 9, know they can do 9 + 3. The way this property is mobilized, revealing or not the contextual aspects of the tasks, can vary depending on the age of the children. In this regard, several authors (De Corte & Verschaffel, 1987; Greer, 2012) report that the semantic aspects of the tasks influence how young children solve them. Pupils who understand the various compositions of a number in different parts (for example, 1 + 7, 2 + 6, 3 + 5, and 4 + 4 = 8…) and decompositions (e.g., 8 = 1 + 7, 2 + 6, 3 + 5, 4 + 4) are more likely to develop ways of thinking as "doubles +1" (e.g., 7 + 8 = 7 + 7 + 1 = 14 + 1) or making a "ten" (9 + 7 = 9 + 1 + 6 = 10+6). As the network of relationships is being built, children acquire the flexibility to use these relationships in concrete situations of calculation, which depends on their knowledge of numbers and operations (Rathgeb-Schnierer & Green, 2013).

In our perspective, adaptive thinking refers to a thinking that can be flexibly adapted to new as well as familiar tasks. Its focus is not on calculation-strategy, but on quantitative reasoning. Children can mechanically use learned strategies without considering the context or the numbers involved in the task (Brocardo, 2014) and in this sense, they can compute accurately without flexibility. The flexible calculation and the additive quantitative reasoning are two dimensions that are interrelated to each other. Because the quantitative reasoning focuses on the description and modeling of situations and comparative relationships involved (Thompson, 1993), it ultimately underlies the development of flexible calculation as a calculation that mobilizes numerical relationships, in an intelligent and adaptive way to situations and numbers themselves. So the adaptive thinking involves the development of a flexible and relational understanding enabling the pupils to produce new known facts from old ones.

The quantitative reasoning involves reasoning about relationships between quantities. It "is the analysis of a situation into a quantitative structure — a network of quantities and quantitative relationships" (Thompson, 1993, p. 165). What matters are the relationships between quantities and not the numbers and number relations. In this regard, this kind of reasoning approaches the algebraic reasoning. To clarify the distinction between quantity and number, Thompson (1993) connects the idea of measure to the notion of quantity, although this is not only applicable to continuous measurable quantities, and the reasoning does not depend on their measures. It is important to develop research in children's abilities to deal with complexity in situations. A relationally complex situation involves at least six quantities and three quantitative operations. Comparing two quantities to find the excess of one relative to the other is a quantitative operation. The result of the quantitative operation of comparing two quantities additively is the excess found, that is to say, the *quantitative difference*. The author stresses also the distinction between the concepts of numerical difference, as the result of subtracting, and quantitative difference. On the one hand, a quantitative difference is not always evaluated by subtraction and on the other hand, subtraction can be used to compute quantities that are not quantitative differences. The results of the teaching experiment held with 5th-grade children referred in Thompson (1993) show that these children (i) did not distinguish the quantitative and the arithmetical operations, and (ii) had trouble with two aspects of the concept of quantitative difference, namely the difference as an additive comparison of quantities and when they conceived the quantitative difference as an invariant numerical relationship as they assumed the relative change as an absolute amount and needed to know absolute values before they could make comparisons.

The additive comparison is closely linked to inverse reasoning, involving the mobilization of reversible thought. According to Greer (2012), the inversion is of central importance to the arithmetic of natural numbers and the four basic operations involving these numbers, with important implications in relation to flexible computation. Regarding comparison problems, the author draws attention to the fact that the inverse relationship relates the difference between A and B to the complementary difference between B and A, which is "quite a different conception" (p. 434). So, although this author refers to the inverse relationship between addition and subtraction and the quantitative reasoning involves additive quantitative operations that are distinct of these arithmetic operations, we can consider that the inversion is an intrinsically topic underlying the quantitative reasoning.

METHODOLOGY

This study follows a qualitative approach within an interpretive paradigm. It aims describing and interpreting an educational phenomenon (Erickson, 1986). Data collection for this paper was done through clinical interviews (Hunting, 1997). It is a technique that is directed by the researcher and seeks a description of the ways of thinking of respondents.

Individual interviews were conducted in January 2014 by the authors of this paper, both members of the research team of the Project. The four pupils were attending for the first time the respective grades and were selected by their teachers. The selection criterions were: (i) pupils that usually express what they think, and (ii) pupils with reasonable performance in Mathematics. For the ethical principle of confidentiality, we use fictitious names for the children interviewed. The interviews were audiotaped and occurred in a room outside pupils' classrooms and had lasting less than 30 minutes. We also used the observation technique in the course of interviews, recording after its end the children's performance observed in field notes.

Each pupil solved three/four tasks but not all solved the same tasks. The task *boxes with balls*, inspired by Cobb, Boufi, McClain and Whitenack (1997) (Figure 1), was proposed to two first graders (Ana and Rui) and two second graders (João and Diogo).

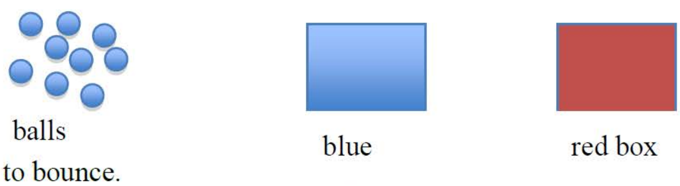
The task *game of marbles,* adapted from Thompson (1993) (Figure 2), was only solved by João of 2nd grade.

Because the limited size of the paper we do not present all five tasks proposed in the interview. We chose these two tasks for the paper because they have relevant features to reveal adaptive thinking. The task *boxes with balls* was chosen because it reveals the children's thinking about flexible partitioning (e.g., a collection of 9 items conceptualized in imagination as: five and four, three and six, etc.). It is embedded in a fairytale context with the purpose of captivating young children and appealing to their imaginary world in which inanimate objects (such as balls) come to life and jump from one box to another, without human interference. The idea of movement (change of state) was central for the task design. So, consideration of the dynamic part of that movement will induce the pupils to explore different possibilities of decomposition of 9, since the balls are not distributed statically into two boxes but continue to jump from one box to the other, varying in number at each moment. The existence of two and no more boxes relates to the fact that it is desired to induce the representation of 9 into two groups, facilitating the development of the additive structure of **N** and the obtaining of certainty of the totality of solutions by the use of some organization in the disposition of them. For instance, in this scheme, we can see a structure of increasing and decreasing sequences and a central symmetry that support the exhaustion of splittings (Freudhental, 1983):

$$9 = + \frac{9}{0}\ \frac{8}{1}\ \frac{7}{2}\ \frac{6}{3}\ \frac{5}{4}\ \frac{4}{5}\ \frac{3}{6}\ \frac{2}{7}\ \frac{1}{8}\ \frac{0}{9}$$

The other task was chosen because it aims to emphasize the notion of quantitative difference as signifi-

Once upon a time two boxes, one blue and one red, and 9 magical bouncy balls that spent their lives jumping from one box to another.



The balls will continue to bounce.
Imagine the different ways that we can see all nine balls in the two boxes.

Figure 1: Task *boxes with balls*

Ana, Luís and André played two games of marbles together.
Ana won 3 marbles from Luís and 7 marbles from André.
Luís won 4 marbles from André and 9 marbles from Ana.
André did not win marbles.
a) What is the least number of marbles that André had at the beginning of the games?
b) Compare the number of Luís's marbles before and after these two games.

Figure 2: Task *game of marbles*

cantly independent of the knowledge of the values of the additive and subtractive. It reveals the children's ability to reason inversely and to distinguish between quantitative difference and the absolute value. This is a fundamental aspect in flexible calculation.

Based on our adopted approach to flexible calculation and adaptive thinking in which we integrate the theoretical framework of Threlfall (2009) and Thompson (1993) that is presented in the previous section, the data were analyzed trying to understand how the children were able to establish a network of connections through their reasoning about different representations of the numbers, and about relationships between numbers and quantities. The analytical categories built from the theoretical framework and inductively emerged from the data focused on pupils' process of solving the tasks: applied relationships (relating the numbers, relating the operations, using the inverse relationship, comparing quantities); applied properties of addition (exhausting all possibilities).

SOME EMPIRICAL RESULTS

Addition and subtraction: From concrete to abstract thinking

In the task *boxes with balls* the collection of balls represented in the sheet of paper remained visible throughout the interview so that each child might be able to propose various ways in which the balls could be in the boxes. A sheet of paper with two drawn boxes was available for the pupils.

Once the first grade pupils had trouble with reading, the researcher read the task to be sure that there were not problems of understanding. Ana answered immediately:

Ana: 5 + 4

Researcher: And other ways?

Ana wrote immediately on the paper: 2+7, 7+2, 8+1, 1+8, 4+5, 3+6, 6+3.

After these records, Ana added there could still be 9 + 0. When questioned if it would be needed to write 2 + 7 and 7 + 2, Ana replied: "It gives the same, but it is not the same. Here [*pointing to the firs box*] there are 2 and there 7 [*pointing to the second box*] and here [7 + 2] is the opposite."

It seems that Ana thought about the concrete balls, and looked at the sums as ordered pairs of numbers.

In the case of Rui, after registering 5 + 4, the sequence of registration was: 4+5, 6+3, 3+6, 8+1, 1+8, 9+0.

After a moment, Rui wrote on the paper: 7+2 and 2+7.

Rui also responded to the question whether or not 6 + 3 is the same as 3 + 6: "It is. Only that is unlike."

Both children, Ana and Rui, represented first the situation of 5+4. Both pupils were able to visualize all decompositions of 9 thinking about the real situation — boxes and balls, although they did not need to draw them in the boxes. So, it seems that both thought about ordered pairs of numbers, trying to write all the pairs, using their different images of 9. Both seem to identify the commutative property because they wrote commutative pairs of numbers in a consistent way. Rui, after having written 5+4 and 4+5, he wrote 6+3, 3+6, using the increase/decrease 1 property. The same seems to happen with Ana, when she wrote 8+1, 1+8 following 2+7, 7+2.

In case of the two second grade pupils, João wrote "4+5, 3+6, 2+7, 1+8" and then stopped. Asked if there were more chances, João replied: "No, because I could change the order of numbers, but it would be the same thing, the sum is the same." Diogo wrote on the paper: 5 + 4, 6 + 3, 8 + 1, 7 + 2.

When the researcher asked if he already had written all the possibilities, he said: "Yes. If I change, its sum is the same, 9".

Both second graders made all possible non-empty decompositions of 9, not having considered the possibility of 9 + 0 (or 0 + 9). It should be noted that João used the increase/decrease 1 property to write all the decompositions, while Diogo appeared to start in that way, but changed his strategy when wrote 8+1 after 6+3 (increase/decrease 2?) and then seems to come back to the first one. But they did not express their ways of thinking.

These pupils seem to be able to think about the numbers abstracting from real situations. More, it appears that they have already understood the commutative property of addition.

Thus, we see that the consideration of the contextual situation was taken over by first graders but not by second graders who ignored the fact that the parcels play different roles in the proposed situation. The first grade pupils understand the concrete situation, and their thoughts are close to real situations since they considered ordered pairs of numbers. Instead, the second graders overcame the concrete situation.

Quantitative difference

In the task *game of marbles,* João used a tabulated registration. He began to register the total wins of marbles for each player: "+10"; "+13"; "+0". After, he put the total losses for each player by reading the sentences allusive to the wins: "-9"; "-3"; "-11". For that, he mobilized an inverse reasoning, understanding that the number of marbles won from someone is the number of marbles that someone had lost. His resolution can be seen in Figure 3.

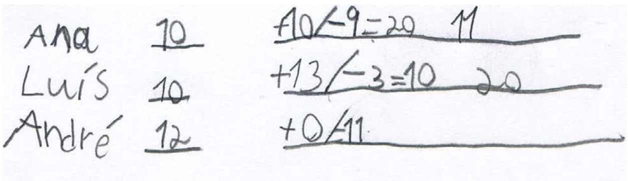


Figure 3: João's resolution of the task *game of marbles*

Then he focused on the item a) of the task, considering that André would have the minimum number of 12 marbles at the beginning of the games to have lost 11. He raised other hypotheses for this initial number like 20 or 30.

Researcher: And less than 12, no?

João: No, he had to have marbles.

This question focuses the absolute quantity of marbles. João held various hypotheses for the number of marbles of André before the games, all above 11, but assumed that at least André would have had 12 marbles. Probably, he did not equate the hypothesis of 11 marbles for having discarded the possibility of André having no marbles at the end of the games.

After, João did the balance of wins and losses of Luís's marbles, concluding that Luís would have 10 marbles more at the end of the games and recorded "=10" ("+13/-3=10"). In the trace corresponding to the beginning of the games, João wrote "10".

João: [At the end] Luís got ten more (...).

Researcher: At the beginning, did Luís have 10 or 10 more?

João: He had ten marbles.

João wrote "20" in the final of Luís's line corresponding to the total number of Luís's marbles at the end of the games. Next, the researcher guided João to the case of Ana:

Researcher: And Ana? She won ten and lost nine. After all, did she have more or less marbles at the end of the game?

João: Less. Before, she had ten marbles.

Researcher: If she started the games with ten marbles, won 10, with how many would she have at the end?

João: Twenty.

Researcher: And then she lost nine...

João: She had eleven.

João failed to make the balance between wins and losses of Ana's marbles, and concluded that Ana would have less marbles without mentioning how many. He wrote "10" in the trace corresponding to the beginning of the games. After, he registered "=20" ("+10/-9=20") as the number of Ana's marbles after 10 marbles won in the two games, and finally recorded "11" after losses, corresponding to the total number of Ana's marbles at the end of the games. João did not confront this final record with his previous statement ("Less") or verbalized that Ana had one more marble at the end of the games.

The critical issue inherent to this task is the distinction between quantitative difference and the absolute value. João did not make confusion between one thing and another, distinguishing the relative change (plus 10) from the absolute amount (20) in the second trace of the Luís's line, allusive to the end of the games. However he was not able to express the quantitative difference for the start of the two games (minus 10), needing to put absolute numbers for each player. João used the same equal symbol in the lines of Ana and Luís ("=20"; "=10"), but he attributed different meanings to the numbers: in the case of Ana, 20 is the absolute amount; in the case of Luís, 10 is the quantitative difference, that is to say, it is the result of relative change — the amount by which one quantity fell short or exceeded of another. The need to refer to the absolute amount — the concrete number of marbles — is also evident in the way João determines the absolute value of the number of marbles of Ana and Luís at the end of the games ("11"; "20").

FINAL REMARKS

In the task *boxes with balls* pupils established different decompositions of the number 9 using their network of connections to have 9 based on properties of addition or making a direct subtraction and realizing that, for instance, by taking 4 from 9 they get 5. In both situations, pupils dealt with the operations addition and subtraction as being intrinsically inverse to one another (Greer, 2012). The quantity of nine balls can be symbolized by the number nine (Thompson, 1993) expressed by different sums representing the partition of a collection of objects or the decomposition of the number nine. The results show that all pupils dealt with the number, and not properly with the quantity. They did not divide the set of balls. Although the collection of balls represented in the sheet of paper remained visible, the pupils ignored them, thinking in a higher level about the number 9 conceptualized in imagination as sums representing its decompositions. For that, they seem to understand the relationships between those sums.

Although all the pupils started with the numbers 4 and 5 (or 5 and 4) adopting the approach of double through the decomposition of 9 into almost equal groups, the first and second graders solved the first task in different ways. Even though, first grade pupils did not need to materialize the situation with manipulatives or drawings, they solved the task very close to its context. We suspect that they were sure that they had generated all the possibilities because they applied some organization in the generation of the pairs of numbers writing consistently commutative pairs. So they looked for ordered pairs of numbers that together make 9. Instead, the second graders disengaged from the concrete situation, and only considered the fact that they had to obtain 9 from a sum. João did it systematically (increase/decrease 1) while Diogo did not do it for all decompositions. As they already know the commutative property (though not in a formal way) they applied it to justify that they found all the cases. So, they solved the problem in mathematics terms but not the actual proposed problem, where it should be considered the two different boxes and, in this perspective, it is not the same to have the balls in the red box or in the blue box. All the pupils already seem to understand the commutative property, but use it in a different way: the first graders use it to exhaust all possibilities through the symmetry of ordered commutative pairs of numbers (Ana: "It gives the same but it is not the same"), and the second graders use it not to present the commutative pairs, whereas the symmetrical parts would be the same (Diogo: "If I change, its sum is the same 9"). De Corte and Verschaffel (1987) stress that younger children are more influenced by the semantic aspects of the tasks. So it seems that the differences in the answers of first and second graders may be related with their age and their level of mathematical thinking.

In the task *game of marbles*, João shows an additive adaptive thinking as he seems to apply the inverse relationship between the wins and losses of marbles. Unlike the pupils of 5th grade reported by Thompson (1993), João did not confuse the notions of quantitative difference and absolute value of marbles nor needed to know the initial number of marbles to be able to think about wins and losses. However, he needed to be anchored in concrete numbers of marbles as happened with the pupils studied by Thompson (1993). Because João felt the need to attribute absolute values to the initial numbers of marbles, he showed to reason in terms of difference as quantitative operation without separating it from the involved particular arithmetical calculations. It is to say, João could not speak of relative changes associated to additive comparisons without referring to absolute amounts, showing conceiving the quantitative difference as an invariant numerical relationship. Thompson (1993) argues that it is important to conceive a quantitative difference independently of numerical information about quantities and relationships. However, we suspect that young pupils of 2nd grade are not able to conceive the independence of the values of the additive and subtractive when they reason quantitatively. For that reason, we consider that this task is not suitable for pupils of this grade, and we will not implement it in the teaching experiment.

The results reported here support the idea that flexible calculation is related to the knowledge and use of numerical relationships, being richer as pupils are developing their number sense, and are able to use the network of relationships that are building (Baroody & Rosu, 2006; Rathgeb-Schnierer & Green, 2013).

Improving classroom assessment in primary mathematics education in the Netherlands

Michiel Veldhuis[1] and Marja van den Heuvel-Panhuizen[1,2]

1 Utrecht University, Freudenthal Institute for Science and Mathematics Education, Utrecht, Netherlands, m.veldhuis1@uu.nl

2 Faculty of Social and Behavioural Sciences, Utrecht University, Utrecht, Netherlands

We report on the results of the Improving Classroom Assessment (ICA) project in the Netherlands that was aimed at improving primary students' mathematics achievement through improving their teachers' classroom assessment. Towards this end we first investigated primary teachers' assessment practice in a large-scale survey study. After having described and profiled teachers' current assessment practice, we designed a number of classroom assessment techniques, which were tested for feasibility in two small-scale sub-studies. Finally, we evaluated the effectiveness of the use of these classroom assessment techniques in a large-scale evaluation. Results indicate that students generally benefit from their teachers' improved use of classroom assessment techniques in mathematics.

Keywords: Classroom assessment; primary school; assessment technique; achievement.

BACKGROUND AND FOCUS OF THE PROJECT

Developing and keeping track of students' mathematical abilities are important parts of every primary mathematics teacher's daily practice. In order for teachers to gauge their students' learning, classroom assessment plays a pivotal role (Cizek, 2010). By using classroom assessment teachers can gather information about their students' mathematical skills and level of understanding. Collecting information on students' learning is primordial for at least two reasons: to find out whether the instruction has had its desired effect and to generate ideas for how to proceed in the subsequent lessons. Based on assessment information teachers can align their teaching to their students' needs, which in turn can result into adapting their teaching, but can of course also mean not changing anything and continuing with what was planned before.

Many of the characteristics of classroom assessment appear to be part of merely good teaching practice, as Ginsburg (2009) wrote in the context of mathematics education:

> Good teaching […] sometimes involves the same activities as those comprising formative assessment: understanding the mathematics, the trajectories, the child's mind, the obstacles, and using general principles of instruction to inform the teaching of a child or a group of children (p. 126).

Classroom assessment is broader: it comprises all activities that permit teachers to find out where their students are at a particular moment in terms of comprehension of the subject and to give information on what is going right and wrong. Policymakers as well as influential researchers have urged the educational community, and in particular teachers, to embrace (formative) classroom assessment in their practice. For instance, the U.S. National Council of Teachers of Mathematics (NCTM, 2013) recently took the following position on formative assessment in mathematics education:

> The use of formative assessment has been shown to result in higher achievement. The National Council of Teachers of Mathematics strongly endorses the integration of formative assessment strategies into daily instruction (p. 1).

Teachers are the only ones that can actively integrate these formative assessment strategies into their practice. Advocating positions such as these were mainly inspired by the influential review study by Black and Wiliam (1998) that reported the different practical expressions of classroom assessment to be the most effective interventions for teachers to improve student learning. Recently, several researchers have questioned the size of the effectiveness of (formative) assessment on student learning through reviews or meta-analyses of existing studies (e.g., McMillan, Venable, & Varier, 2013). Common to these critical examinations, although their specificities differ, is that they do not contest the positive effect formative assessment is purported to have on student achievement, but only the size of this effect.

Why then is classroom assessment by teachers supposed to lead to improved student learning in mathematics? In order to answer this question researchers have drawn parallels between the concepts and practices of formative assessment, self-regulated learning, feedback, and scaffolding (see for an overview, among many others, Clark, 2012). An intuitive way of saying it would be: if teachers are better aware of their students' mathematical abilities and understanding, then they can undoubtedly better adapt their teaching to the needs of the students. In doing this and providing explicit and implicit feedback students also become more aware of their own functioning, and the circle is complete: students and teacher simultaneously advance. This does have its limits, because "the teacher *must actually use the assessment data* to inform some change in the conduct of instruction" (Erickson, 2007, p. 189, original emphasis). In order for teachers to be willing to use classroom assessment techniques, these have to provide them with valuable and easily usable information about students' understanding of mathematics in a timely manner, otherwise it would not contribute to better teaching and, in the end, to better student achievement.

In the ICA-project we strived to improve primary students' mathematics performance through improving their teachers' use of classroom assessment in Grade 3. As a start we investigated the current classroom assessment practice of primary mathematics teachers in the Netherlands (Study 1). Secondly we identified a meaningful profile characterization of these teachers' mathematics assessment practice (Study 2). Now that the current practice was known we could test the feasibility of classroom assessment techniques that were designed to match the mathematics curriculum of the second half of Grade 3 in the Netherlands and provide valuable information to the teachers (Study 3). Finally we evaluate the effectiveness of the use of these classroom assessment techniques in a large-scale experimental study (Study 4).

STUDY 1: PRIMARY TEACHERS' USE OF CLASSROOM ASSESSMENT IN MATHEMATICS

We conducted a survey of the classroom assessment practices of Dutch primary school teachers in mathematics education (Veldhuis, van den Heuvel-Panhuizen, Vermeulen, & Eggen, 2013). International studies have shown that teachers use a wide range of methods to collect information about their students' learning (e.g., Suurtamm, Koch, & Arden, 2010). To find out students' skills and comprehension level, teachers can use methods ranging from standardized tests and tests that come with a textbook, to asking questions and observing students while they are working. The assessment methods teachers choose to reveal their students' learning processes depend on several factors. A first factor that has been found to affect this choice is teachers' beliefs concerning classroom assessment (Dixon, Hawe, & Parr, 2011). A second factor in choosing a particular assessment method, beside beliefs, concerns the assessment purpose teachers have in mind (Suurtamm et al., 2010), for instance a formative or summative purpose. A further determining factor of using particular assessment methods is the view on education in which the assessment takes place. The methods used for assessment often correspond to the approach to education as reflected in the adhered learning theory and the curriculum that is taught (Shepard, 2000).

Method

We investigated, using an online questionnaire, how primary teachers in the Netherlands collect information on their students' progress in mathematics and how teachers' assessment methods, purposes, and beliefs about the usefulness of assessment are related. This questionnaire contained 40 items, pertaining to the teachers' (i) background characteristics, (ii) mathematics teaching practice, (iii) assessment practice, and (iv) perceived usefulness of assessment. Questions with different formats were included: fixed-response and items with a rating scale, but also some open-ended items. The sample of participating teachers was obtained through an open invitation by e-mail, which was sent successfully to 5094 primary schools for regular education in the Netherlands. Teachers who were willing to respond to the online questionnaire were promised a set of digital mathematical exercise material as a reward.

Results and discussion

In total 960 teachers at 557 Dutch primary schools responded to the questionnaire. Observation-based assessment methods of questioning, observing, and correcting written work, were the most frequently – that is weekly – applied methods, whereas instrument-based methods, particularly using textbook tests and student monitoring tests were employed several times a year (see Figure 1).

Teachers used assessment mainly for formative purposes and they considered the assessment methods they used themselves as most relevant. We found that teachers in primary mathematics education in the Netherlands use a variety of assessment methods, use instrument-based and observation-based assessment methods on average just as frequently and find assessment generally useful. This perceived usefulness is shown by the overall very positive reactions teachers gave on the different uses of assessment. The two main instrument-based assessment methods, textbook tests and tests from a student monitoring system, are reported as the most relevant, with asking questions and observing students the most relevant of the observation-based assessment methods. Furthermore, the teachers' responses to the questionnaire revealed that they used assessment both for formative and summative purposes. The results of our survey indicate that teachers do use assessment information for various purposes, from giving feedback via adapting instruction to stimulating thinking.

STUDY 2: PRIMARY TEACHER PROFILES IN MATHEMATICS ASSESSMENT

After this general overview of the current assessment practice we were interested in finding out more about individual teachers. The second study was aimed at gaining knowledge of how the assessment practices of individual teachers could be characterized within the universe of assessment skills and activities. In fact, we wanted to understand assessment from the conglomerate of choices a single teacher is making when collecting information about his or her students' learning process. To achieve this we performed a secondary analysis of the earlier gathered questionnaire data to identify a profile characterization of every teacher's assessment practice (Veldhuis & van den Heuvel-Panhuizen, 2014). The rationale for distinguishing assessment profiles of teachers is that these can contribute to our theoretical understanding of assessment as it teachers carry it out. In addition, knowledge about these assessment profiles can help us in a practical sense with designing tailor-made courses for professional development that fit the teachers' needs.

Analyses

We analyzed the survey data in two steps. To identify the latent structure of what was measured by the questionnaire and be able to construct assessment profiles of teachers we used a combination of latent variable modeling techniques. To explore the underlying structure of the items measuring teachers' math-

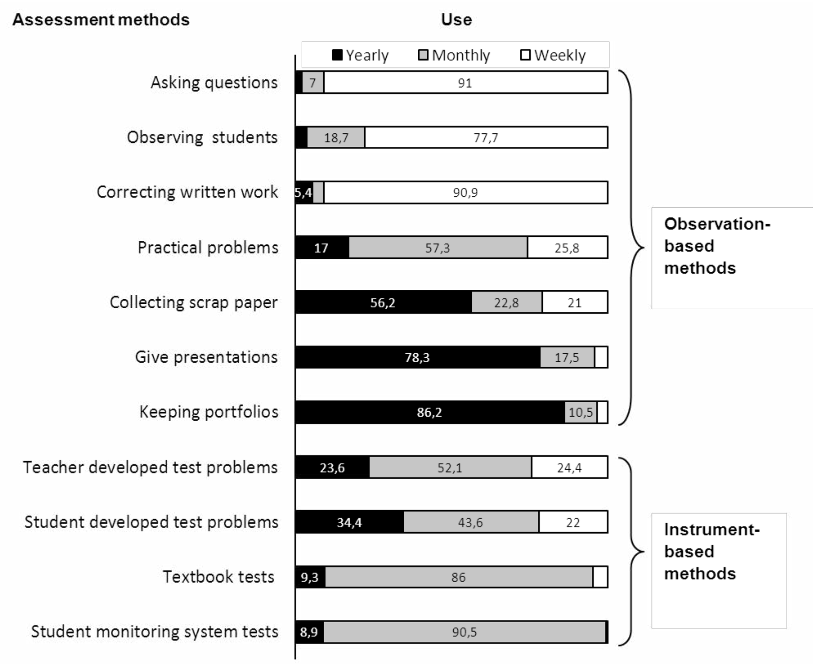

Figure 1: Percentages of frequencies of assessment methods' use (*ns* > 940)

ematics assessment practice, we performed exploratory factor analyses. To investigate whether these latent factors could also be used to interpret classes of teachers, we performed a latent class analysis. This is a statistical technique permitting the identification of underlying classes of individuals based on differences in their responses on items in a questionnaire or test. The teachers in our sample were assigned to the different latent classes–that we will call assessment profiles–through modal assignment, i.e. they were assigned to the latent class to which they had the highest probability of belonging.

Results and discussion

After comparing one- to seven-factor solutions and eliminating items with cross loadings over |0.4|, an exploratory factor analysis delivered a five-factor solution that had a good enough fit ($\chi^2(1076, N = 960) = 5494.1$, $p < .001$, RMSEA = .064, CFI = .961). We named the five factors based on the items they contained: *Goal centeredness of assessment* (items on teachers' purposes of assessment), *Authentic nature of assessment* (items on authentic assessment methods), *Perceived usefulness of assessment* (statements on usefulness), *Diversity of assessment problem format* (items on problem formats), and *Allocated importance of assessing skills and knowledge* (items on the importance of assessing particular skills and knowledge). To be able to characterize teachers' assessment practice and assign them to different assessment profiles we performed a latent class analysis using all variable scores as input. As such we were able to check whether we would be able to show differences between the latent classes of teachers on the five factors we found in the separately performed factor analysis. Four latent classes provided the best fitting solution. To find out whether teachers thus assigned to the four latent classes differed on the five factors of assessment practice identified before, we performed several analyses of variance. The results showed that teachers from one latent class to another differed significantly from each other (see Figure 2 for the size and the direction of these differences). These differences suggest that teachers with particular assessment profiles have qualitatively different assessment practices.

The assessment profile to which most teachers (35.5%) in our sample belonged was the *mainstream assessors* profile. In this profile most teachers regularly used different types of assessment, test-based and observation-based, for both summative and formative purposes. On all factors teachers with this profile scored around the mean.

The next biggest group (28.5%) were the *enthusiastic assessors*. Teachers with this profile were very aware of the different possibilities assessment offers them and used them likewise. On all components these teachers scored above the mean, with a peak on *Goal centeredness of assessment*. An almost equally large

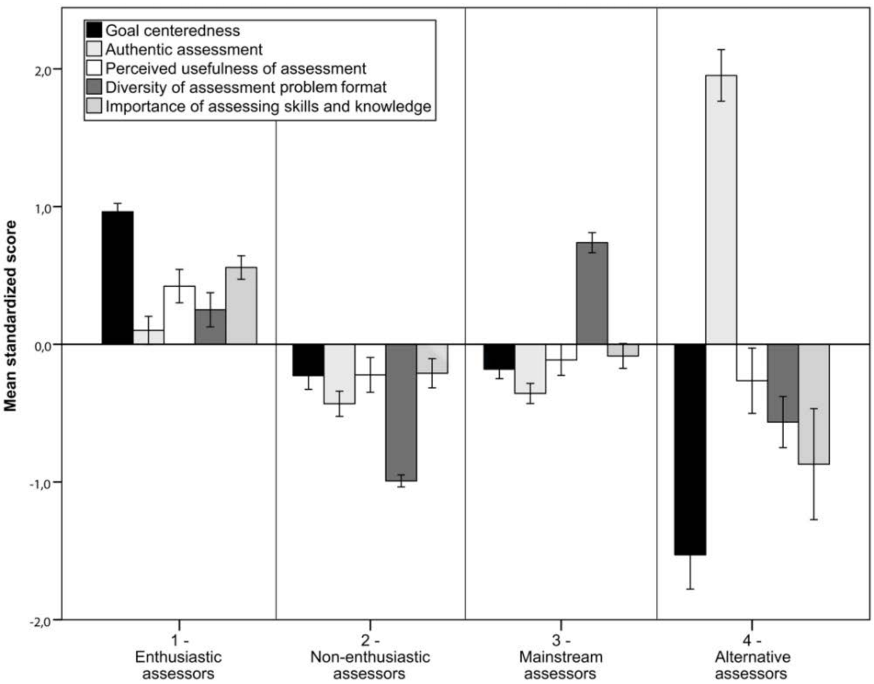

Figure 2: Mean standardized scores on factors for teachers in the four latent classes

group of teachers (25.8%) were the *non-enthusiastic assessors*. These teachers viewed assessment more often in a negative way and used it accordingly less. On all factors, teachers with this profile scored below average. Finally, there were the *alternative assessors* (10.3%). Teachers with this profile had an ambiguous view of assessment. Although they reported a lot of own input in assessment and devised their own tasks and tests, they did not find assessment important or necessary.

Through this profile characterization of teachers' assessment practice we were able to select some of the skills and activities from the universe of assessment skills and activities of teachers. In this way we brought structure to the many possible characterizations of assessment practice and gained a more clear idea of what to expect from teachers prior to the introduction of the assessment techniques in our consecutive studies.

STUDY 3: EXPLORING THE FEASIBILITY AND EFFECTIVENESS OF CLASSROOM ASSESSMENT TECHNIQUES IN MATHEMATICS

In this small-scale study the focus switched from the current practice of teachers to how this practice could be improved. Many types of formative or classroom assessment techniques have been proposed and used in international research (e.g., Black, Harrison, Lee, Marshall, & Wiliam, 2004) or in more practice-oriented work (e.g., Keeley & Tobey, 2011). In mathematics education there exist many different forms of these classroom assessment techniques, through our survey of current practice we could determine that these techniques were not very often used by primary teachers in the Netherlands. The Dutch Inspectorate (Inspectie van het onderwijs, 2013) also pointed out that many primary (40%) and secondary schools (33%) do not systematically use assessments to monitor their students' progress. In any case, from available findings it becomes clear that there is a need for investigation of the use of classroom assessment techniques in mathematics education.

The purpose of this study was to investigate the feasibility and effectiveness of classroom assessment techniques for mathematics in primary school. We wanted to find out whether teachers and students were prone to use assessment techniques and whether the use of an ensemble of these techniques would be related to an increase in achievement.

Method

Ten teachers (with 214 students; 14 to 29 students per class) participated in monthly workshops in the second semester of Grade 3 in two consecutive sub-studies (four teachers in the first; six teachers in the second). In the workshops, consisting of three or four teachers and the first author, classroom assessment techniques were presented, discussed, and evaluated. The teachers were approached by e-mail and volunteered to participate. The schools were all situated in urbanized areas with highly mixed student populations, and the teachers used four different textbooks that were all based on realistic mathematics education principles as is common in the Netherlands.

The feasibility of the classroom assessment techniques was investigated by conducting regular classroom observations of every teacher in between workshops. These observations were intertwined with short informal interviews. To investigate the effectiveness of the use of classroom assessment techniques we used a pre-/post-test evaluation of students' mathematics achievement. The pre-test data consisted of the results from the midyear student-monitoring test for Grade 3 (Cito LOVS M5) and the results from the end of year student-monitoring test for Grade 3 (Cito LOVS E5) served as post-test data (Janssen, Verhelst, Engelen, & Scheltens, 2010). These biannual student-monitoring tests are used in virtually all primary schools in the Netherlands to monitor students' development in mathematical ability over the years. The teachers administered the tests in their own classes as is common in educational practice in the Netherlands. The scores on these tests are mathematical ability scores calculated through item response theory models.

We proposed a collection of classroom assessment techniques consisting of short activities of less than 10 minutes to the teachers. The techniques were supposed to help teachers to quickly find out something about their students' mathematical skills and understanding, provide teachers with indications for further instruction, and focus on some of the mathematics content of the second semester of Grade 3. Most techniques were centred on the assessment of number knowledge, mainly in the context of addition and subtraction, but they could also be used to assess multiplication and division tables. In Figure 3 we provide an example of a technique called Red/Green cards.

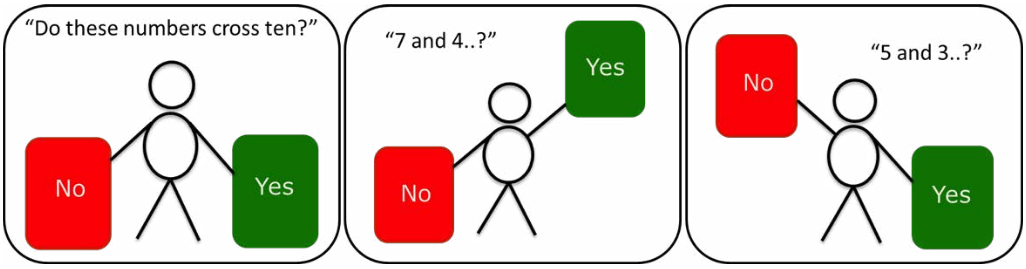

Figure 3: An example of the Red/Green cards. The focus is on number sense: the comprehension that two numbers together can be more or less than 10, 100, or 1000

The teacher asks all students a series of questions that can be answered quickly with Yes (green) or No (red). By inspecting the waving red and green cards the teacher gets an immediate overview of all students' responses. Especially when students have to carry out mental additions and subtractions with two-digit numbers it is crucial that they can instantaneously identify whether two numbers cross ten or not, because this has consequences for the strategy to be applied. This technique provides the teacher quickly with information on particular number sense knowledge of the students.

Results and discussion

Teachers and students reported enjoying the techniques and finding them useful in the sense that they provided them with valuable information that supported their teaching and learning. Teachers also mentioned that the techniques were easy to apply in their classrooms. In terms of mathematics achievement, results indicate students improving considerably ($M_{\text{gain substudy 1}}$ = +9.7; $M_{\text{gain substudy 2}}$ = +7.6). It could of course be expected that students advance in their mathematical ability, whether teachers perform specific assessment activities or not; the scores of the national norm sample also showed this direction ($M_{\text{gain norm}}$ = +5.1).

Even though the treatment group was relatively small and there was no control group in this study, these results do provide an indication for the feasibility and effectiveness of the use of the classroom assessment techniques in mathematics: teachers use the techniques and students appear to advance more from the midyear to the end of the year testing than expected.

STUDY 4: TEACHERS' USE OF CLASSROOM ASSESSMENT IMPROVING STUDENTS' MATHEMATICS ACHIEVEMENT

To verify whether the students' achievement improvement we found in Study 3 was really due to the teachers' use of the classroom assessment techniques in mathematics and not just to an attention (also Hawthorne) effect, we replicated this investigation in a large-scale experiment.

Method

The same pre-/post-test design was used as in Study 3, but now with a control group and an extra manipulation. Thirty teachers (and their 616 students) participated and were randomly distributed over the three experimental conditions and one control condition. In the experimental conditions teachers participated in the same type of workshops as in Study 3. These experimental conditions differed on the intensity of the professional development teachers received: in Experimental I there was one workshop, in Experimental II, two workshops, and in Experimental III, three workshops, and in the control condition teachers did not have any workshops. In these workshops the same classroom assessment techniques were discussed; there was more time for every technique if teachers had more workshops.

Results and discussion

Teachers' use of classroom assessment techniques in mathematics was associated with students' improved mathematics achievement. More specifically, when teachers participated in three workshops and, as such, developed more ownership of the techniques, their students showed more improvement in terms of mathematics achievement than in the other conditions ($M_{\text{gain Experimental III}}$ = +8.1; $M_{\text{gain other}}$ = <+5.9; cf. Figure 4 with the results of an ANCOVA, correcting posttest scores for pretest differences). Supporting teachers in the use of classroom assessment techniques for math-

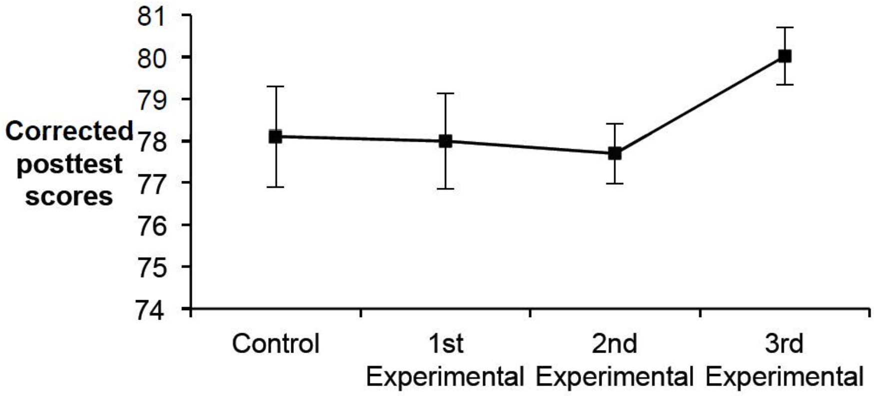

Figure 4: Posttest scores corrected for pretest differences for the four conditions (with error bars)

ematics in three workshops clearly benefits students' mathematics achievement.

ACKNOWLEDGEMENT

The ICA (Improving Classroom Assessment) project was supported by a grant from the Netherlands Organization for Scientific Research (NWO MaGW/PROO: Project 411-10-750).

Poster

A socially built understanding of rational numbers

Helena Gil Guerreiro[1] and Lurdes Serrazina[2]

1 Universidade de Lisboa, Instituto de Educação, Lisboa, Portugal, hg@campus.ul.pt

2 Universidade de Lisboa, UIDEF, Escola Superior de Educação Lisboa, Lisboa, Portugal, lurdess@eselx.ipl.pt

This poster focus on an exploratory study which is part of a research study which aims to understand how to develop students' emerging understanding of rational numbers, at elementary school, looking into how number sense development is promoted, through the use of different representations - percents, decimals and fractions - being the percentage the introductory one. Through a design research, based on a teaching experiment, guided by a conjecture, we intend to analyse the interactions, the strategies and the students' productions when solving tasks. In this poster some data analysis from the exploratory study, concerning the use of percents, will be presented. This data show that percentage seems to be a good starting to introduce rational numbers.

Keywords: Learning, rational numbers, number sense, taken-as-shared meaning.

Rational numbers is a complex content for the development of a sustainable construction of mathematical knowledge (Fosnot & Dolk, 2002). Moss and Case (1999), developed an experimental curriculum to introduce rational numbers where the first topic was percentage, following by two-place decimal numbers and fractional notation as introduced last. Based on this idea, the first author of this poster is developing a design research study, based on a teaching experiment, guided by a conjecture. This conjecture sustains that a detailed and sequenced work with percentage, and the subsequent interrelation with the other representations (decimal and fraction), can be a powerful learning pathway in emerging student's understandings of rational numbers, as they participate in social activity in the classroom and build taken-as-shared meanings, in a number sense development perspective. This conjecture has two dimensions: a mathematical content dimension and a pedagogical dimension. The first one focuses on a comprehensive concepts' learning construction related with rational numbers, in a perspective of number sense development. Teaching for development of number sense, as Fosnot and Dolk (2002) say, can be seen as the development of powerful strategies, models and big ideas that provide practical, flexible, and efficient computation, to handle numerical problems. The pedagogical dimension is based on a sociocultural perspective, where the construction of knowledge happens in the classroom, through active engagement in communication and interaction. These two dimensions complement each other and allow the study of pupils' learning and its evolution, by articulating a social perspective with a psychological perspective of the learning process (Cobb et al., 2011).

An exploratory study was developed at the beginning of third grade, in a class of 20 students and aimed to identify students' perception on percentage and their intuition regarding proportions. The results show that all the involved students recognize the expression 100% and associate it, in the context of a mobile phone battery, to a "full" battery, that is completely charged. The majority of those students are able to correspond 50% to half. Justifications like "Codfish with 50% discount costs half the price" or " It's 20€ because the jumper was 40€ and since it has a 50% discount it is half-price" reveal that this intuition exists and seems to come about, in some way, associated to the student´s experiences, mainly outside school.

Also, in the exploratory study, students were asked to take a stand concerning the statement "More than half of the document is saved!" in a situation where it was possible to see a computer status bar, when 80% of a document would already be processed. Agreement statements like "saving document ends at 100% and half has passed, which is 50%, because it is already in

82%" or "Because the saving document ends in 100% and that has already passed half 100, which is 50 and it is already in 82%" show that most of the students in the classroom reveal some knowledge related to this domain. Other situations presented involved mainly reference numbers and were associated to strong visual models, as percentage bars. It is worth noting that percentage had not been a topic worked in the context of the classroom. Using communication technologies in life creates a set of opportunities that can enhance school learning contexts. The data analyses of this exploratory study pointed towards integrating in school the knowledge built from the use of technologies in life. Percentage makes sense in school because it is part of life. Percentage bars provide a powerful visual concrete representation and can further contribute to build a connection between children's intuitions about proportions and rational numbers. The purpose is to grasp those experiences and trigger the construction of a knowledge network, towards rational numbers.

The ongoing study will seek to reconstruct episodes of student's work, in a detailed analysis of the events that took place, guided by the chosen interpretative theoretical framework. This analysis should allow the presentation of student's understandings embedded in the emergence of taken-as-shared meaning, in the learning of rational numbers, which may provide some clues for research in this area.

TWG03

Algebraic thinking

Introduction to the papers of TWG03: Algebraic thinking

Jeremy Hodgen[1], Reinhard Oldenburg[2], Valentina Postelnicu[3] and Heidi Strømskag[4]

1 University of Nottingham, Nottingham, UK, Jeremy.Hodgen@nottingham.ac.uk
2 University of Augsburg, Augsburg, Germany
3 Texas A&M University-Corpus Christi, Corpus Christi, USA
4 Norwegian University of Science and Technology, Trondheim, Norway

In CERME9, as a long-standing group, TWG03 "Algebraic thinking" continued the work carried out in previous CERME conferences (e.g., Cañadas, Dooley, Hodgen, & Oldenburg, 2013).

There were a total of 15 papers and 7 posters with a total of 24 group participants representing 18 countries: Argentina, Canada, Cyprus, Czech Republic, Germany, Hungary, Ireland, Italy, Mexico, Norway, Portugal, Romania, Spain, Sweden, Turkey, Ukraine, UK, the USA.

THE RANGE AND DIVERSITY OF RESEARCH FRAMEWORKS

As we have observed in previous CERME working group reports, algebraic thinking is a "mature" sub-domain within mathematics education research (e.g., Cañadas et al., 2011). As a result, our group discussions touched on many familiar themes. Of particular interest to the group was the range of research frameworks, models and theories that participants drew on. In order to understand this diversity, we developed a categorisation of the frameworks used in TWG03 papers, where authors of TWG03 papers are given in square brackets.[1]

A. Models for conceptualising algebra, algebraic activity and algebraic thinking

— Kaput's (2008) model for conceptualisation of algebraic thinking [Chimoni & Pitta-Pantazi] [Glassmeyer & Edwards] [Twohill]

— Arzarello, Bazzini and Chiappini's (2001) model for analysis of algebraic thinking [Cusi & Malara]

— Drijvers, Goddijn and Kindt's (2011) model for categorisation of algebra [Pittalis, Pitta-Pantazi, & Christou]

— Kieran's (2004) model for conceptualisation of algebraic activity [Strømskag]

— Driscoll's (1999) framework for algebraic habits of mind [Eroglu & Tanisili]

— Pittalis and colleagues' (2013, 2014) model of early number sense [Pittalis, Pitta-Pantazi, & Christou]

B. Frameworks of variables and equation solving

— Bloedy-Vinner's (1994) dichotomy of "algebraic-analgebraic" to analyse students' difficulties with parameters [Postelnicu & Postelnicu]

— Hadjidemetriou and Williams' (2010) concept of linearity prototype for graphs [Pilous & Janda]

— Lima and Healy's (2010) notion of didactic cut in equation solving [Block]

— Star and Rittle-Johnson's (2008) strategies for solving linear equations [Block]

C. Frameworks of functions and functional thinking

— Vinner and Dreyfus' (1989) distinction between concept definition and concept image for the concept of function [Panaoura, Michael-Chrysanthou, & Philippou]

— Isoda's (1996) application of van Hiele levels as a model for development of the function concept [Szanyi]

— McEldoon and Rittle-Johnson's (2010) framework for functional thinking assessment [Xolocotzin & Rojano]

— Rivera and Becker's (2011) framework for pattern generalisation [Twohill]

D. General theories about teaching and learning mathematics

— Duval's (2006) theory of semiotic registers [Cusi & Malara]

— Bikner-Ahsbahs and Halverscheid's (2014) theory of interest-dense situations [Janssen & Radford]

— Radford's (2007) theory of objectification [Janssen & Radford]

— Godino, Batanero and Font's (2007) onto-semiotic approach to research in mathematics education [Godino, Neto, Wilhelmi, Aké, Etchegaray, & Lasa]

— Dekker and Elshout-Mohr's (1998) model for interaction and mathematical level raising [Simensen, Fuglestad, & Vos]

— Matute, Roselli and Ardila's (2007) framework for neuropsychological children assessment [Xolocotzin & Rojano]

— van der Niet, Hartmann, Smidt and Visscher's (2014) framework for modelling relationships between bodily movement and academic achievement [Henz, Oldenburg, & Schöllhorn]

— Wertsch's (1991) concept of mediating tools [Wathne]

E. Holistic theories encompassing instructional design

— Brousseau's (1997) theory of didactical situations, TDS [Norquist] [Strømskag]

— Chevallard's (2003) anthropological theory of the didactic, ATD [Mavongou & González-Martin]

— Marton, Runesson and Tsui's (2004) variation theory [O'Neil & Doerr]

Interestingly, the research frameworks are at different levels. The most common type of research framework (as outlined above in A, B and C) can be considered as what Eisenhart (1991) refers to as conceptual frameworks. They are skeletal structures of justification, rather than structures of explanation based on a formal theory (which would be the case with a theoretical framework). The frameworks described in D are conceptual frameworks that are "general" in their roots, where algebra is the focal topic "imported" into the framework by the authors.

The frameworks in F are holistic theories that encompass a methodology of instructional design. The methodological principle of TDS is that a piece of mathematical knowledge is represented by an epistemological model – a situation – that involves problems that can be solved in an optimal manner, using the targeted knowledge. The general epistemological model provided by the ATD proposes a description of mathematical knowledge in terms of mathematical praxeologies whose main components are types of tasks, techniques, technologies, and theories. In this way, TDS and ATD provide tools for both designing and analysing mathematical activities. The concepts and models of these theories provide guidance for task design, so that the mathematical tasks – as research instruments – will be an integrated part of the whole research enterprise.

FUNCTIONAL THINKING

We were struck by the large number of papers at this conference that addressed the nature and role of functional thinking in the development of algebraic thinking and focused on students' and teachers' difficulties with functions and functional thinking (Cusi & Malara; Eroglu & Tanisli; Glassmeyer & Edward; Godino, Neto, Wilhelmi, Aké, Etchegaray, & Lasa; O'Neil & Doerr; Panaoura, Michael-Chrysanthou, & Philippou; Pilous & Janda; Postelnicu & Postelnicu; Prendergast & Treac; Szanyi; Xolocotzin, & Rojano).

The following considerations were prompted by the mathematical content of the tasks of the research studies presented in the papers and posters of the Algebraic Thinking group. Euler's, Dirichlet's, and Bourbaki's definitions of function were used, paralleling the historical development of the concept of function and matching the students' developmental stage. With few exceptions, like O'Neil and Doerr's paper on logarithmic functions, or Pilous and Janda's poster with examples of rational functions, linear and quadratic functions and equations were predominant. There seemed to be a consensus on the importance of students' and teachers' fluency within and between various perspectives of functions, and connecting between multiple representations of functions. Some papers and posters presented tasks specific to Early Algebra approaches such as pattern-based or quantitative reasoning approaches (Mavoungou & González-Martín; Strømskag; Twohill; Ugalde & Zazueta). Some tasks reflected our traditional algebra curriculum, influenced by the historical quest for solving equations, by focusing on the equation approach to algebra (Block).

In several papers, the contexts of tasks and the focus of research departed somewhat from the functional thinking, like in papers that dealt with factors that may influence algebraic thinking. Among those factors were other ways of thinking (Chimoni & Pitta-Pantazi; Norqvist), the interaction of the task with the teacher's actions, type of learner, and the learning environment and its affordances (Henz, Oldenburg, & Schöllhorn; Janssen & Radford; Pittalis; Pitta-Pantazi & Christou; Simensen, Fuglestad, & Vos). Theses shifts in the focus of research, away from the nature of algebraic thinking and thought, prompted a discussion about the new borderlines of the research on algebraic thinking.

BORDERLINES: LOOKING FORWARD TO CERME10

In the working group, we noticed various borderlines that define but also limit the scope of the algebraic thinking TWG. It is an interesting strategic question how the group, particular as a mature group, should react to these borderlines.

As in past conferences, the TWG has concentrated much on the core of algebra and algebraic thinking that includes approaches to algebra, early algebra, functional thinking, algebraic reasoning, development issues related to all that, misconceptions, epistemic actions in algebra, learner generated examples and teachers' goals. In recent conferences (but not 2015), we have discussed papers on the history and philosophy of algebra and the use of technology to promote algebraic thinking. Yet, although revolutionary new insights have become rare, but still the situation of algebra in schools is not satisfactory. What hinders progress is, among other things, the existence of subtle differences in understanding notions (e.g. what is a functional approach) that result in borders within the subject. Moreover, differences between teaching cultures in different countries (and within countries) are enormous and restrict generality of results very much.

Furthermore, we observe a number of emerging borderlines which have been studied to some extent, but in our view not yet sufficiently. For example, how much algebraic thinking is needed, how is it applied and how can algebraic 'defects' be hindered in various other aspects of education in schools? For example:

- Probability, e.g. what algebraic competence is needed to work with expressions like $P(|X - np| < k) > 95\,\%$.
- Geometry: $g \perp h \wedge h \perp l \Longrightarrow g \parallel l$
- Computer science: f vs. $f(x)$
- Physics: $U = RI$

The crucial question that should be cleared in further discussion is if these points are within or beyond the border of algebraic thinking.

Another related question is how do other school subjects act back on algebra? How do students cope with the fact that in other areas different rules apply? For example:

- A random variable is not a variable
- A physical quantity may not be a variable (but a function of time)
- Letters in geometry are labels or names of objects, not variables

Some of the paper in CERME9 hinted at emerging opportunities to cross boundaries to other subjects of research:

— Inclusion of lower achieving students raises questions usually studied in social sciences

— Gestures, bodily movement and brain research are traditionally more central in cognitive science

These new 'borderline' areas certainly open up the opportunity to understand algebraic thinking from new perspectives. The group acknowledges this but has a strong view about maintaining a strong mathematical focus to the algebraic thinking group.

Finally, a feature of the group has been continuity and we hope very much to be joined by many of the CERME9 TWG03 participants at CERME10.

Research papers

Flexible algebraic action on quadratic equations

Jan Block

Technische Universität Braunschweig, Braunschweig, Germany, jan.block@tu-braunschweig.de

This paper describes a study that explores the competencies of flexible algebraic action of German students in grade nine and ten when dealing with quadratic equations. A theoretical framework for the concept of flexibility in algebraic action in the context of quadratic equations is provided. Further on, data analysis and some important early results of the study are discussed. The study examines which features of quadratic equations the students perceive, what meanings they infer from these features and to what extent this is conducive to or obstructive for flexible algebraic action. Two types of meta-tasks were used in the study and analyzed with qualitative data analysis methods.

Keywords: Quadratic equations, flexibility, algebra.

INTRODUCTION

When professional mathematicians solve quadratic equations like (1) $x^2 + x - 6 = 0$, (2) $x^2 + 2x = 0$, (3) $(x - 3)(x + 5) = 0$ or (4) $(x - 3)(x + 5) = 7$ they will use different methods to find the solutions in effective and less error-prone ways. They do so, because they recognize different features of the equations and they are able to draw appropriate conclusions for solving the equations. E.g., equation (1) and (2) look very similar with a sum as the term on the left-hand side and zero on the right-hand side. The difference is the missing constant in (2), which indicates that this equation can be easily solved by factoring. In contrast, using the pq-formula[1] is a suitable procedure for solving equation (1). The equations (3) and (4) have the same structure on the left-hand side. The only, but important difference is the number on the righthand side. The solutions of (3) can be immediately determined without any calculation, whereas for solving (4), it is necessary to expand the brackets and use the pq-formula. Although all quadratic equations can be solved by using the pqformula, for (2) und (3) it is not an effective way because the calculations performed before or while using the pq-formula are not necessary. Furthermore these calculations are error-prone, especially for students with problems in algebraic conversions. When they use the pq-formula for (2) a common mistake is using a wrong value for q in the formula. The expanding of brackets in (3) is also a wellknown field of mistakes. Using different solution methods depending on the characteristics of the equation can be called flexibility in contrast to the use of only one standard routine like the pq-formula for each type of quadratic equations.

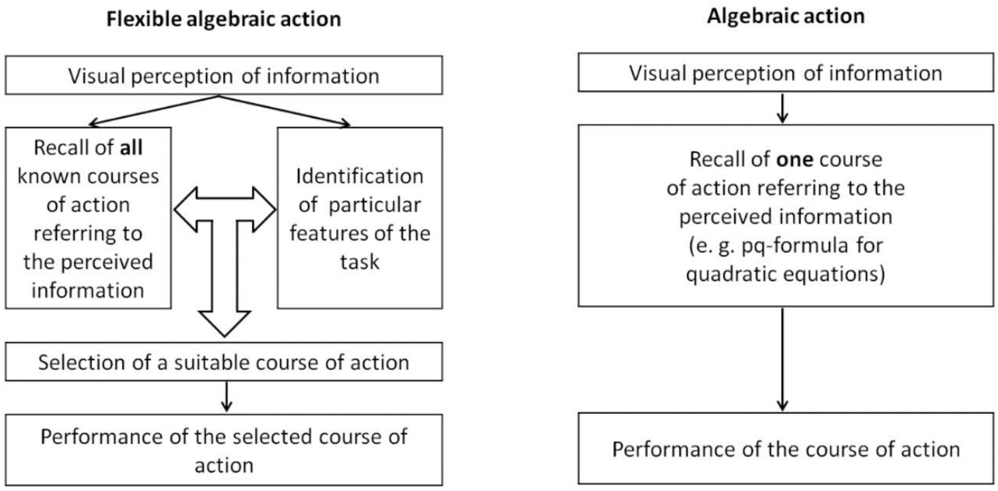

Figure 1: Comparison of flexible algebraic action and algebraic action

QUADRATIC EQUATIONS AND FLEXIBLE ALGEBRAIC ACTION

Flexible algebraic action is defined as the ability to choose an adequate processing method depending on the specific features of the task and the abilities of the individual. This definition refers to the concept of flexibility in mental calculation (e.g., Rathgeb-Schnierer, 2006; Threlfall, 2002) and a general discussion about what flexibility can mean (e.g., Star & Newton, 2009). Figure 1 shows the comparison of flexible algebraic action and algebraic action just with one standard routine.

For quadratic equations a didactical map can show the complexity of the situation students have to cope with, when they learn to solve this type of equation. A didactical map is a graphic depiction on an issue which contains important information for didactical considerations under special questioning. To clarify the difference between linear and quadratic equations in situations of learning and regarding the necessity of flexibility, a didactical map of linear equations (Figure 2) will be contrasted to a didactical map of quadratic equations (Figure 3). The construction refers to the "Didactical cut" which was first named by Filloy and Rojano (1984, 1989) and later on discussed by several researchers (e.g., Herscovics & Linchevski, 1994; Lima & Healy, 2010; Vlassis, 2002).

The map shows, that linear equations can be divided into two main groups: In the first, the unknown is only appearing once on one side of the equation. These equations can be solved by arithmetical procedures. It is not necessary to act on or with the unknown because they can be solved by using the reverse operations, e.g. $3x + 7 = 19$ can be solved by calculating $(19 - 7) \div 3$. To solve the second group of equations, in which the unknown occurs on both sides or more than once on one side, it is necessary to use algebraic procedures to act on or with the unknown. According to this classification, Lima and Healy (2010) call these two groups 'evaluation' and 'manipulation' equations which resembles the classification by Filloy and Rojano (1984, 1989) for linear equations, but which is farther-reaching also for classifying quadratic equations. Lima and Healy focus on the activities which are necessary to solve an equation and not on the question, where or how often the variable occurs. In contrast to the evaluation equations, for the manipulation equations it is necessary to manipulate algebraic symbols. The group of manipulation equations can be divided into two subgroups. For the first, where the variable is only appearing on one side but more than once, algebraic procedures are only necessary for the terms on one side. For the second, where the variable appears on both sides, equivalent transformations on both sides of the equation are necessary. To describe the important differences between the three groups regarding the different requirements of arithmetical and algebraic skills, the author suggests using the term "cognitive step" which is also suitable for the quadratic equations.

The aim of each algorithmic solving process for linear equations is to transform the equation into the form of the first group. The possible transformations are indicated by the arrows on the map. One facet of flexibility on acting with linear equations should be e.g. the ability to recognize that $3x + 4 = 3x + 5$ has no solution without starting algebraic procedures on this equation. The map shows that the field of linear equations has got a manageable number of cases. Nevertheless, there are also flexible and intelligent strategies to solve linear equations by simplifying the given equation without strictly using algebraic

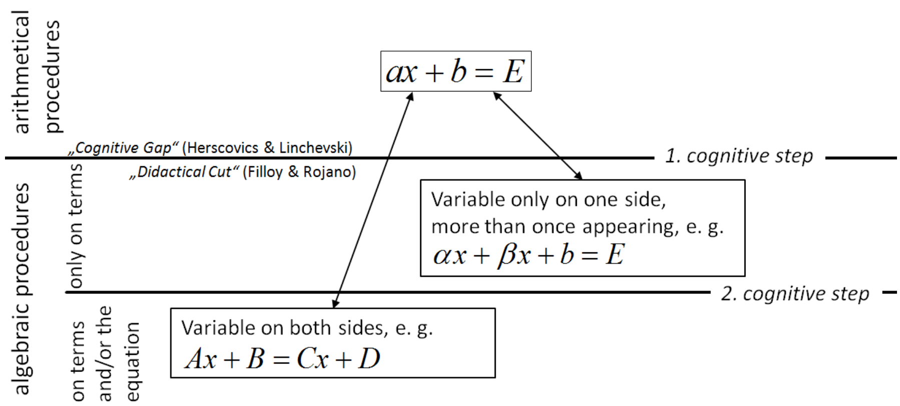

Figure 2: Didactical map of linear equations

algorithms (e.g., Star & Rittle-Johnson, 2008). For example for solving the equation $5(x + 2) = 20$ it is not necessary to expand the brackets, when recognizing that the term in brackets has to be 4 and then solving the equation $x + 2 = 4$ instead of the given equation. But this type of flexibility is depending only on special numbers. The idea behind this is to get an equation which is solvable with arithmetic procedures but the way to achieve this type depends on the numbers and the structure and it is not strictly algorithmically performing.

In contrast to this fairly simple model, the didactical map of quadratic equations (Figure 3) shows the wide variety of types of quadratic equations under the view of different effective solution methods. The study is only focussing on basic types of quadratic equations and not on non-standard examples like $\sin^2(x) + 2\sin(x) + 1 = 0$ or $x^4 - 6x^2 + 9 = 0$, for which identifying and interpreting of features as a basis for acting flexible is also very important. There are two main groups of equations: The first is solvable with quasi-arithmetical procedures such as inverse operations, extracting radicals or using the fact, that a product equals zero if one of the factors equals zero. The last case is indicated as a special case by the vertical spotted line, because a special knowledge is needed and no arithmetic operations are necessary. To solve the second group, algebraic procedures are necessary. This group can be divided into two subgroups: The first is characterized by the fact that the algebraic procedures are explicitly done when factoring the equation with the missing constant term. After this, the solutions are obvious using the knowledge about cases when a product equals zero. Using the pq-formula for all other types, the algebraic procedure of solving is not completely visible, so it is called implicit. This classification of the two main groups is according to the terms 'evaluation' and 'manipulation' equations Lima (2007) used. In contrast to the linear equations, the cognitive steps do not depend on the fact where and how often the variable appears.

The dashed arrows indicate that some equations can be interpreted as special cases of other types of equations. The types of equations differ in the types of the terms appearing. The structure of the terms is indicated by the form of the frames. A product is indicated by a frame shaped like an ellipse and a sum by a hexagon. The rectangle indicates the special case, where the unknown appears linear in a product but the term is a sum. To indicate the different suitable methods of solving, the frames have different kinds of lines. The dashed lines indicate the *pq*-formula, the dot-dash-lines extracting radicals as an appropriate method and the dot-dot-dash-lines stand for the possibility to get the solutions by factoring the term.

It is obvious that the types of quasi-arithmetical and algebraic solvable equations correspond in a complex way. For choosing an effective solution method it is not sufficient to look just at the type or structure of the term on one side of the equation. It is also necessary to look at the structure of the equation as a whole and the appearing numbers at special places in the equation (e.g. zero on one side of the equation). The main difference between the linear and the quadratic equations in the process of flexible solving is, that for quadratic equations it is not the aim to transform all types just into one, which can be solved by a stand-

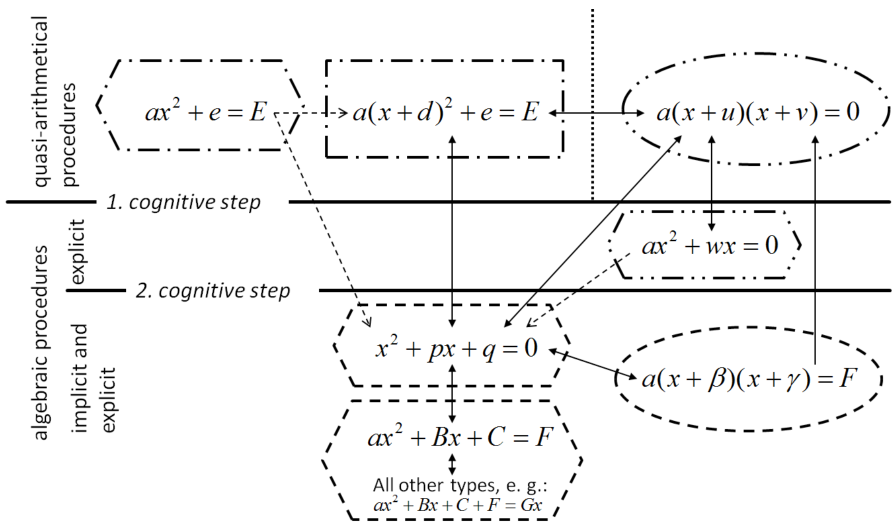

Figure 3: Didactical map of quadratic equations

ard method, as it is with the linear equations where it is the aim to produce a type of equation which can be solved by arithmetical procedures. Flexibility in solving quadratic equations means choosing different algorithmic solving methods, depending on special features of the equations. To master this, it is required to consider the relationships shown in the didactical map and to know, which features of an equation are important to indicate a suitable more or less algorithmic solving method.

METHOD OF THE STUDY

The three main questions in this study are: 1. Which features of quadratic equations do students perceive? 2. What meanings do they infer from these features? 3. To what extent is this conducive to or obstructive for flexible algebraic action?

To answer these questions two types of studies were made: 1. Laboratory study in a one-to-one situation (researcher and participant) with eleven students from grade nine from four different classes from two different German high-schools (Gymnasium). 2. Classroom study with 26 students from grade nine and 20 students from grade 10 from yet another Gymnasium. In the classroom study the tasks were integrated in a lesson by a teacher who was exactly instructed how to moderate the lesson. In the German high-school curriculum normally quadratic equations are a topic at the end of grade eight, so that all participants had taken part in lessons about quadratic equations and regarding this the groups are comparable. From another point of view potential varieties of the two groups in the classroom study can be recognized during the process of data-analysis. The frame-data from the participants in the laboratory study, marks for mathematics and results of the DEMAT 9-Test (Schmidt, Ennemoser, & Krajewski, 2013) reveal that this is a mixed group regarding the level of general mathematical skills. For the classroom study frame-data couldn't be collected. The teacher reported that both classes show no abnormality regarding the level of general mathematical skills.

In the laboratory study, the participants had to process three tasks. In the first task, a quadratic equation was given and the students were asked to create new equations by varying the given one. In the second task, they had to solve five quadratic equations of different types to check which strategies the students use to solve the equations.

The third task, which is at the centre of the study, is a meta-task like the first one. 20 quadratic equations were given on cards of carton and the participants had to assort them. These equations represent the different categories shown in the didactical map of quadratic equations, e.g. the equations discussed in the introduction are part of the selection. The number 20 was chosen based on the time needed to get an overview of the equations and the capacity of the visual field. There were no rules given and the participants had all freedom to assort the equations as they like. It was remarked that there was not only one possibility to assort them. While working on the tasks, the participants were video recorded and asked to think aloud. The students were asked to explain the meanings of the features of the groups.

The participants of the classroom study had to process two tasks. The variation-task was left out because the laboratory study showed that the most interesting information of this task was given by the thinking aloud of the participants which was not recordable in the classroom study. Deviating from the laboratory study, the students had to work in pairs on the sorting-task to encourage multiple solutions for the assorting. This seemed to be necessary because there was no researcher beneath the participants during process on the task like in the laboratory study to initiate more than one solution. The participants had to write down their assorting with an explanation of the meanings of the features on a special documentation sheet which referred to a tool used in sorting-tasks in a study with teachers by Zaslavsky and Leikin (2004). Selected pairs of students presented their arguments for assorting and their reasoning in the class which was recorded by video.

The transcriptions of the videos and the documentation sheets for the sorting-task were analyzed with qualitative data analysis methods, like an open coding, with the aim to develop categories (cf. Corbin & Strauss, 2008) of reasoning for assorting and the meanings of the recognized features of the equations. The sorting-task as an analyzingmeta-task is particularly suitable to examine the questions of the study. To process on this task it is insufficient to know a routine to handle quadratic equations. It is necessary to have an explicit look on the features of the equations and to detect the syntactic or semantic differences which are preconditions for flexible algebraic action. By reasoning for assorting, the meanings of the features can be explained. Evaluating the identified categories of assorting and meanings can show how far the mental structures of the students are conducive to or obstructive for flexible action.

DATA ANALYSIS: SELECTED RESULTS OF THE SORTING-TASK

Analyses of the data in the classroom studies reveal that there were six main categories for assorting the equations, which were also found in the laboratory study. These categories and some main sub-categories are shown in Figure 4.

The meanings inferred from the features for assorting the equations were first and mainly evaluated by analyzing the interviews from the laboratory study because the videos contain much more information than the documentation sheets from the classroom study. The meanings can be divided into helpful and conducive to or obstructive for flexible algebraic action. There are also features and meanings which are obscure for flexible action but they show insight into the students' mental concept concerning the dealing with equations. In the following selected examples, features and reasons for assorting are discussed.

One dominating reason for the assorting in the category "Term" was the appearing of brackets in the equations. A lot of participants argued, that terms with brackets had to be expanded to simplify them. This result is in accordance with a result Lima and Tall (2006) found in a study, where the quadratic equation $(x - 3) \cdot (x - 2) = 0$ was (not successfully) solved by the most participants by expanding the brackets. Similar difficulties with equations in this structure were also noticed by Vaiyavutjamai, Ellerton and Clements (2005). The brackets operate as a signal to expand the term regardless whether it is necessary or useful or not. In other studies (e.g., Dreyfus & Hoch, 2004; Wenger, 1987), other signals like radicals or fractions, which evoke routines regardless of the context or the questions that should be answered, were identified. Focussing on such signals could be an indication, that the students do not plan their approach (cf. Wenger, 1987) which is a necessary step in flexible action. Expanding the brackets can prevent an efficient solving process and can lead to mistakes during expansion or the subsequent use of the pq-formula. One reason for this habit can be the way transforming terms is taught. When transforming is called "simplifying" and most of the tasks require expanding products then it is obvious that for most students, brackets have to be expanded in any case. This hypothesis is supported by the explanation that terms with brackets are more complicated, which was remarked by a lot of participants of the laboratory study.

The remarks about brackets often occur together with remarks about solving methods. The participants describe that it is more difficult to isolate the variable when it occurs in brackets. This argument mirrors the strategy for linear equations, i.e. isolating the variable on one side of the equation, which was used in the solvingtask for 26.8% of the equations (from all samples) but successful only for 45.1% of these equations. The correct solutions with this strategy were all produced for the equation $(x - 8)^2 = 0$ by using the inverse operations or arguing with the semantics of

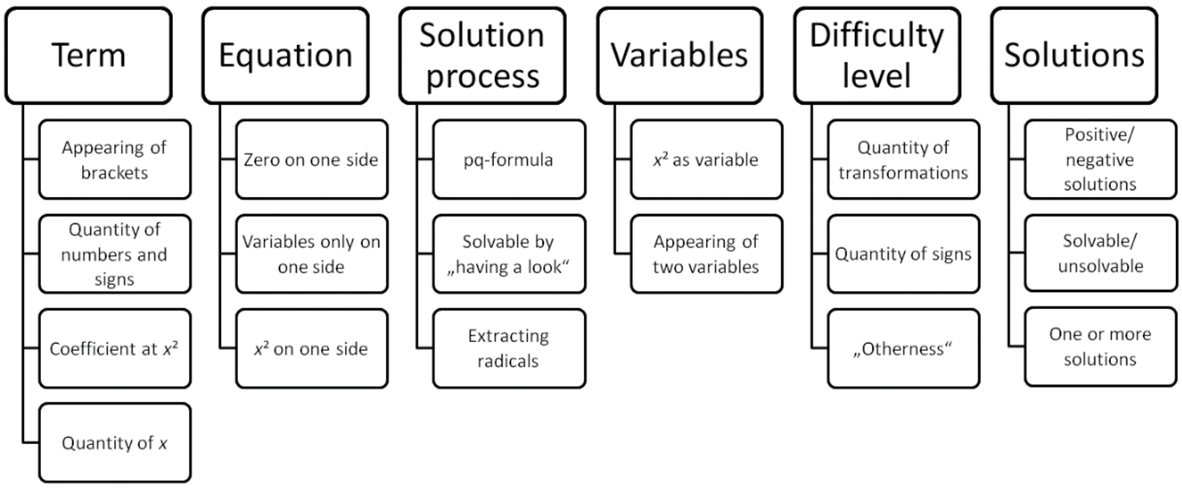

Figure 4: Categories and main sub-categories of assorting quadratic equations

this equation. The other strategies used for isolating the variable, misapplied on equations for which the pq-formula or factorizing is a suitable solving method, were division by the variable x or eliminating the exponent of x^2 by a division by 2, by extracting radicals just from this monomial or by summarizing monomials with different exponents. These faulty strategies of isolating the variable are all related to the idea of solving the equation by extracting the linear variable on one side of the equation to find the solution then on the other side. This is the idea of solving linear equations which works for quadratic equations only in special cases. Obviously, a generalization of this strategy leads to the effect that it is used in situations where it is unsuitable. The argumentation of the participants in the sortingtask points to a lower level of understanding of the concept of equations in general and especially of different types of equations like linear and quadratic equations. This hypothesis is promoted by results of studies about the understanding of equations (e.g., Lima & Tall, 2008). The isolation-strategy, which evokes the expanding of brackets, is opposed to strategies for solving quadratic equations where brackets are produced when factoring a term or where the brackets indicate a simple way to find the solutions because they show that the term is a product.

A more general problem is the mentioned difficulty to identify the equations as quadratic when brackets are appearing. This topic responds to the aspect of symbol sense in algebra in the context of understanding the meaning of variables and parameters in equations (cf. Postelnicu & Postelnicu, 2015) and to the ability to anticipate the effect of transforming terms.

Another feature that appeared in the category "Equation" for nearly every participant as a category was the presence of zero on one side of the equation. In contrast to the reasons of the importance for the occurrence of brackets, no blocking points for flexible action were found in the argumentation for this feature. However, only one pair of students in the classroom study explained, that the occurrence of zero on one side of the equation is the necessary precondition to use the pq-formula or to find the solutions when the term on the other side is a product. A lot of participants explained that zero on one side is necessary to use the pq-formula. This explanation is not wrong, but it was referred to all equations with zero on one side, regardless of the type and structure of the term on the other side of the equation, e.g. $(x-3)(x+5)=0$ or $4x^2-10=0$ which can be easily solved by the fact that a product should be zero or by extracting a radical. The students focussed only on one single feature not following the need to analyse potential sub-features of this group of equations. If this feature works as a signal to use the pq-formula, it can be obstructive for flexible algebraic action. This is as much more remarkable when looking on the results of the solving-task. From all samples 34.3% of the equations were solved by using the pq-formula, 70.3% of these correct. This indicates, that the pq-formula as a standard-method is not executed as well as you can expect for a standard algorithm. These results are compatible to a study by Lima and Tall (2006) where most participants solved quadratic equations with trial-and-error or with the pq-formula, but mostly unsuccessfully. Similar to this focussing on only one single feature, for the feature x^2 on one side of the equation some participants argued that if x^2 is on one side, extracting radicals is a suitable solving method without regarding what is on the other side of the equation, e.g. $x^2=x$ or $x^2=-16x-64$. Following the faulty meaning of this feature and the revealing solving method can produce individual faulty strategies to handle the other side and wrong solutions.

Another explanation for assorting by zero on one side was that there are special rules to be regarded when a zero appears. It is true that the special rules (like division by zero is not possible) are valid for handling equations. This argumentation, at a first glance, seems not to be connected to flexibility therefore it is neither conducive to nor obstructive for flexible action. But if this is the only and dominating importance of this feature in the awareness of the students, it can overlay meanings which are important for flexible action and in this way it can be obstructive.

CONCLUSION

The first data analyses of the sorting-task show some important findings regarding the competencies of flexible algebraic action in the context of quadratic equations. A lot of explanations in the sorting-task which can be obstructive for flexible action were identified and only a few participants show that their understanding of quadratic equations and solving methods is based on a concept of flexibility. The qualitative analyses used in this study are appropriate to identify the reasons for the established deficits. This knowledge can be used to develop improvements for teaching. The results show that some problems the students have with quadratic equations are founded in the teaching of previous topics (like transforming terms and the dominance of expanding brackets). Other problems like focussing just on one feature (e.g. zero on one side or x^2 on one side) should be addressed in the lessons by using suitable types of tasks which focus not on finding solutions of equations but on classifying different types of equations. It would seem that the meta-tasks, used in this study, have the potential to be a useful tool for the design of mathematic lessons which aim to enable the learners to act flexibly.

Connections between algebraic thinking and reasoning processes

Maria Chimoni and Demetra Pitta-Pantazi

University of Cyprus, Department of Education, Nicosia, Cyprus, chimoni.maria@ucy.ac.cy

The aim of the present study is to investigate the relationship of algebraic thinking with different types of reasoning processes. Using regression analyses techniques to analyze data of 348 students between the ages of 10 to 13 years old, this study examined the associations between algebraic thinking and achievement in two tests, the Naglieri Non-Verbal Ability Test and a deductive reasoning test. The data provide support to the hypothesis that a corpus of reasoning processes, such as reasoning by analogy, serial reasoning, and deductive reasoning, significantly predict students' algebraic thinking.

Keywords: Algebraic thinking, cognitive mechanisms, reasoning processes.

INTRODUCTION

In recent years, researchers, policy makers and curriculum designers have recommended that algebraic thinking should become central to all students' mathematical experiences across K-12 grades (e.g., NCTM, 2000; RAND Mathematics Study Panel, 2003). The realization of this need stems primarily from the fact that algebra and algebraic thinking are closely linked to the development, establishment and communication of knowledge in all areas of mathematics, including arithmetic, geometry and, statistics (NCTM, 2000). Secondly, students' abrupt and isolated introduction to algebra in the middle school has led them to experience difficulties in understanding core algebraic concepts (Cai & Knuth, 2005).Thirdly, it has been argued that the mere focus of elementary mathematics on arithmetic and computational fluency deprives the conceptual development of mathematical ideas (Blanton & Kaput, 2005). Fourthly, the call for reconceptualising the nature of school algebra across all grades is underlined by the belief that algebraic thinking is within the conceptual reach of all students. This belief is supported by several research findings which offer evidences that as early as the elementary grades students are able to develop algebraic thinking in supportive classroom environments (e.g., Radford, 2008). Moreover, available research provide insights into appropriate pedagogical factors, such as curriculum materials, technological tools, and instructional strategies that facilitate this development (e.g., Blanton & Kaput, 2005).

Despite the considerable advances in the field, still realizing and achieving the goal for developing algebraic thinking as early as the elementary grades is challenging. The NCTM's research agenda (Arbaugh et al., 2010) highlighted that a main topic of focus is the identification of mathematical concepts and reasoning processes which facilitate the learning of algebra. English (2010) also stressed that one of the main priorities in the field of mathematics education is to define the key mathematical understandings, skills, and reasoning processes that students need, in order to succeed in mathematics. In this context, the present study aims to unfold the relationship between algebraic thinking and specific reasoning processes. This analysis might provide useful insights onto the skills which enable younger students to think algebraically. Students of the 4th, 5th, 6th and 7th grades were selected, in order to illuminate the ways by which abilities involved in reasoning processes might facilitate or restrict algebraic thinking within this age range.

THEORETICAL FRAMEWORK

The notion of algebraic thinking

Several researchers made efforts to analyze the nature and content of algebraic thinking, focusing on what individuals do and the way in which their abilities for generalizing and using symbols develop. One of the most influential developments of the past decades in respect to conceptualizing the notion of algebra as a multidimensional activity is Kaput's theoretical model. Kaput (2008) specified that there are two core aspects of algebraic thinking: (i) making generalizations and expressing those generalizations in increasingly, conventional symbol systems, and (ii) reasoning with symbolic forms, including the syntactically guided manipulations of those symbolic forms. In the case of the first aspect, generalizations are produced, justified and expressed in various ways. The second aspect refers to the association of meanings to symbols and to the treatment of symbols independently of their meaning. Kaput (2008) asserted that these two aspects of algebraic thinking denote reasoning processes that are considered to flow through varying degrees throughout three strands of algebraic activity: (i) generalized arithmetic, (ii) functional thinking, and (iii) the application of modeling languages for describing generalizations.

This conceptualization breaks down the wide field of algebraic thinking into major components of mathematical activity. Furthermore, Kaput's (2008) ideas articulate ways in which algebraic activities might be applied both in early and secondary school algebra contexts.

Algebraic thinking and reasoning processes

The view of algebraic thinking reported above focuses on the establishment of generalizations, taken to mean the detection and expression of structure and a growing understanding of symbolization. This approach raises the question: "which are the cognitive mechanisms that regulate this process?". English and Sharry (1996) show that analogical reasoning constitutes an essential mechanism when students resolve algebraic tasks. Specifically, they describe analogical reasoning as the mental source for extracting commonalities between relations and constructing mental representations for expressing generalizations. For example, the action of noticing differences and commonalities among different expressions of equations is considered as cognitive in nature and includes the formulation of a generalized concept that does not completely coincide with any of its particular cases.

Likewise, Radford (2008) developed a definition of the process of generalizing a pattern which unfolds the involvement of various forms of reasoning:

> Generalizing a pattern algebraically rests on the capability of grasping a commonality noticed on some particulars (say $p_1, p_2, p_3,..., p_k$); extending or generalizing this commonality to all subsequent terms ($p_{k+1}, p_{k+2}, p_{k+3}, ...$), and being able to use the commonality to provide a direct expression of any term of the sequence. (p. 84)

As the quotation suggests, this process first involves the identification of differences and similarities between the parts of the sequence – described as analogical reasoning by English and Sharry (1996). Then the commonality founded is generalized through predicting a plausible generalization. This stage is considered by Rivera and Becker (2007) as abductive in nature since it is abductive reasoning that boosts conjecturing and adopting a hypothesis that is considered testable. Finally, the tested commonality becomes the basis for inducing the generalized concept of the sequence. Here, the role of inductive reasoning is considered as pivotal (Ellis, 2007).

The role of processes of induction and deduction has also been highlighted by recent literature. Ayalon and Even (2013) emphasized the role of inductive reasoning when students investigate algebraic expressions. Martinez and Pedemonte (2014) have shown that a prerequisite for linking inductive argumentation in arithmetic and deductive proof in algebra is the co-existence of arithmetic and algebra for supporting the arguments developed within an argumentation.

METHODOLOGY

Research Question

The purpose of the present study is to investigate the way specific reasoning processes influence achievement in tasks that examine their algebraic thinking. Specifically, the present study addresses the following question: *Is there a relation between specific reasoning processes and individuals' algebraic thinking abilities?*

Participants

The participants were 348 students that were selected by convenience from four different schools. The students were divided to four age groups: 55 were students of Grade 4 (10 years old), 89 were students of Grade 5 (11 years old), 101 were students of Grade 6 (12 years old) and, 120 were students of Grade 7 (13 years old). Taking into consideration the fact that the data collection instruments would be the same for all of the participants of the study, no younger or older groups of students were selected. On the one hand, third grade students would not be able to manipulate the tasks, probably due to developmental reasons and absence of experience. On the other, eighth grade students were considered as more skillful in solving algebraic tasks due to their intensive involvement in algebra courses.

The tests

The participants were tested with three tests. Forty minutes were allowed to complete each of the three tests.

Algebraic thinking test

The test consisted of 25 tasks that were adapted from previous research studies related to the notions of algebra and algebraic thinking or algebraic proof (e.g., Blanton & Kaput, 2005; Mason et al., 2005) and past studies that evaluated students' mathematical achievement in international or national level (e.g., TIMSS, 2011; NAEP, 2011; MCAS, 2012). These were accordingly categorized into four groups:

(a) The use of arithmetic as a domain for expressing and formalizing generalizations (generalized arithmetic). These tasks involved solving equations and inequalities. The participants had to treat equations as objects that expressed quantitative relationships, without any reference to the meaning of the symbols.

(b) Generalizing numerical patterns to describe functional relationships (functional thinking). These tasks required finding the n^{th} term in patterns and functional relationships and expressing them in a verbal, symbolic or any other form.

(c) Modeling as a domain for expressing and formalizing generalizations: These tasks required the expression and formalization of generalizations by analysing information that are presented verbally, symbolically or in a table.

(d) Algebraic proof: These tasks reflected different activities and associated abilities of algebraic proof. For example, one of these tasks required the use of a generalization that was previously established (what is the sum of two odd numbers) for building a new generalization (what is the sum of three odd numbers).

The first three groups reflected the three strands of algebra as these were described by Kaput's (2008) theoretical framework. The fourth group was added to the test addressing the strand of algebraic proof. The examination of the construct validity of the items in the test to measure the factors of algebraic thinking was assessed through Confirmatory Factor Analysis using the MPLUS statistical package. The results indicated that the data fit the model well (CFI=0.95, x2=103.345 df=131, x2/df=1.19, RMSEA=0.03), verifying the structure of the proposed model. Table 1 presents examples of tasks for each of the four categories.

The Naglieri Non-Verbal Ability Test (NNAT)

The NNAT measures cognitive ability independently of linguistic and cultural background (Naglieri, 1997). There are seven different levels of the test corresponding to different age-groups of students. The test is a matrix reasoning type of exam that contains patterns formed by shapes that are organized into designs. All the tasks are multiple choice and students are asked to choose the answer that best completes the pattern.

Generalized Arithmetic	The sum ***245676 + 535731*** is odd or even number? Explain your answer.
Functional thinking	Bill is arranging squares in the following way. How many squares there will be in the 16th figure? Figure 1 Figure 2 Figure 3 Modeling as a domain of expressing and formalizing generalizations	Joanna will take computers lesson twice a week. Which is the best offer? **OFFER A:** €8 for each lesson **OFFER B:** €50 for the first 5 lessons of the month and then €4 for every additional lesson
Algebraic Proof	What is the sum of three odd numbers?

Table 1: Examples of tasks in the algebraic thinking test

The NNAT was selected among other tests that are used extensively for assessing students' cognitive ability due to the fact that the NNAT includes different categories of questions which reflect different types of reasoning skills. Specifically, it contains four different groups of questions: pattern completion, reasoning by analogy, serial reasoning and spatial visualization.

Based on available mathematics education literature, the reasoning processes that seem to be related to algebraic thinking and at the same time are measured by the NNAT are:

(a) Reasoning by analogy: In this category of items, students have to recognize commonalities between several geometric shapes and determine which answer is correct by focusing on how the objects change as one moves across the rows and down the columns in the design. Correspondingly, English and Sharry (1996) have described as analogical reasoning the process where students map similarities between algebraic expressions.

(b) Serial reasoning: The items in serial reasoning matrices are constructed using a series of shapes that change across the row horizontally and the columns vertically throughout the design. As the design moves down the matrix it also moves one position to the right, creating a series of designs that changes over the matrix. Students have to identify where the sequence finishes and starts again from a different starting point. The strategy that students follow in this kind of items shares common features with inductive reasoning. According to mathematics education literature, inductive reasoning is pivotal when students explore pattern sequences (e.g., Rivera & Becker, 2007). In these tasks students have to make generalizations, based on recognizing that a series of numbers or figures constitute a sequence that follows a specific rule.

The NNAT test' reliability was tested with norms based on a sample of more than 100,000 students (Naglieri, 1997). In this study, the internal consistency of scores measured by Cronbach's alpha was satisfactory for the NNAT test (a=0.84).

Deductive Reasoning Test

A test on deductive reasoning was constructed, guided by existing theory and research on deductive reasoning. In particular, items in this test were adapted from a test that was used by Watters and English (1995). This test was considered as appropriate due to the fact that it was used and validated for measuring deductive reasoning among students that were approximately of the same age as the participants in the current study. In Watters and English's study, students' performance in the deductive reasoning test was related to their performance in scientific problem solving. In our case, students' performance in the deductive reasoning test will be related to their performance in algebraic thinking. The items in this test represented 10 syllogisms which requested the students to reason deductively. This process included the analysis of premises that describe formal truth relationships, without reference to their empirical or practical truth value and the extraction of a logical fact, result or consequence. The internal consistency of scores measured by Cronbach's alpha was satisfactory for this test (a=0.79).

Analysis

The quantitative analysis of the data was carried out using the SPSS statistical package. Pearson correlation analysis and Regression analyses were performed. This study assumes that reasoning processes (as these are indicated by available literature) might predict algebraic thinking abilities. To test this assumption, Regression analysis was selected since this kind of analysis informs on the way one or more independent variables predicts the variance of a dependent variable.

The assumptions of multilinear regression are met since the Tolerance and VIF values were for all of the independent variables close to 1 (.972, .863, .876 and 1.03, 1.16, 1.14). This fact indicates that the multicollinearity and singularity assumptions are met. Moreover, standardized predicted X standardized residuals plot showed that the residuals did not violate the homoscedasticity of residuals and linearity assumptions.

RESULTS

The question of the present study addressed the relationship between algebraic thinking abilities and specific reasoning processes. Therefore, a correlation analysis was conducted in order to find out whether algebraic thinking and abilities involved in reasoning processes are significantly correlated. According to Pearson indicator, there is a statistically significant correlation between the individuals' achievement in the algebraic thinking test and the NNAT test (R=0.510, p=0.000<0.05). Moreover, the results show that there is a statistically significant correlation between the achievement in the algebraic thinking test and the deductive reasoning test (R=0.278, p=0.000<0.05). These results support previous reports which denoted that successful engagement with algebraic tasks involves several types of reasoning processes.

The nature of the relationship between algebraic thinking and specific reasoning processes was further explained by conducting regression analyses. Specifically, the analysis examined the way in which the achievement in the NNAT test and the deductive reasoning test (control variables) predict the achievement in the algebraic thinking test (depended variable).

Table 2 presents the results of the regression analysis. The B is the regression coefficient and represents the change in the outcome resulting from a unit change in the predictor, whereas, the beta coefficient (β) is the standardized version of the B coefficient where all variables have been adjusted to standard score form (Field, 2005). As the R-square shows, a percentage of 54.2% of the variance can be explained by the independent variables NNAT and deductive reasoning. This result indicates that as achievement in the two tests increases, the total achievement in the algebraic thinking test also increases. NNAT categories and deductive reasoning are indicated as predictors of algebraic thinking abilities. In order to further examine this relationship, multiple regression analysis was conducted with criterion (depended variables) the total achievement in the algebraic thinking test and predictors (independent variables) the abilities in three reasoning processes: reasoning by analogy, serial reasoning, and deductive reasoning. The results of the multiple regressions are presented in Table 3. According to these, all of the three reasoning processes exert a significant influence on the prediction of individuals' achievement in algebraic thinking.

Algebraic thinking	B(SE)	B
NNAT categories	.391 (.040)	.473*
Deductive reasoning	.471 (.122)	.188*
R^2=.542 , *p=.000		

Table 2: Regression Analysis of the achievement in NNAT test and the deductive reasoning test with dependent variable the achievement in the algebraic thinking test

The data show that the factor with the greatest effect on the prediction of achievement in algebraic thinking tasks is reasoning by analogy (β=.308). Serial reasoning also seems to be a significant predictor of individuals' total achievement in the algebraic thinking test (β=.238). Serial reasoning addresses the recognition of sequences and finding changes in the sequence. The abilities involved in the serial reasoning tasks share common features with the abilities involved in activities with pattern. According to the model, deductive reasoning (β=.180) explains a respectable proportion of variance in individuals' total achievement in the algebraic thinking test. It is anticipated that the effect of deductive reasoning could be higher if deductive reasoning was measured through non-verbal methods, as in the NNAT. The deductive reasoning test was not a language-free test of ability. Students from different linguistic groups where tested through a test that involved logical premises written in Greek. In contrast, the NNAT is not dependent on verbal abilities.

Algebraic thinking	B(SE)	B
Reasoning by analogy	.883 (.161)	.308*
Serial reasoning	.962 (.229)	.238*
Deductive reasoning	.452 (.123)	.180*
R^2=.544 , *p=.000		

Table 3: Regression Analysis of the achievement in each of the three reasoning processes with dependent variable the achievement in algebraic thinking test

DISCUSSION

As English (2010) suggested, a priority for mathematics education research is the definition of fundamental skills and reasoning processes which enhance students' efforts for achieving understanding in mathematical learning. NCTM (Arbaugh et al., 2010) also emphasized the need for coherently defining mathematical concepts and reasoning processes that enable individuals to develop algebraic thinking. Motivated by this argument, the present study aimed at examining students' algebraic thinking abilities with different reasoning processes. The importance of this study also lies in the fact that aims to capture a more holistic view of the algebraic thinking concept, by using Kaput's theoretical model as a referent point.

The findings obtained from the quantitative data indicate that students' achievement in algebraic thinking tasks is influenced by reasoning by analogy, serial reasoning, and deductive reasoning. Reasoning by analogy appears to be the factor with the most significant effect on algebraic thinking abilities. This result lends support to the findings of previous studies which indicated a relationship between algebraic thinking and analogical reasoning. According to English and Sharry (1996), analogical reasoning provides the basis for algebraic abstraction in tasks where students have to identify similarities and differences between a group of algebraic equations. Therefore, it seems reasonable to argue that analogical reasoning constitutes a basic process for succeeding in tasks of identifying structure and relationships.

Our findings also suggest that serial reasoning has a significant role in algebraic thinking. This result might be attributed to the fact that serial reasoning shares common features with inductive reasoning. This ability has been reported by related literature as crucial for the engagement in activities of determining pattern rules, recognizing the part that is repeated, and finding not observable terms (e.g., Rivera & Becker, 2008). Deductive reasoning also seemed to account for some variance in the algebraic thinking test. One plausible explanation for this result might be the fact that deductive reasoning is associated to the notion of proof. According to Blanton and Kaput (2005) activities such as using generalizations to build other generalizations, generalizing mathematical processes, and testing conjectures, and justifying reflect categories of algebraic thinking that are interwoven with proof.

As Kaput (2008) recommended, several reasoning processes run through algebraic activities. The analysis of the data provides empirical validation of these ideas and sheds some light on the crucial issue of which might these processes be and what is their nature. Furthermore, these findings can be used for informing educators about the sources that act as means for mastering different forms of algebraic thinking. Future teaching interventions might support the development of different types of reasoning, in order to test advances in developing algebraic thinking. According to English (2011), the key to reach advanced forms of reasoning is the creation of cognitively demanding learning activities in appropriate contexts.

The present study seemed to provide some evidence regarding the associations between students' algebraic thinking and fundamental reasoning processes. Yet, one limitation of the study is the context in which it was conducted. The relationships found in the present study need to be further examined, in other educational systems in which algebraic thinking might be approached through the mathematics curriculum in a different way. In respect to the methodology, a limitation of the study seems to be the fact that analogical reasoning and inductive reasoning were examined with a non-verbal test and deductive reasoning was tested with a verbal test. Future research could examine these associations within tests that follow similar design and features. Also, students of lower primary grades or higher secondary grades could be added to the sample. Finally, future research could identify the associations of algebraic thinking with other core processes and mental operations, in order to approach a wider picture of the algebraic thinking concept.

Which algebraic learning can a teacher promote when her teaching does not focus on interpretative processes?

Annalisa Cusi[1] and Nicolina A. Malara[2]

1 University of Torino, Torino, Italy, annalo@tin.it

2 University of Modena and Reggio Emilia, Modena, Italy, malara@unimore.it

In this paper, we will focus on the effects of teachers' lack of the algebraic knowledge and sensitiveness that are necessary to effectively control the plurality of levels of interpretation involved within activities aimed at making students aware of the meanings associated to their use of algebraic language. Our analysis of class discussions conducted by a group of middle-school teachers involved in university training courses enabled us to highlight profound gaps, between modeling and interpretation, that prevent them from becoming aware of what it is important to stress when facing this kind of activities with students.

Keywords: Interpretative processes, algebraic thinking, algebraic teacher knowledge, teacher education.

FOCUS ON INTERPRETATIVE ASPECTS IN THE TEACHING OF ALGEBRA: KEY ROLE OF THE TEACHER

Since the development of the first studies on the problems related to the learning and teaching of algebra, many researchers reject the previous widespread idea that students' difficulties are mainly related to the complexity of algebraic syntax (see, for instance, Ursini, 1990; Kieran, 1992). The focus has therefore shifted on students' control of the meanings associated to their use of algebraic language. Different studies stress the importance of stimulating them with the aim of fostering their aware use of symbols as tools to represent, communicate, generalize, solve problems, develop reasoning (Arcavi, 1994; Arzarello, Bazzini, & Chiappini, 2001; Kieran, 2004). Bell (1996) states, in particular, that if students are given the possibility to have experience of the use of algebraic symbolism as a tool to express regularities and represent relationships, they could be guided through what he calls the "essential algebraic cycle", characterised by three main typical algebraic activities: to represent, to manipulate and to interpret.

In this work we focus on the third component of the essential algebraic cycle: the interpretative processes that are typical of algebraic activities. When we use the term '*interpretative processes*' we refer both to Duval's (2006) idea of conversions between different representation registers (in the case of algebra, from symbolic to verbal register and vice versa, but also from graphic, to symbolic, to verbal) and to Arzarello, Bazzini and Chiappini (2001)'s model for teaching algebra as a *game of interpretations*. These last researchers highlight, in particular, how the activation of conceptual frames (defined as an "organized set of notions, which suggests how to reason, manipulate formulas, anticipate results while coping with a problem") and the changes from a frame to another and from a knowledge domain to another could represent fundamental steps in the activation of interpretative processes.

The problem of algebraic modeling and of the coordination between verbal and algebraic language have been a central focus of research since the eighties. A paradigmatic study is the one developed by Clement (1982), who documented erroneous approaches developed by science-oriented college students in facing simple kind of algebra word problems. As regard to this problem, Smith and Thompson (2007) suggest that students' difficulties with algebra result not only from algebra curricula that lack meaning and coherence, but also from elementary curricula that fail to develop students' abilities to reason about relationships. This observation has been shared by different research studies developed in the realm of Early Algebra. Blanton and Kaput (2005, 2011), for example, highlight the crucial role played, in elementary school mathematics, by the algebraic reasoning embedded in finding, describing, justifying and symbolizing mathematical relationships between quantities, advocating a functional approach to algebra in the elementary grades. This is in tune with Kieran (2004), who refers to the shift of focus from the calculation of numerical answers to the relationships between quantities as one of the fundamental adjustments that students should make in their transition from arithmetic to algebra. This vision is in tune with the approach that we have developed within the ArAl Project (see, for instance, Cusi, Malara, & Navarra, 2011), aimed at proposing a relational and linguistic approach to Early Algebra and also meant to constitute an integrated teacher education program.

A recent study by Magiera, van den Kieboom and Moyer (2013) has highlighted that pre-service middle school teachers demonstrated a rather limited ability to recognize the full potential of algebra-based tasks to elicit algebraic thinking in students. They suggest, therefore, that there is a need of making teachers understand the contexts in which the various features of algebraic thinking might arise in order to enable them to effectively engage students. In tune with these results, Strand and Mills (2014), in their survey of research literature on prospective elementary school teachers' knowledge of algebra, state that it is well documented that these teachers tend to struggle to effectively interpret and use algebraic symbols (even those that they have produced themselves), to interpret graphical representations and to make connections between representations.

Our experience as teacher educators enabled us to observe similar problems also in the Italian context. Although research results about the importance of guiding students through the whole essential algebraic cycle have been widespread, Italian teachers are frequently not used to focusing on interpretative aspects. As a result, formalism and application dominate. This requires us to shift the focus on the teacher knowledge of the interpretative aspects connected to algebraic thinking and on the effects of this knowledge on students' learning. A framework to identify the knowledge for teaching school algebra has been developed by McCrory, Floden, Ferrini-Mundy, Reckase and Senk (2012), who stress the role played by teachers' capability of selecting, applying, and translating among mathematical representations and of making connections between manipulatives and mathematical ideas explicitly. But this way of behaving in the class must be educated. In order to foster teachers' overcoming of these difficulties and their effective approach in guiding students in the transition from arithmetic to algebra, in our in-service training courses for middle-school teachers we propose specific laboratorial activities focused on this theme.

In this paper we will present the main results from the analysis of the first of these activities, which was aimed at making trainee-teachers (in the following TT) directly experience how (and if) they are able to foster students' activation of interpretative processes during whole class discussions about a task involving proportional relations. In particular, we will highlight how this analysis enabled us to document the effects, in the way TT conducted class processes, of their lack of the specific knowledge that could favour students' development of interpretative attitudes.

METHODOLOGY OF WORK WITH TRAINEE-TEACHERS

The laboratorial activity we present was the first one proposed to a group of 58 middle-school (grades 6–7–8) TT involved in a training course aimed at making them achieve a teaching qualification. This course, which lasted six months, was specifically devoted to temporary teachers that have been working in school for at least three years. In Italy, in fact, also people who do not have a teaching qualification could work as teachers in school. As regards, in particular, the middle-school context, mathematics is mainly taught by teachers who do not have a mathematics background (their degrees could be in biology, chemistry, natural science, geology...).

During the whole training period, the TT attended to different courses in Mathematics Education, carried out by the authors themselves and by another colleague involved in the ArAl project. Many lessons were devoted to the problem of the teaching of algebra, with a specific focus on the main new trends in Early Algebra and on the role played by the teacher in the class. The first laboratorial activity in which the TT were involved was focused on a problem that we are going to analyse in detail in the following section. The

TT were asked to propose the problem to their students and to carry out its resolution during a whole class discussion. This is the text of the problem:

"A florist sends to a flower grower an email, asking to send him plants of sage and rosemary. However he does not indicate the exact number of plants, but specifies that for every 4 plants of sage he wants 6 plants of rosemary. Let r represents the quantity of plants of rosemary and s the quantity of plants of sage. Represent: (a) the relation between these two quantities; (b) the number of plants of sage through the number of plants of rosemary; (c) the number of plants of rosemary through the number of plants of sage.

Draw, in the Cartesian plane $O(r, s)$, the graph of the relation that expresses the quantity of plants of sage through the quantity of plants of rosemary. Then draw, in the plane $O(s, r)$, the graph of the relation that expresses the quantity of plants of rosemary through the quantity of plants of sage.

The flower grower delivers 66 plants of sage and tells him that he will send later the plants of rosemary. How many plants of rosemary does he have to deliver?"

This problem can be located among the activities, usually proposed in grade 7, which are aimed at linking the discrete arithmetic of natural numbers to the arithmetic of rational and real numbers.

We have chosen this specific problem because it could be both faced: (1) Adopting an "arithmetical approach" – typical of the Italian school tradition – focused on the application of properties of proportions; (2) Referring to an idea of proportionality as a functional relation, idea that could open the way to the development of algebraic reasoning. The approach that we have suggested TT to adopt in their classes was the second. Our aim was, in fact, to make them become aware that classical problems that, according to the Italian school tradition, are usually faced through the application of "rules" could instead be solved through the study of relations and, therefore, through the activation of an interesting game of interpretations. This approach to the resolution of the problem involves, in fact, the intertwining of different interpretative levels (as we will highlight in the next section) and the activation of different representations of the proportional relation involved.

The objectives of the problem and the main processes to be activated during a class discussion on its resolution were therefore shared with TT with the aim of making them recognise the potential of the task to elicit algebraic reasoning in students.

RESEARCH AIMS AND RESEARCH METHODOLOGY

In this paper we are going to focus on our analysis of the transcripts of the class discussions conducted by TT. Our main aim is to highlight what kind of difficulties they faced when they implemented the problem in their classes, trying to follow our suggestion of adopting an 'algebraic approach' to its resolution (namely an approach focused on the algebraic representation of the relation involved and aimed at the activation of different interpretative processes).

In the following we will analyse the problem introduced in the previous paragraph. This a-priori analysis of the problem has two main aims:

(1) The first aim is to highlight the multifaceted interpretative processes that could be activated in its resolution. Since this analysis was shared with TT, this "hypothetical" resolution represents also the path that they were asked to follow when facing the problem during the whole class discussions with their classes.

(2) The second aim is to identify specific indicators for our analysis of the transcripts of the class discussions conducted by TT. These indicators refer to the games of interpretations and the meta-level reflections that TT should have tried to develop in their interaction with students.

Analysis of the problem and identification of the indicators for the analysis of the way TT guided their classes in its resolution

As we stated above, if we focus on an "algebraic approach" to the resolution of the problem, it could be characterised by a deep twine between aspects related to the use of different representation registers and aspects related to the activation of interpretative processes at different levels.

To carry out the task in the class the teacher should initially guide students in the analysis of the text of the problem and in the identification of the key verbal relation that has to be translated into a mathematical sentence. This requires considering proportions between couples of numbers that exemplify the relation itself and their classical representation (i.e., 8:12=4:6, 12:18=4:6...), then translating them into fractional terms (i.e., 8/12=4/6, 12/18=4/6...).

A discussion aimed at a real sharing of the meaning of the letters *r* and *s*, introduced in the text of the problem, should precede the formalization of the relation between the number of plants of sage and the number of plants of rosemary. The possible formalizations of this relation should be compared and interpreted through their verbalisation. For instance: if the relation is represented through the proportion , it can be interpreted as "the quantity of plants of sage is to the quantity of plants of rosemary as 4 is to 6"; but it could also be represented through , that can be interpreted as "the fourth part of the quantity of plants of sage is equal to the sixth part of the quantity of plants of rosemary"; etc. This moment, devoted to the interpretation of the formalizations proposed by students, prevents from the uncritical acceptance of erroneous symbolic formalizations such as , where letters play the role of simple labels.

During this discussion, the teacher should also foster the representation and subsequent verbal interpretation of the previous proportions in terms of equivalence between fractions. This leads to the required representation of the number of plants of sage through the number of plants of rosemary and vice versa. For example, starting from the equality and the simplified , the class could interpret the latest as "the ratio between *s* and *r* is 2/3" and then as "*s* is 2/3 of *r*", that can quickly lead to , which is the required symbolic representation of the number of plants of sage through the number of plants of rosemary.

After the identification of the two representations – and – of the relations between *s* and *r*, another interpretative process should be activated: the particularization of the two formulas through the analysis of specific numerical cases, which could foster students' acquisition of the concept of variable. The couples of values determined through this particularization could be inserted into two tables that better enable to highlight the interrelations between one couple of values and the one that is obtained inverting the values.

After the construction of the two required graphs through the identification of the points corresponding to the couples of values collected in the two tables, the teacher should guide students in noticing that, although the alignment of the points could induce the idea of drawing a continuous line, not all the couples of numbers that are solutions of the two equations are also representatives of the phenomenon that has been modelled. Another aspect to be discussed in this phase is the pertinence of the solution $r = 99$, $s = 66$ according to the florist's request. These observations could be followed by a geometrical examination of the model, discussing the meaning of the two ratios 2/3 and 3/2 and introducing the neutral reference system (x,y) to compare the graphs of the two equations and empirically identify their geometrical relation.

This analysis enabled us to identify four main key-phases that characterise the resolution of the problem and four main groups of indicators, corresponding to the different phases, which are summarised in the Table 1.

As we stated above, this a-priori analysis was shared with TT before they proposed the problem to their classes. TT were asked to audio-record the discussions they conducted with their students and to reflect on these discussions referring to three different perspectives: the mathematical content at play, the role played by the teacher, the students' approaches to the problem and reactions to the teacher's interventions. After they performed this task, they sent us both the transcripts of their class discussions and the corresponding reflections.

We therefore analysed both the transcripts themselves and the reflections of the TT and the results of our analysis were discussed with them during a further lesson. In this paper, because of space limitations, we are focusing only on our analysis of the transcripts of the discussions of the TT, aimed at highlighting the difficulties they faced when they implemented the problem in their classes trying to follow our suggestions. The transcripts' analysis, whose main results will be presented in the next section, was performed referring to the four key-phases and the corresponding indicators that we have identified thanks to the a-priori analysis of the problem.

Key-phases in the resolution of the problem	The teacher guides the students in the:
Phase 1: *The transition from proportions to the formalization of the proportionality law*	Identification of the couples of numbers that satisfy the condition required in the problem; Generalization and corresponding construction, through the introduction of letters, of the proportions representing the relation between the two quantities; Verbalization of the constructed proportions; Interpretation of the proportions in fractional terms.
Phase 2: *The twine between syntactical and semantic aspects in the transition from the implicit forms of the relation to its two explicit forms*	Control of the syntactical transformations that lead to the two explicit formulas; Identification of the calculation process subtended to each formula; Verbalization of the meaning expressed by each formula; Conceptualization of the letters as variables and identification of their different roles (independent vs dependent variable); Discovery of the predicting power of each formula; Conceptualization of each formula as an equation and of the couples of numerical values that verify it as solutions of this equation; Discovery of the direct connection between the two formulas and exploration of the interrelation between their solutions.
Phase 3: *The representation of the two relations on the Cartesian plane.*	Coordination between symbolic and graphic registers to represent the graphs of the two formulas in the Cartesian planes (r,s) and (s,r); Re-nominalization of the variables to represent both the formulas in the Cartesian plane (x,y); Interpretation of the graphs in relation to the problem and discovery of their predicting power.
Phase 4: *Control of the adherence of the mathematical model to the specific problem-situation.*	Comparison between the domain and codomain of each relation and the domain and codomain of the corresponding restrictions that model the problem-situation; Reflection on the acceptability of certain couples of values (e.g., $s = 66$ and $r = 99$) as solutions of the problem.

Table 1: Indicators for the analysis of the transcripts of the discussions conducted by TT in their classes

DATA ANALYSIS: IDENTIFICATION OF SOME PROBLEMATICAL ASPECTS IN THE DISCUSSIONS CONDUCTED BY TT

Through our analysis of discussions of TT we have identified specific problematic aspects, connected to their incapability of guiding students within the games of interpretation and reflection necessary to make them develop those competencies and awareness that are objectives of an "algebraic approach" to this kind of activities.

As regards the first phase in the resolution of the problem (*the transition from proportions to the formalization of the proportionality law*), some TT were not able to support students in abandoning the quantitative/ numerical level. They adopted a procedural approach, making students only formulate the numerical proportions necessary to determine the couples of values that satisfy the relation and directly construct the graphs from the table of values. The modeling process was therefore inhibited.

In some classes students were able to formulate different proportional laws starting from the numerical examples they constructed, but the TT accepted all these laws without asking students to interpret them through their verbalization. Many TT declared, during the class discussions, that "all the constructed proportions are the same proportion", instead of highlighting that, although their equivalence, the relations expressed by these proportions are different. This erroneous conception, probably induced by some textbooks, could be overcome only through the activation of interpretative processes.

As regards the second phase in the resolution of the problem (*the twine between syntactical and semantic aspects in the transition from the implicit forms of the relation to its two explicit forms*), we have highlighted a really alarming phenomenon. Most of the TT did not support students in controlling and discussing the meaning of the two formulas derived from the proportional laws. In fact, very few of them made students analyse the formulas through their particularization to introduce the role played by the letters as variables;

almost none of them made students verbalize the formulas they had determined.

Another problematical aspect connected to this phase is that different TT often used terms such as "find *s/r*; search for *s/r*; calculate *s/r*" – instead of "make *s/r* explicit" or "express *s/r* through *r/s*" – to invite students to construct the two explicit formulas. Also the use of this procedural language inhibits the conceptualization of variable. Finally, most of the TT guided students in the determination of the two explicit formulas starting from the constructed proportions, but they did not highlight how they could be obtained from each other, nor foster a reflection on their relationships.

As regards the *third phase* in the resolution process (*the representation of the two relations on the Cartesian plane*), an aspect that we have highlighted is that some TT let that students construct the graphs determining the couples of values that are solutions of the two explicit equations through proportions, without stressing on the predicting power of the two formulas. In our view, this behaviour testifies that they conceive the modeling phase as something unnecessary and that they do not interpret the two formulas as the representation of all the possible pairs of numbers having the same ratio. Moreover, the fact that students do not refer to the formulas in constructing the graph is an evidence of a lack in their control of the meaning that the formulas convey.

Another widespread problem related to the capability of TT of coordinating the verbal, the algebraic and the graphic registers is that, although many TT examined with students the geometrical properties of the graphs, almost none of them made students interpret the graphs, highlighting their predicting power. Moreover they accepted continuous lines or semi-lines as graphs of the relations, without developing a reflection on the fact that only some points of these lines are representatives of the phenomenon that has been modelled.

This last aspect is also connected to the problematic ones that we have noticed in analysing the discussions of the TT according to the indicators concerning the *fourth phase* of the resolution process (*control of the adherence of the mathematical model to the specific problem-situation*). Few TT, in fact, made students reflect on the domain and codomain of the relations that model the problem-situation and on the acceptability of certain couples of values as solutions of the problem (during most of the discussions the value 66 as a possible number of plants of sage was uncritically accepted).

CONCLUSIONS

Through the analysis of the transcripts of discussions of TT, we highlighted that, although they had shared with us the aims of the activity and the *a priori* analysis of the problem, many of them were unable to activate the necessary interpretative processes and meta-level reflections and therefore to exploit the potential of this task to elicit algebraic reasoning in students.

The evident blocks in the games of interpretation that should have been activated during the class discussions testify corresponding profound gaps in the knowledge of the TT. These gaps, in fact, prevent them from becoming aware of what it is important to stress when facing this kind of activities with students. If teachers do not overcome these difficulties, they will not be effective models for their students, making them develop erroneous attitudes. This is a crucial problem in the didactic of algebra, because of the plurality of levels of interpretation that a teacher is required to effectively control.

These results suggest that research should better scrutinize teachers and students' difficulties in coordinating the different levels of interpretation often involved in the algebraic activity, in order to identify possible strategies to overcome them. At the same time, as it was also stressed in the discussion within the TWG03, a reflection should be developed on how teacher education programs must be engineered according to these results with the aim of enabling teachers to become effective activators of interpretative processes.

Does bodily movement enhance mathematical problem solving? Behavioral and neurophysiological evidence

Diana Henz[1], *Reinhard Oldenburg*[2] *and Wolfgang I. Schöllhorn*[1]

The present pilot study investigates how bodily movement and mental motion interact during solving of different types of mathematical tasks. In an experimental study, subjects performed algebraic, geometric, and numerical reasoning tasks at three complexity levels under static and dynamic postural control affordances during sitting. Electroencephalographic brain activity was recorded at resting baseline and during all experimental conditions. Results support the hypothesis that bodily movement has a positive effect on cognitive processing of demanding cognitive tasks. Moreover, our results indicate that mental symbolic transformations are processed within a visuo-motor representation that is aligned with the mental representation of physical space.

Keywords: Mental motion, bodily movement, electroencephalography.

INTRODUCTION

Current research in cognitive science demonstrates close interrelations between the cognitive and the motor system. One interesting research question for teaching and learning mathematics is how bodily movement interacts with cognitive processing of mathematical problems, both in learning of concepts and in the application of learned procedures. Recent research shows that spatial abilities predict mathematical performance (Tosto et al., 2014), but it is unclear how this correlation depends on the specific type of the task. Moreover, this influence may result from prior learning that has been influenced by bodily experiences or by bodily movement during cognitive task processing. In the present study, we focus on mathematical thinking that might have been developed using metaphors that ultimately build on experiences of moving in space. We assess students' behavior in terms of mathematical performance, and measure the corresponding electrical brain activity during solving mathematical tasks under different manipulations of movement behavior.

Bodily movement and cognitive performance

Ongoing research has demonstrated effects of bodily movement on cognitive and psychological functioning (for a meta-analysis see Etnier, Nowell, Landers, & Sibley, 2006). Positive effects of moderate aerobic exercise have been shown for attentional, executive, and sensorimotor task performance (van der Niet, Hartmann, Smith, & Visscher, 2014). A large body of research shows close interrelations between the cognitive and the postural control system (e.g., Hwang et al., 2013). To test interactions between the cognitive and motor or postural control system, usually a dual task paradigm is administered in an experimental setting in which participants are asked to perform two tasks, one task taxing motor, and the other task cognitive demands, at the same time. Most studies show that performance is affected in either one or both tasks depending on task difficulty and type of tasks administered compared to conditions where only one task has to be performed. One explanation is that cognitive processing is impaired when two tasks are performed taxing the same informational processing subsystem and therefore occupy its capacity, completely. For instance, the famous working memory model proposed by Baddeley and Hitch (1974) postulates specific subsystems, one for verbal, and the other for visuo-spatial information processing where cognitive resources are allocated depending on their coding format. Several studies have shown that movement information and visuo-spatial information are processed within the same subsystem. This was shown for spatially directed movements (e.g., Logie & Della Sala, 2005), and gestures (Rumiati & Tessari, 2002).

Bodily movement and mathematical problem solving

The famous book "Where mathematics comes from" by Lakoff and Núñez (2000) puts out the strong thesis that "all abstract ideas are built by metaphors that are based on experience made possible by our body interacting with the physical world" (p. 496) and thus has triggered research in mathematics education that investigates the role of bodily movement in learning and explaining mathematics. A similarly strong conception is found in Wittmann , Flood and Black (2012):

> All human concepts, including mathematical concepts, are based in the perceptual motor system experiences we have while interacting with the world around us.

With this background they investigate gestures of mathematics students while solving differential equations and formulate and give support for the hypothesis that algebraic symbols are moved during computation in a way similar to physical objects. When students multiply an equation by a denominator d their behavior is consistent with the view that d moves along some path from one side of the equation to the other.

In judging the strong claim that all mathematical concepts are formed by metaphors that are based on bodily experiences it might be useful to introduce the notion of 'metaphorical distance'. Concepts that are directly linked to bodily experiences have a short metaphorical distance to bodily experiences, while others may have a long distance that spans a chain of metaphors. It seems likely that concepts with smaller metaphorical distance to bodily experience might be stronger related to other concepts with short distance to similar bodily experiences. We suppose, although we have no a-posteriori empirical evidence for this, that the metaphorical distance increases, e.g., in the following sequence: spatial rotation, moving symbols in equations, applying inverse operations, performing algorithms of numeric calculations. This line of argumentation suggests that arithmetical tasks are affected less by bodily movement than spatial geometry tasks or algebra tasks that afford moving symbols mentally.

Besides the metaphorical distance another dimension concerns the question whether bodily experience was essential in forming the concepts but is no longer relevant when these concepts are applied or if actual bodily experience (such as movements or gestures) becomes relevant during applications.

Further, we elaborate the above mentioned point that algebraic sub-expressions may be moved in a way similar to physical objects. It is interesting to note that researchers from different teaching traditions have noted that students tend to use the language of moving objects (e.g., Tall, 2013, p. 12). From the point of view of diagrammatic thinking signs do not refer to mathematical objects, but they are the mathematical objects. If this is combined together with the above theory of moving symbolic objects, the distinction between physical objects and symbolic mathematical objects is completely blurred.

From this discussion, we extract the following *hypothesis of the existence of an algebraic symbol space*: algebraic manipulations are carried out in a visuo-motor representation, either physically or mentally. Mental processes within this visuo-motor representation are supposed to be metaphorically close to experiences of bodily movements.

Moving in physical space may involve similar brain regions as moving in algebraic symbol space. Thus, it may be, that prior exercising one of them may have positive effects on the other, and it may be that simultaneous exercising may decrease (due to capacity limits) or increase (due to psychophysiological activation) performance. Neurophysiological evidence for a pre-motor implementation of metaphorical motion could be demonstrated by Fields (2013). In the present study, we investigate effects of unspecific bodily motion (i.e. motion that is not directly related to the structure of the mathematical task) on mathematical performance by variation of postural control affordances during sitting while participants are working on the mathematical tasks. The corresponding brain activation is assessed as a neural substrate for the postulated common visuo-motor representation that underlies the processing of algebra and geometry tasks. Increases in electroencephalographic (EEG) theta (4.0–7.5 Hz), and alpha (8.0–13.0 Hz) activity in central, and posterior (parietooccipital) brain areas should reflect visuo-motor information processing in algebra and geometry, whereas increases in EEG beta (13.0–30.0 Hz), and gamma (30.0–70.0 Hz) activity should indicate concentrative, attentionally mediated information processing.

In summary, the present paper advances two research questions: The first is whether bodily movement has an effect on mathematical performance measured in terms of behavioral data and corresponding brain activity. The second section tests the hypothesis that transformational algebraic manipulations are processed within a visuo-motor representation by investigating correlations between tasks that differ in the metaphorical distance to bodily movement and measure corresponding brain activation in areas related to processing of visuo-motor information in a frequency range (theta and alpha activity) that indicates working memory processes. We therefore expect increases in EEG theta and alpha activity in central, parietal, and occipital brain areas indicating visuo-motor working memory processes in algebra, similar to brain activation patterns in geometry.

MATERIALS AND METHODS

Participants

In the present study, $n = 15$ university students (mean age = 22.1 years, age range = 19–25 years) were tested. For a sub-sample of students ($n = 6$), electroencephalographic (EEG) activity was recorded for the entire duration of the test. All subjects were right handed, had normal or corrected to normal vision, and no history of neurological impairments. All participants gave informed consent and were naïve as to the purpose of the study. Due to small sample size and its selection, the present pilot study has to be considered as an exploratory study.

Study design and tasks

The laboratory study was carried out in a 3 (mathematical task: algebra, geometry, numerical calculation) x 3 (task difficulty: low, intermediate, high) x 2 (postural control: static, dynamic) within-subject design. We presented three different types of mathematical tasks within each type three levels of difficulty have been distinguished. The last factor was that of control of bodily movement. In the static condition, students were instructed not to move, while in the dynamic sitting condition participants sat on a stool that allows to move in all directions, and therefore promotes a dynamic control of bodily posture. For a sub-sample of students, EEG was recorded for the entire duration of the test.

The three types of mathematical tasks were arithmetics or numerical calculations (Num), algebra (Alg) and spatial geometry (Geo). All tasks were presented in a multiple choice format and processed mentally by the students, i.e. they were not allowed to write down any calculations or notes. The 3 x 3 x 2 item sets were presented in a randomized order. Within each cell students worked on the items for five minutes. To avoid exhaustion the whole test was split up into three sessions.

The arithmetical items were constructed ad hoc but informed by established theories of task difficulty in calculations (e.g. number of digits and carries). Example items are shown in Table 1.

Algebraic items tested the ability to determine the solution of linear equations in one unknown. On the basic level 1 the unknown was located on the left-hand side of the equation and could be determined by arithmetical calculation as read of directly from the equation. At level 2, difficulty is increased by larger number involved and by flipping right and left side of the equation. Both of these levels concern equations that are classified by Filloy (2008) as arithmetical equations, as they do not require to operate on the unknown itself, but only on numbers around it. At level 3, equations are of Filloy's algebraic type, i.e. they require true operating with unknown. All test items require to move the unknown across the equal sign as in $20x + 4x = 50 - x$. Example items for algebra are shown in Table 2.

Performance in spatial geometry tasks was measured by the "Bausteine-Test" (Birkel, Schein, & Schumann, 2002). The test is not designed to have three levels of difficulty but the solution probabilities of all items in a large sample are published in the test manual and we used this to group the items into three level sets.

A constraint of our setup is that all items are presented in a multiple choice form so that taking possible solutions as distractors might lead participants to find the right answer not by transformational algebra but by checking which of the numbers matches the equation. However, it is well known that students usually apply learned transformational methods even when inserting is more effective (e.g., Kouki &

Level	Task	Distractors
1	279 – 69 =	191, 190, 210, 220, 230
2	283 – 144 =	125, 139, 129, 149, 141
3	1980 / 44 =	47, 46, 45, 44, 43

Table 1: Examples for arithmetic items

Level	Task	Distractors
1	$8x + 7 = 47$	1, 2, 3, 4, 5
2	$79 = 11x + 2$	2, 7, 3, 5, 6
3	$x + 15 = x + 10 + x$	5, 10, 15, 20, 25

Table 2: Examples for algebra items

Chellougui, 2013, for a recent confirmation) so that we expect that most students choose transformational strategies. Violations of this assumption would tend to decrease sensitivity of our tests, so that results that we can show would remain valid.

Analysis of behavioral data

As measure of the students' performance in each experimental condition we take the number of correct answers achieved in the fixed time frame of five minutes. These numbers are denoted by a type signifier (Num, Alg, Geo), and the level, e.g., Geo1, Alg3, Num2. Lower levels are easier so that there are more correct answers, e.g., Alg1 > Alg2 > Alg3. When forming sum scores for the types of tasks, we calculated weighted sums to achieve approximately equal weight of all levels, e.g., Alg = Alg1 + 2 * Alg2 + 3 * Alg3. Classical test theory was applied to determine effects of the factors on achievement.

EEG recordings and data analysis

Electrical brain activity was recorded at resting baseline with eyes open before and after experimental tasks, and during each experimental condition. EEG was recorded (Micromed Brainquick, Micromed Systems Evolution) from 19 electrodes positioned according to the international 10–20 system. Vertical and horizontal electrooculogram was recorded from two electrodes. Impedances were kept below 4.0 kΩ. The EEG signal was digitized at 256 samples/s. After removal of oculomotor and electromyographic artifacts EEG data were subjected to Fast-Fourier-Transformations. Power density spectra were calculated for the theta (4.0–7.5 Hz), alpha (8.0–13.0 Hz), beta (13.0–30.0 Hz), and gamma band (30.0–70.0 Hz) for each subject. Data of power density spectra were averaged over all participants and were subjected to a 2 (postural control: static, dynamic) x 3 (mathematical task: algebra, geometry, numerical calculation) x 3 (level: low, intermediate, high) analysis of variance for repeated measurements with Bonferroni-corrected post-hoc t-tests.

RESULTS

Behavioral data

For all conditions we found that – according to what one would expect – the higher the level, the smaller was the number of correct answers. Cronbach's alpha for the scales formed by the three levels for each type were 0.79, 0.95, 0.74 for Num, Alg, Geo respectively. However, the Shapiro test for normality of this scales had p-values of 4.9e-05, 0.028 and 0.21 due to the skewness introduced by one exceptional well performing student. In the smaller sample without this student, normal distribution can be assumed. We checked that the results presented below vary only very little when run with the full or the smaller sample. We decided to report results including this student because n is already rather small.

The unspecific effect of bodily motion was positive in all cases, i.e. working in the dynamic condition yield-

Task type	Num	Alg	Geo
Cohen's d	0.41	0.39	0.12

Table 3: Cohen's d effect sizes

ed higher scores. The Cohen's d effect sizes for paired samples are shown in Table 3.

However, all of these differences fail slightly to be significant (significance level $p = 0.05$) as measured by the Wilcoxon test due to the rather small sample size.

Considering the first research question we performed a linear regression (R 2013, method lm). Results are shown in Table 4. In this case, it is important to note that with the smaller sample that satisfies normality assumption almost the same results appear. The most interesting β-weight of Geo in Alg3 is 0.064 in this case and significant as well. To complete data analysis, we calculated correlations of the relevant variables (see Table 5). The high correlation between Alg1 and Num is to be expected as reading these equations backwards yields a calculation task. Basically, to deal with Alg1 items one needs to determine by calculation a numerical unknown. This last aspect explains the rather high correlation between Alg1 and Alg3.

In all 3 x 3 combinations of levels and task types students performed better under the dynamic sitting condition. However, due to the small number of participants the effects could not be shown to be significant although effect sizes (Cohen's d for paired samples) indicated at least medium effects going up to $d = 0.49$ for Alg3.

EEG data

Results for EEG brain activity are depicted in Figure 1 (the nose of the head models is directed towards the top of the page). Significant main effects were obtained for posture control, $F(1, 5) = 7.02$, $p < .05$, task, $F(2, 10) = 5.46$, $p < .05$, and level, $F(2, 10) = 5.72$, $p < .05$, with a significant posture control x task x level interaction, $F(4, 20) = 4.13$, $p < .05$. EEG data show increased theta and alpha power in central and posterior regions during algebraic and geometric tasks at high complexity level in the dynamic postural control condition ($p < .05$) indicating an increase of activity in brain regions related to processing of visuo-motor information. Gamma power was increased over all brain regions during numerical reasoning at high complexity level under dynamic postural control ($p < .05$) which is a correlate for an internalized attentional processing mode that is not dependent on sensory modality of information.

DISCUSSION AND CONCLUSION

To our knowledge, this is the first study examining effects of postural control manipulation on mathematical performance. Behavioral and neurophysiological data show positive effects of dynamic postural control on mathematical reasoning performance. Different patterns of brain activation could be observed depending on postural control affordances, mathematical task, and task difficulty. Task-dependent EEG activation patterns indicate that mathematical reasoning is affected differently by manipulation of postural control affordances. We suppose that stimulation of the postural control system activates a visuo-motor representational mode during solving of algebraic and geometric tasks which is indicated by an increase in EEG theta and alpha activity in central and posterior brain areas, whereas attentional information processing is enhanced in numerical reasoning tasks indicated by increases in gamma activity in all brain regions. Therefore, our results confirm the hypothesis that algebraic and geometric tasks are processed in a different mode than arithmetic tasks.

	Alg1 ~ Geo + Num		Alg3 ~ Geo + Num	
	β-weight	p-value	β-weight	p-value
Geo	0.004	0.89	0.067	0.039 *
Num	0.246	0.3×10^{-9} ***	0.135	0.45×10^{-6} ***

Table 4: Linear models for Alg1 and Alg3

	Num	Alg1	Alg3	Geo
Num	1	0.90	0.76	0.47
Alg1		1	0.87	0.43
Alg3			1	0.58
Geo				1

Table 5: Correlations of task types

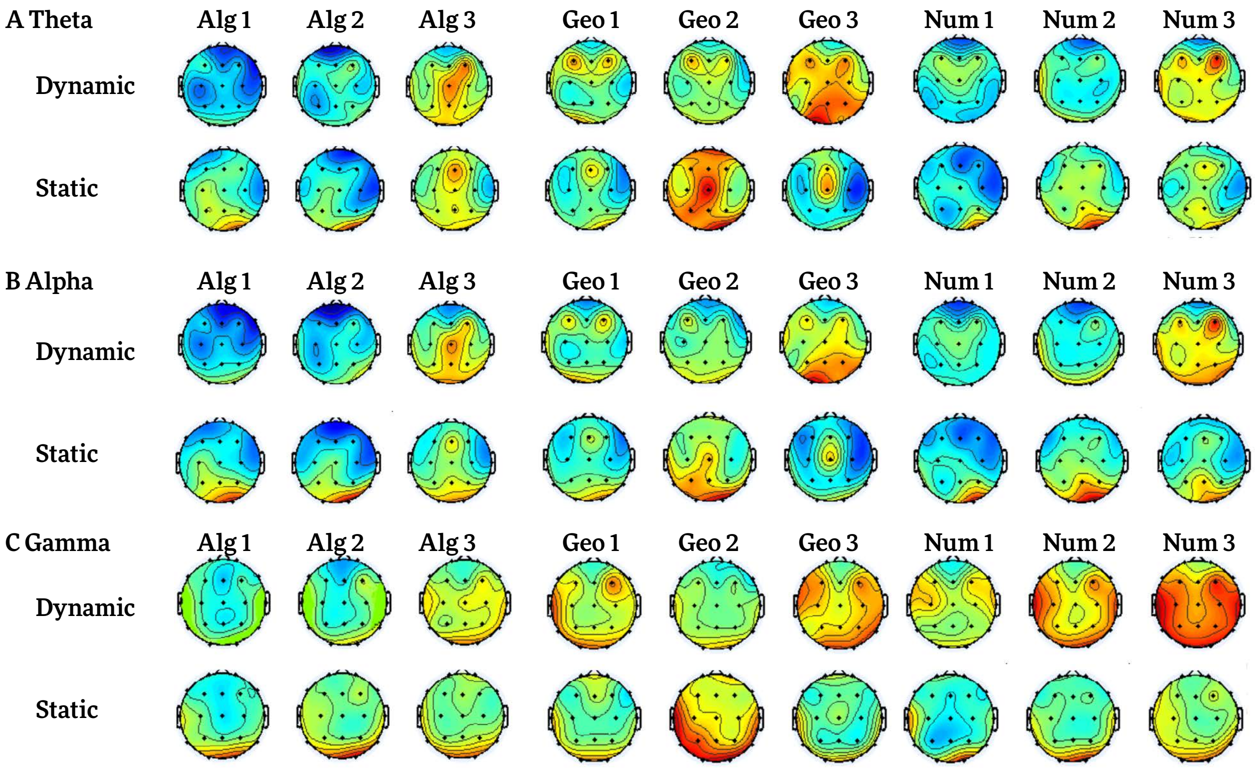

Figure 1: EEG activity during mathematical problem solving in static and dynamic postural conditions. The nose of the head models is directed towards the top of the page. EEG frequency bands: A Theta (4.0–7.5 Hz). B Alpha (8.0–13.0 Hz). C Gamma (30.0–70.0 Hz)

Further, our results support the hypothesis of an algebraic symbol space. The significant non-zero correlation found in behavioral data supports the hypothesis of the existence of an algebraic symbol space. Increased EEG theta and alpha in algebraic and geometric reasoning tasks indicate that both tasks are processed within a common working memory representation when the cognitive system is stimulated by bodily movement. However, further research is needed to clarify this hypothesis.

Finally, we present two theoretical explanations for the found patterns of results: (1) Increased mathematical performance is found in conditions of dynamic postural control affordances due to an increase of level of psychophysiological arousal, and therefore enhanced wakefulness. In a previous study (Maus, Henz, & Schöllhorn, 2013) increased attentional performance during dynamic sitting was demonstrated. EEG brain activation mirrored the found patterns of results as shown by an increase in beta activity in brain areas related to visual processing. EEG brain activation at high task difficulty level under postural control supports the hypothesis of increased psychophysiological arousal. Our results are in line with a study conducted by Vourkas and colleagues (2014) who observed differences in EEG brain activity in arithmetic tasks depending on task difficulty in children. (2) The occurrence of different EEG brain activation patterns in algebraic and geometric tasks in contrast to arithmetic tasks under dynamic postural control confirms the hypothesis that the presented tasks are processed within different cognitive subsystems. Increased central and posterior EEG alpha and theta activity in algebraic and geometric tasks at high task difficulty levels under dynamic postural control indicates that visuo-spatial working memory processes are stimulated by additional bodily movement, and therefore are responsible for the observed enhanced mathematical performance.

With the design of the current pilot study, we present a new methodological approach to investigate the underlying cognitive and neurophysiological processes in mathematical problem solving and their interaction with bodily movement. The found results contribute to a better understanding of cognitive processes that occur during solving of different types of mathematical problems, and encourage to design movement interventions which alleviate mathematical processing in learners. Our results have important implications for designing environments that promote bodily movements in learners of mathematics to increase their academic performance as could be shown in current research (e.g., van der Niet et al., 2014). Further, our results encourage to apply visuo-motor learning and teaching strategies in algebra, such as gestures (for a discussion see Janßen & Radford, 2015), due to the shown physiological preference of the brain for visuo-motor processing of algebra.

Solving equations: Gestures, (un)allowable hints, and the unsayable matter

Thomas Janßen[1] and Luis Radford[2]

1 University of Bremen, Bremen, Germany, janssent@uni-bremen.de

2 Université Laurentienne, Sudbury, Canada, lradford@laurentian.ca

The goal of this paper is to contribute to the research on the introduction of solving linear equations. Subsumed in the "Comparing and Contrasting" category introduced in Prediger, Bikner-Ahsbahs and Arzarello's (2008) networking strategies, we contrast two episodes informed by two distinct theories and offer an insight into the teacher's role in introducing new knowledge in the classroom and the meaning-making narratives of hands-on didactic approaches to algebra. We examine the teachers' gestures and hints and what appears to be unsayable in the teacher-students' interaction.

Keywords: Linear equations, networking theories, teaching-learning, gestures.

INTRODUCTION

In the discussion of a particular classroom episode we found that our distinct research projects resorted to a very similar approach to introducing the process of solving linear equations. However, the equation's contexts, as well as the student-teacher interaction – in particular what the teachers were willing to say – were substantially different. The analysis of the episodes through the lenses of the theories that informed the design and implementation of the tasks as well as the interpretation of the data – the Gathering-Connecting-Structure-seeing (GCSt) model (Bikner-Ahsbahs & Halverscheid, 2014) and the Theory of Objectification (Radford, 2007) – led us to achieve a deeper understanding of the teaching-learning that is usually involved in a hands-on introduction to solving linear equations. In particular, resorting to a comparative analysis, which corresponds to what Prediger, Bikner-Ahsbahs, and Arzarello (2008) identify as "Contrasting and Comparing" theories, gave us new insights into the constraints and affordances with which teachers are endowed in their interaction with the students. Our comparative analysis also makes visible the limits of what is considered to be unsayable (i.e., that which would be *improper* to mention by the teacher) and how this unsayable shapes the contour of the space and kind of gestures teachers deploy in the interaction with the students. Last but not least, we reached a new awareness about the learning impact that the didactic context has as a potential horizon of narrative-based meaning production in the introductory steps in learning to solve linear equations.

RESEARCH BACKGROUNDS AND THE CONTEXT OF THIS RESEARCH

The authors of this paper both study the development of algebraic thinking. The first author is interested in algebraic structure sense (Hoch & Dreyfus, 2010) as a dynamic entity. The second author is interested in the social co-transformative sense-making processes through which the students gradually become critically acquainted with historically constituted cultural meanings and forms of reasoning and action.

In the course of a discussion about two classroom episodes dealing with students solving linear equations, one informed by research following the GCSt model and the other following the Theory of Objectification, an important distinction became apparent between the social-constructivist first theory that leaves lots of freedoms to the actors in the classroom on the one hand, and on the other hand the second theory that stresses the importance of the cultural nature and basis of the mathematical content – the idea that the algebra we teach in school is not a natural developmental outcome, but the outcome of a historical-cultural evolution. This important distinction turned out to set limits to what teachers can say in the classroom and thus defines what they cannot say – the unsayable. It also has an impact on the teacher's hints, gestures, and their meaning. This paper is an attempt to describe what we learned from comparing the same phenomenon – teaching-learning linear equations – and to formulate it in terms of the specificities of the target algebraic knowledge and the teacher's role in the introduction of a new concept.

THEORETICAL BACKGROUND

The Theory of Objectification (TO) considers knowledge as a historically developed cultural synthesis of actions and reflections (e.g., how to solve linear equations), which is concretized or realized in certain activities. In most cases, and especially in school, students do not enter this process on their own. Teachers and students engage in joint activity in order to make the cultural synthesis of actions and reflection noticeable to the students. In doing so, knowledge becomes an object of consciousness and thought. In the TO, the teacher's and students' joint activity or joint labour is referred to as "teaching-learning activity." The joint nature of teaching-learning does not mean that teachers and students play the same role. There is an asymmetrical division of labour that makes teaching-learning a tense process (Radford & Roth, 2011) filled with emotionality and fragility. Under this premise, the TO can be used as an instrument to thoroughly plan teaching-learning, however always with an awareness for the ever-developing relation between the actors.

The Gathering-Connecting-Structure-seeing (GCSt) model (Bikner-Ahsbahs & Halverscheid, 2014) aims at describing the epistemic actions that are carried out in so called interest-dense situations. In these situations, the class or parts of it collectively participate in the name-giving epistemic actions: *Gathering* refers to the collection of bits of mathematical meaning in the given situation, e.g. empirical values. These are then *connected* with limited scope. In the example that may be a table or a graph. Based on the connections, the students may come to *see structures*, an event which is understood as constituting the construction of new knowledge. In the example, the students may see linearity as a feature of the examined function. Therefore, what qualifies as knowledge is not so much defined a priori, but rather by the observed behaviour of the students. This also implies a rather open task design and requires the teacher to be open towards the learning routes taken by the students.

METHODOLOGICAL CONSIDERATIONS

In the TO, learning is mediated by teaching-learning activities underpinned by a range of semiotic resources, such as signs (e.g., spoken and written language, diagrams), embodied actions (gestures, tactility, perception), and rhythm. Furthermore, the relationship between the involved individuals is seen as an important factor. In the GCSt model, the epistemic actions form the centre of the researchers' attention. As discussed above, no presuppositions are made about the nature of the actions, thus, depending on the context, they may cover the same semiotic resources that are of interest in the TO. As a result, to investigate learning, both the TO and the GCSt model privilege video analyses.

The analysis of the classroom episodes below is an instance of the "Comparing and Contrasting" category introduced in Prediger, Bikner-Ahsbahs, and Arzarello's (2008) networking strategies, seeking to conceptualize the role of the individuals, social interaction, and the specificities of the target knowledge.

DATA OVERVIEW

The data to be discussed here was originally collected in two projects with different foci and scopes. In the German project a grade 8 class (13–14-year-old students) in an integrated school in Bremen was filmed for about seven months in those lessons where algebraic structures were the target topic. The episode discussed here is from the very first of these lessons. In the Canadian project a Grade 2 class (7–8-year-old students) in Sudbury was followed for 5 years when the students were learning algebra. The episode discussed here is from the second day of the algebra lessons.

In both cases the solving of linear equations was introduced in a non-mathematical context that emulated the mathematical rules of linear equations. In the Canadian project, the students were presented a task that went as follows (the equation was illustrated by envelopes and cards on the blackboard see Figure 1):

Sylvain and Chantal have some hockey cards. Chantal has 3 cards and Sylvain has 2 cards. Her mother puts some cards in three envelopes making sure to put the same number of hockey cards in each envelope. She gives 1 envelope to Chantal and 2 to Sylvain. Now, both

Figure 1: The envelope equation can be seen on the blackboard in the background

children have the same amount of hockey cards. How many hockey cards are in an envelope?

In the German project, the students had matchbox equations on their tables that were introduced as puzzles. The students were told that on both sides of the equal sign there was the same total number of matches, some of them hidden in matchboxes. All of the matchboxes would contain the same amount of matches.

Abstracting from the two scenarios in both cases there were a) representations of unknown quantities with each of them representing the same quantity, and b) two sets composed of known and unknown quantities of objects with the same total quantity of objects in each set. Based on these two rules, linear equations may be presented in many more imagined contexts.

As implied by the GCSt model, the teacher of the class in Germany had instructions to give as little help as possible to allow the students develop their own ways of finding the correct solution. In contrast, the teacher in Canada had talked about the method of isolation on the previous day: the method that consists of removing same quantities from both sides of an equation in order to isolate the unknown.

For the purpose of this analysis, both transcripts were translated into English. Where the transcripts indicated important actions by the students or the teacher, stills were created from the video to accompany the transcript.

ANALYSIS OF THE EPISODES

The episode from the Canadian study is framed as a classroom discussion, while the episode from the German study shows a discussion solely between the teacher and two students who work on the task together. In both cases the students first followed an arithmetic trial-and-error approach and had already found and tested the correct solution to the equation. However, each teacher still wanted the students to get to the target algebraic approach.

As mentioned above, the teachers' instructions were very different in the two cases. The teacher in Canada engaged the class in a discussion about various methods to solve equations and was comfortable asking questions, submitting ideas and a new vocabulary. Thus, in the discussion below, which happened after the students suggested a trial-and-error method (see Radford, 2014), she suggests to use what the class has come to term the previous day the "isolating strategy," that is, the strategy based on removing equal terms from both sides of the equation. As we shall see, the teacher follows the still not fully linguistically articulated actions of Cheb and Cheb's pointing gestures, by moving the concrete envelopes and cards on the blackboard, making thereby apparent to the class:

94 Teacher: I'll go with the isolating strategy, Ok? Cheb? (*see Figure 1*)

95 Cheb: Umm... you remove one of Sylvain's envelopes and one of (*the teacher has already put the hand on the envelope, yet she stops to wait for the next part of C's utterance, turning her head towards C)* Chantal's envelopes

96 T: Is it important to remove the same thing from each side of the equal [sign]? (*she makes a two-hand gesture around the equal sign moving the hands to the bottom of the blackboard, where envelopes and cards have been moved, to indicate that removing action is happening in both sides of the equality*)

97 C: Yes. And you can remove the other envelope... Oh non! One of Sylvain's cards and one card from Chantal's (*the teacher removes one card from Chantal's, see Figure 2, left image*).

98 T: Aw! Again, one envelope, we remove one envelope (*see Figure 2, centre image, where the teacher points to the removed envelopes*), one card , [and] one card (*see Figure 2, right image, where the teacher touches the two removed cards*) ...

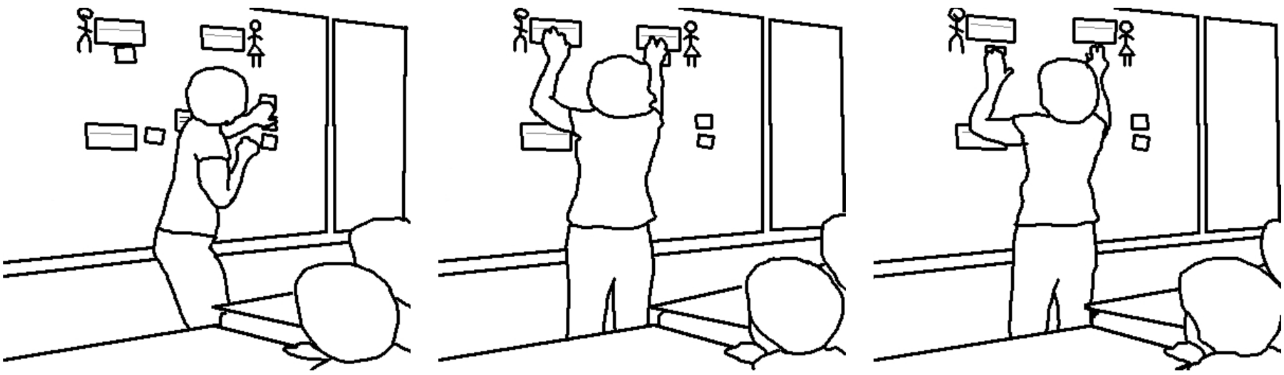

Figure 2: The teacher takes a card from the right side and moves it to the top of the blackboard (left image); she indicates the two envelopes (centre image) and then the two cards (right image) that have been removed

99 C: You remove one of Sylvain's cards and you remove one of Chantal's cards (*the teacher moves the cards towards the top of the blackboard*)
100 T: We remove another card of Chantal's cards. Then, that gives us...
101 C: The answer!

As we can see, the teacher moves the objects and performs the proposed actions. Where appropriate, she interrupts the flow of the discussion to emphasize for the whole class the algebraic conceptual meaning of the actions.

In contrast, the teacher in Germany has trouble doing so due to her professional self-concept (that was, at least in part, a result of the layout of the study she and her class were involved in). This leads to an interaction that is much longer than the one laid out above, and can thus only be presented in a condensed form. We particularly investigate how the teacher's struggle becomes apparent through her gesturing.

In the beginning of the interaction analysed here (line 10), the teacher gestures towards the two sides of the equation:

10. Teacher: (*briefly lays her hand on the right side, where Herbert is just finishing his counting – see Figure 3, left image*) Well what can one change here for example. so that it stays (*briefly holds both her hands above the two tables*) the same. (*multiply taps the tables with all of her fingers – see Figure 3, right image*) that must always stay the same that is very important.

A closer analysis of this first scene reveals that there are two gestures (see Figure 3). First, the teacher briefly and unspecifically lays her hand on the right side of the table and refers to this gesture by the word "here". Her idea is to focus on one side of the equation. However, at the same time the equation must stay an equation, which the teacher tries to stress by saying "so that it stays the same". The pronoun is concretised by the gestures shown in the right image: She means that the number of matches on both sides stays the same. This is too complex for the students, as neither the matches nor the sides of the equation are explicitly named as the relevant objects. Of course, this problem also applies to the aforementioned gesture. As a result, the students can make no sense of the teachers hint.

Figure 3: The two gestures in the first scene: Pointing at the right side of the equation (left) and highlighting the equality of the two sides (right)

After this first occurrence of gestures the teacher refrains from using any for almost two minutes. This is even more striking as she does in two instances use unspecific pronouns that would require clarification about what they refer to. The teacher's behaviour is probably due to the agreement that she should refrain from direct hints to the solution of the problem – an approach founded in the idea that the students should come to see structures on their own. However, during this time, she does talk about the two sides of the equation as the relevant objects. One could argue that from this explicit talk about the two sides it should indeed be clear for the students where they are expected to act, in terms of the GCSt model, the teacher helps with the gathering to make connecting and structure-seeing happen. But the structure is a new one, and it is hard to see without a break with the existing view.

In the scene that ends the comparatively long absence of gestures, the teacher uses gestures that point more directly at the two sides of the equation:

64 Sabine: (*moves her torso backwards, then to the front again, gestures with both arms*) The simplest would be if you simply tell us the solution. (*runs her fingers through her hair, Herbert laughs*)
65 T: Well it must (*points with her right hand first at the left and then at the right side, then turns it with the palm up*) always be the same but maybe- a bit (*makes a sudden upward movement with her right hand*) clearer. (*stands up straight again, crosses her arms*)
66 S: (*looks up at the teacher*) What does clearer mean? (*Sabine and the teacher look at each other*) (2sec)

However, she still uses the unspecific singular pronoun "it", again referring to the number of matches on the two sides. At the same time the word "it" stands for the whole situation that should become "a bit clearer". The students thus focus on what she means by "clearer". They demand a plan for action – this becomes visible already in the line before. In the last two utterances to be discussed here, the teacher reproduces the two gestures from the beginning, as can be seen in Figure 4. The teacher multiply taps on the right side (see Figure 4, left image). Here, for the first time, she adds a hint that taking away something might help, by claiming that "that are so many". However, the students still keep on aimlessly guessing what to do (88–91), meaning that they have no goal for their actions. Finally, the teacher additionally makes clear where the equality is to be preserved (see Figure 4, right image).

But only when the teacher gives her very concrete advice ("take away something"), Sabine is very quick at finding out what to take away. Here it proves that the groundwork laid before may not have been in vain, but can now be activated:

98 T: Okay what can one do on both sides so that it gets clearer you must always do the same. (*Herbert removes some dust from the table, the teacher looks at Sabine for some time, Sabine looks at the table, still holding the three boxes in her hand*) (3sec) (*gets up and walks away, whispering in Sabine's ear*) ‚take away something.

Figure 4: The two gestures re-enacted: Indicating the relevant side of the equation (left) and making clear that equality must be preserved (right). See Figure 3 for comparison

DISCUSSION

What are the students to learn and how can they learn it?

The isolation method is not the first method to which children resort when they are asked to solve an equation. Indeed, it is far from trivial to "isolate" the unknown to solve the equation. This is the method of analysis that the ancient Greeks devised. It is a deductive method, where relationships are deduced through a long chain of deductions, the last one being one in which you have the unknown equal to something. For students, it is at first much more reasonable to assume numbers and try and see if the assumption confirms the story (trial-and-error method), which is indeed what can be seen in both episodes.

In the examples presented here, the (linear) equation is supposed to emerge from an original context from where things and actions acquire an initial meaning (cards and envelopes in one case, matches and boxes in the other). This context is set in terms of a narrative that establishes an equality involving known and unknown numbers. Formally speaking, the two contexts explored here are similar. We can say that, in principle, the context offers the same potential in terms of algebraic meaning-making. Our analysis suggests, however, that the narrative (i.e., the linguistically connected account of events) is much more emphasized in the Canadian study. Cheb and the teacher talk much more in terms of cards and envelopes than the students and the teacher talk about matches and boxes in the German study. The potential significance of the context appears hence not to be equally exploited.

However, the exploitation of the significance of a meaningful context is not enough for the students to envision the algebraic isolation method. Indeed, to proceed to the simplification of the equation, the original narrative has to be disrupted by a (mathematical, in this case algebraic) sense that is already a real-life counter-sense. It is hardly natural to think about *removing* cards from the individuals in the story, while in fact the question is about the number of cards in an envelope. There is a shift from quantities as such to relations between quantities. The teacher and the students have to expand the narrative so that the removing actions and their results may acquire a new meaning. Hence there is a need for the teacher to interrupt the flow of actions and to make sure that the class finds a new mathematical meaning in what has been done to the equations, after the removal of same quantities. In the Canadian episode, the teacher shows a developed sense of the importance of this interruption and the special value of the algebraic solution so that she can refer to it at the appropriate moment. This developed sense is not natural. It was nurtured during the design of the classroom activity. The German episode ends with the teacher telling one of the students what to do on the two sides of the equation, which she has just identified as the place of action. The course of action appears improvised under the impression of the difficulties that arise rather than didactically planned.

Teacher intervention by gestures and its limitations

Until she decides to help the students in a more direct manner, the German teacher's attempts to guide her students consist mainly of gestures, as if the contextual actions required to simplify the equations had an ostensive meaning. However, gestures always work within the parameters of how teachers conceive of themselves in their teaching. They are directed to oneself and to others. It supposes that they work within the parameters of what we take a good teacher-students interaction to be, i.e., the meaning ascribed to interaction in the classroom. We see this tension in the manner in which the teacher in Germany refrains from telling the students. She tries to point to a solution solely by gestures.

However, to be understandable, to be meaningful as a hint to make connections (in the GCSt model) or as a guide into a cultural activity (in the TO), gestures need an explanation about what they refer to, and what it is that can be done. As has been pointed out, this is far from trivial, especially when we consider the framings of the problem: In both cases it is embedded in a narrative that makes the required actions meaningful in an abstract sense – an abstract sense that is opposed to the more quotidian sense where one may try to use trial-and-error methods.

The central hypothesis about the teacher's gestures in this episode is that they are too abstract. They require a deeper students' understanding than the one they have at this point. In particular, the teacher presumes that the students already see the same objects and relations between these objects as she does. It seems that the gestures are made from the standpoint of someone for whom the equation is already of a symbolic nature.

Maybe an understanding of the sides of the equation as the useful unit of analysis would suffice for the gestures to be fruitful, but the teacher does not even try to induce that explicitly. The teacher's gestures cannot find a kind of contextual narrative support to provide a rationale for the algebraic actions to find a meaning that may be accessible to the students.

CONCLUSIONS

The introduction of algebraic methods and ways of thinking is a crucial point in students' individual paths through mathematics – a point where many lose touch with the subject. The two episodes make clear that a teacher with an appropriate understanding of his or her role can help students substantially. Awareness for the novelty of algebraic methods is the essence of this understanding. It can help realize the decisive steps that the students have to take and to position other forms of help, such as gestures, in the teaching-learning situation. Without the consideration of context, otherwise helpful gestures are at risk to stay opaque to the students.

The result is surprising from the point of view where the learning should come from the students and is seen as an autonomous act of construction, as it is in the GCSt model. The episodes and their analysis presented here raises the question how one could even expect students to develop the complex deductive method of solving an equation without getting an introduction by an experienced person. In both episodes, the learning that happens in the end (or more precisely: that begins in the end, as the new knowledge will need to be consolidated) is based on an input from the teacher-students' interaction. To inform better teaching, it should be a goal of mathematics education researchers to better understand what this input is in different content fields, as we have tried here regarding the solving of linear equations.

In a previous paper, we proposed a characterization of algebraic reasoning in primary education, based on the onto-semiotic approach to mathematical knowledge and instruction, where we distinguish three levels of algebraization. In defining these levels we took into account the types of representations used, the generalization processes involved and the analytical calculation performed in mathematical activity. In this paper, we extend this previous model by including three more advanced levels of algebraic reasoning in order to analyze the mathematical activity carried out in secondary education. These new levels are based on the following considerations: 1) using and processing parameters to represent families of equations and functions; 2) the study of algebraic structures themselves, their definitions and properties.

Key words: Algebraic reasoning, primary education, secondary education, onto-semiotic approach, teachers' education.

INTRODUCTION

Recognizing the characteristic features of algebraic thinking is an issue that has attracted many mathematics education researchers, because it is necessary to promote such reasoning at different levels of elementary and secondary education (Kieran, 2007; Filloy, Rojano, & Puig, 2008; Kaput, 2008). Depending on how the school algebra is conceived, decisions are taken concerning whether to introduce such algebra since early levels, or to delay its teaching until secondary education as well as to change the corresponding instructional strategies. In fact, the "early algebra" research and development program (Carraher & Schliemann, 2007; Cai & Knuth, 2011) is supported on a conception of algebra that recognizes signs of algebraic thinking in mathematical activities of initial educational levels, as shown in NCTM (2000). While there has been progress in the characterization of school algebra, the interconnection between primary and secondary education algebra is not completely solved.

In previous publications (Aké, Godino, Gonzato, & Wilhelmi, 2013; Godino, Aké, Gonzato, & Wilhelmi, 2014) we proposed a model of algebraic thinking for primary education, with three different levels of algebraic thinking. Furthermore, we established criteria to delimit these algebraic levels from 0 (arithmetic nature of mathematical activity) to 3 (clear algebraic activity), with two intermediate levels of proto-algebraic activity. The criteria to define these levels were based on the type of mathematical objects and processes involved in mathematical activity, according to the onto-semiotic approach (OSA) to mathematical knowledge (Godino, Batanero, & Font, 2007; Godino, Font, Wilhelmi, & Lurduy, 2011)[1]. These algebraization levels are assigned to the operative and discursive practices performed by a mathematical subject that solves a mathematical task, rather than to the task itself, which can be solved in different ways, and may bring into play different algebraic activity.

1 The Onto-Semiotic Approach of mathematical knowledge and instruction (OSA) is a theoretical framework that adopts semiotic and anthropological assumptions about mathematics, and socio-constructivist and interactionist principles for the study of teaching and learning processes. Due to space limitation, it is not possible to include a synthesis of the main theoretical tools that compose this framework; the readers might consult Godino and colleagues (2007) and Godino and colleagues (2011).

In this paper, we extend that model of algebraization levels to secondary school, mathematical activity. This extension is also supported by the onto-semiotic distinctions considered in the OSA; particularly by the presence, use and processing of functions and equations parameters. The work is organized in four sections. In the following section we summarize the features of algebraic reasoning levels in elementary education; next, we define three new levels of algebraization, include some illustrative examples and connect the new levels to the presence of discontinuities in the onto-semiotic configurations involved in mathematical practices.

LEVELS OF ALGEBRAIC REASONING IN PRIMARY EDUCATION

In Table 1 we summarize the essential features of the three preliminary algebraization levels described by Godino, Aké, Gonzato and Wilhelmi (2014), completed by level 0 (absence of algebraic characteristics). An example is also included to help understanding the distinction among levels. In summary, the definition of levels is based on the following onto-semiotic distinctions:

- Presence of *intensive* algebraic objects (i.e., entities of general or indeterminate character).
- Transformations (operations) based on structural properties applied to these objects.
- Type of used language (natural, iconic, gestural, symbolic).

Obviously, these levels do not exhaust the algebraization processes of school mathematical activity. Instead, they describe the gradual enrichment of solving problems tools with an increasing degree of symbolization in other contexts of use. These processes, in the end of primary school and junior secondary school, may evolve to higher algebraization levels. The criteria used to distinguish the different algebraic levels have been gradually refined through its application to the analysis of responses from different samples of student teachers (Aké et al., 2013; Godino et al., 2014).

LEVELS OF ALGEBRAIC REASONING IN SECONDARY EDUCATION

In this section, we extend the model of algebraization levels to secondary and high school mathematical activity, in describing three additional algebraization levels for this educational stage.

The use and treatment of parameters is a criterion for defining higher levels of algebraization, as it is linked to the presence of equations and functions families, and, therefore it implies new "layers" or levels of generality (Radford, 2011). The intervention of parameters will be linked to the fourth and fifth algebraization levels, while the study of specific algebraic structures will mark a sixth algebraization level of mathematical activity.

Fourth algebraization level: using parameters

The use of parameter for expressing equations and function families is indicative of a higher level of algebraic reasoning, as compared to the third algebraization level considered by Aké and colleagues (2013), which is linked to operations with unknowns or variables. This "first encounter" with parameters and variable coefficients involves the discrimination of the domain and range of parametric functions, i.e. functions that assigns a specific function or equation to each value of the parameter. As suggested by Ely and Adams (2012, p. 22) "A significant conceptual shift must occur in order for students to be comfortable using placeholders in algebraic expressions rather than just numbers".

Example 1: The linear function

In the algebraic expression, $y = 2x$, the literal symbols x and y represent variables, symbols that can take any value from a previously established number set, usually R. The numerical values x and y co-vary in terms of each other, according to the rule laid down in the corresponding expression; in this case, y is twice the value assigned to x. The factor multiplying x can be generalized to any value in a certain domain; as we see in the expression $y = ax$. Here the letter a intervenes as a parameter: it can take different values within a certain domain, so that for each possible value a, we obtain a particular function. For example, for $a = 2$, we have $y = 2x$.

Consequently, a parameter is a literal symbol involved in an expression with other variables, such that for each particular value assigned to it, a function is obtained. We express such families of functions as $F = \{f(x) = ax/aR\}$, or more precisely, a family of functions that depend on the domain D of definition of the functions f: $F_D = \{f(x) = ax \mid aR; xD\}$.

<tr><td colspan="4">Task: Students either go by car or they walk to a certain school. There are 3 students walking for every 3 student going by car. If the school has 212 students, how many of them use each means of transportation?</td></tr>
<tr><td>LEVELS</td><td>OBJECTS</td><td>TRANSFORMATIONS</td><td>LANGUAGES</td></tr>
<tr><td rowspan="2">0</td><td>No intensive objects are involved.
In structural tasks unknown data can be used.</td><td>Operations are carried out with extensive objects.</td><td>Natural, numerical, iconic, gestural; symbols referring extensive objects or unknown data can take part.</td></tr>
<tr><td colspan="3">Example of resolution:
For every 3 students who walk, there is 1 going by car. Hence, in every group of 4 students (3 + 1) there is 1 going by car (a fourth of students). Thus, 50 out of 200 students go by car and 3 out of 12 students use the car. Therefore, 53 students use the car and three times that amount, that is, 159, walk to the school.</td></tr>
<tr><td rowspan="2">1</td><td>In structural tasks unknown data can be used.
In functional tasks intensive objects are recognized.</td><td>In structural tasks relations and properties of operations are applied.
In functional tasks calculation involve extensive objects.</td><td>Natural, numerical, iconic, gestural; symbols referring to intensive recognized can be used.</td></tr>
<tr><td colspan="3">Example of resolution:
For every 4 students there are 3 which walk. We write out the following proportion:
4 (children) ------> 3 walk
212 (children) ------> x walk
$\frac{4}{3} = \frac{212}{x}$; $x = 3 \times \frac{212}{4}$; $x = 159$
Once we obtain the number of children who walk to the school, the number of students going by car is easily obtained, 212 – 159 = 53.</td></tr>
<tr><td rowspan="2">2</td><td>Indeterminate or variables are involved.</td><td>In structural tasks equations are of the form $Ax \pm B = C$.
In functional tasks generality is recognized but operations with variables are not carried out to get canonical forms of expressions.</td><td>Symbolic – literal, used to refer the intensive recognized, although linked to the spatial, temporal and contextual information.</td></tr>
<tr><td colspan="3">Example of resolution:
$212 = x + 3x$
$212 = 4x$; $x = 212/4$; $x = 53$
53 children go by car and 212 – 53 = 159 walk.</td></tr>
<tr><td rowspan="2">3</td><td>Indeterminate or variables intervene.</td><td>In structural tasks equations are of the form $Ax \pm B = Cx \pm D$.
Operations with indeterminate or variables are carried out.</td><td>Symbolic – literal; symbols are used analytically, without referring to contextual information.</td></tr>
<tr><td colspan="3">Resolution example:
x = Children going by car
y = Children walking
$x + y = 212$ $x + 3x = 212$;
$y = 3x$ $4x = 212$; $x = 212/4 = 53$</td></tr>
</table>

Table 1: Characteristic features of elementary algebraic reasoning levels

The symbols x and y ($f(x)$) are variables indicative of a first level of generality; their definition domains and range are the numeric sets in which they are defined. The symbol a is also a variable; however a second level of generality is involved, since its definition domain could either be (D) as before or just another number set, and the range of values is the family of functions F_D.

Example 2: Quadratic equation
Parameters are used not only to express and operate with function families, but also with equation families (Ely & Adams, 2012). For example, $ax^2 + bx + c = 0$ ($a \neq 0$) is the general expression for the quadratic equations family. There is only one unknown, x. The letters a, b, c, usually considered as variable coefficients, take

specific values within a set of possible values (real numbers and a ≠ 0) to produce a particular equation.

Therefore, a parameter is a variable that is used with two or more other variables to specify a family of functions or equations. For families of equations the parameter is commonly named coefficient. In some way, the parameter plays the role of independent variable in a function whose domain is the set in which the parameter takes its values and whose rank is a set of functions. For each value assigned to the parameter a function image is obtained. Therefore, the expression $y = ax^2+bx+c$, is not a function but a family of functions, though it is usually referred to as "the quadratic function." It is an expression in which three parameters indicated by the letters *a, b, c* are involved. Giving a particular value to each of the parameters a specific quadratic function is obtained.

Fifth level of algebraization: treatment of parameters

We can assign a higher level of algebraization to mathematical activity displayed, when analytical (syntactic) calculations are carried out involving one or more parameters. Operations with parameter involve a higher semiotic complexity level, since the objects emerging from these systems of practices are built on algebraic objects of the previous level (equations or functions families).

Example 3: Obtaining the general formula for quadratic equations

To obtain the general formula for quadratic equations we perform symbolic manipulation and use successive equivalences. Assuming the director coefficient a is not 0 (a ≠ 0) – otherwise the equation would not be quadratic – we have:

$$ax^2 + bx + c = 0 \Leftrightarrow x^2 + \frac{b}{a}x + \frac{b}{a} = 0 \Leftrightarrow x2+ \frac{b}{a}x = -\frac{c}{a} \Leftrightarrow$$

$$x^2 + \frac{b}{a}x + \frac{b^2}{4a^2} = -\frac{c}{a} + \frac{b^2}{4a^2} \Leftrightarrow x^2 + \frac{b}{a}x + \frac{b^2}{4a^2} = -\frac{4ac}{4a^2} + \frac{b^2}{4a^2} \Leftrightarrow$$

$$(x + \frac{b}{2a})^2 = \frac{b^2-4ac}{4a^2} \Leftrightarrow x + \frac{b}{2a} = \pm\sqrt{\frac{b^2-4ac}{4a^2}} \Leftrightarrow x = -\frac{b}{2a} \pm \frac{\sqrt{b^2-4ac}}{2a} \Leftrightarrow$$

$$x = \frac{-b \pm \sqrt{b^2-4ac}}{2a}$$

Thus, in this case the solution is written in terms of the parameters linked by rational operations (addition, subtraction, multiplication, division) and square roots.

Example 4: Geometric progressions

We define the general term of a geometric progression (Figure 1) by discursive practices in which two parameters, a_1 (first term of the sequence) and *r* (progression ratio) are involved. The sequence is a function with domain *N* and range *R*; therefore the parameters a_1 and *r* define a family of functions (sequences), and consequently this discursive practice uses an algebraization level 4. The description and proof of the sum of the first *n* terms of a geometric progression (r ≠ 0) involves a computation with parameters, as shown in Figure 1; therefore it implies the algebraization level 5.

Sixth level of algebraization

The introduction of certain algebraic structures (such as vector spaces, or groups) and the study of functional algebra (addition, subtraction, division, multiplication, and composition) start at high school. These practices bring into play higher level algebraic objects and processes according to its onto-semiotic complexity than those considered at level five. It may be useful, therefore, to characterize a sixth algebraization level to focus our attention on the specific nature of the mathematical activity involved. High school

36.8 Finite Geometric Series

When we sum a known number of terms in a geometric sequence, we get a finite geometric series. We know that we can write out each term of a geometric sequence in the general form:

an = $a_1 \cdot r^{n-1}$

where

- n is the index of the sequence;
- a_n is the nth-term of the sequence;
- a_1 is the first term;
- r is the common ratio (the ratio of any term to the previous term).

By simply adding together the first n terms, we are actually writing out the series

Sn = $a_1 + a_1 r + a_1 r^2 + \ldots + a_1 r^{n-2} + a_1 r^{n-1}$

We may multiply the above equation by r on both sides, giving us

$rS_n = a_1r + a_1r^2 + a_1r^3 + \ldots + a_1r^{n-1} + a_1r^n$

....

Dividing by (r – 1) on both sides, we arrive at the general form of a geometric series:

$$\boxed{S_n = \sum_{i=1}^{n} a_1 \cdot r^{i-1} = \frac{a_1\,(r^n - 1)}{r - 1}}$$

Figure 1: Finite geometric series (Free High School Science Texts, Mathematics Grades 10 – 12, p. 469, 2008)

books include texts and activities corresponding to this sixth algebraization level:

Example 5: Vector space
Figure 2 shows a general formulation for the vector space algebraic structure. In this first encounter with this algebraic structure a set of mathematical objects (vectors) are defined on which operations satisfying a set of specific properties are carried out. An initial "structural study" of vectors is required, since in this type of (axiomatic) presentation, the properties of the vector addition and multiplication by numbers have to be established.

Example 6: Composition of functions
In Figure 3 the notion of function is used in all its generality, in replacing a particular family of functions by any function. Operations are carried out over functions to produce new functions, whose properties will be studied in general. For example, properties such as "the composition of functions is not commutative" would arise. In fact, a set of functions (polynomials, for example) satisfying certain operations (addition, multiplication, etc.) is an "algebra".

Algebraization levels and strands of algebraic reasoning

In various studies Kaput has proposed a model of algebraic reasoning as a complex composite organized around five interrelated forms, or strands of reasoning listed below (Kaput & Blanton, 2001; Kaput, 2008):

1) Algebra as Generalizing and Formalizing Patterns & Constraints,

2) Algebra as Syntactically-Guided Manipulation of Formalisms.

3) Algebra as the Study of Structures and Systems Abstracted from Computations and Relations.

4) Algebra as the Study of Functions, Relations, and Joint Variation

5) Algebra as a Cluster of Modeling and Phenomena-Controlling Languages

The algebraization levels we propose are related to strands 1 and 2. Strand 1 is specified in our model by levels 1 and 2 of proto-algebraic reasoning, while strand 2 is associated with level 3, where algebra is already consolidated. Strands 3, 4 and 5 basically correspond to fields or areas of school algebra (generalized arithmetic, study of abstract structures, functions, modeling).

Our algebrization levels of primary and secondary school mathematical activity can be identified in each mathematical content strands, and involve a progressive epistemic and cognitive complexity degree due to the level of generality of mathematical objects, ostensive representations and syntactic calculation used. The presence and manipulation of parameters associated with levels 4 and 5 take place within the strands "Algebra as the study of functions", and "Algebra as a cluster of modeling of phenomena". Kaput's (2008) algebraic reasoning model is oriented mainly to characterize algebra as institutionalized mathematical content, while our model attempts to

Imagining a vector idea as an arrow help conceive the vector space: sets of vectors among which some operations satisfying certain properties are defined. But there are other mathematic entities with the same operations and properties. So, the definition of vector space is much broader and open than collections of "arrows". We have a set, V; among their elements (called vectors) two operations are defined:

SUM OF TWO ELEMENTS OF V: if $\vec{u}, \vec{v} \in V$, then $\vec{u}, \vec{v} \in V$

PRODUCT BY A REAL NUMBER: if $a \in R$ and $\vec{u} \in V$, then $a \cdot \vec{u} \in V$

If $(V, +, \cdot)$ satisfies the following properties then is a vector space on R.

	SUM OF VECTORS
ASSOCIATIVE	$(\vec{u}+\vec{v})+\vec{w}=\vec{u}+(\vec{v}+\vec{w})$
COMMUTATIVE	$\vec{u}+\vec{v}=\vec{v}+\vec{u}$
NULL VECTOR	It is a vector called $\vec{0}$ such that if $\vec{v} \in V$ fulfils: $\vec{v}+0=\vec{v}$
OPPOSITE VECTOR	All v has its opposite $-\vec{v}$: $\vec{v}+(-\vec{v})=0$
MULTIPLYING A VECTOR BY A NUMBER	
ASSOCIATIVE	$(a \cdot b) \cdot \vec{v} = a \cdot (b \cdot \vec{v})$
DISTRIBUTIVE I	$(a+b) \cdot \vec{v} = a \cdot \vec{v} + b \cdot \vec{v}$
DISTRIBUTIVE II	$a \cdot (\vec{u}+\vec{v}) = a \cdot \vec{u} + a \cdot \vec{v}$
PRODUCT BY 1	If $\vec{v} \in V$ then $1 \cdot \vec{v} = \vec{v}$

Figure 2: Vector space (Colera & Oliveira, 2009, p. 62)

It is possible to combine two functions by adding, subtracting, multiplying or dividing two given functions.
There is another way to combine two functions to create a new function. It is called composition of two functions. It is a process through which we will substitute an entire function into another function.
First let's get acquainted with the notation that is used for composition of functions. When we want to find the composition of two functions we use the notation $(f \circ g)(x)$.
Another way to write this is $(f(g(x))$. This is probably the more practical notation although the first notation is what appears most often in books.

Figure 3: Composition of functions (AlgebraLAB. Project Manager. Mainland High School)

characterize the algebraic activity performed by the individuals solving mathematical tasks. Therefore both theoretical school algebra models are compatible and complementary.

ALGEBRAIZATION LEVELS AND ONTO-SEMIOTIC DISCONTINUITIES

Algebraization levels are basically generality levels, combining various registers of semiotic representation (RSR), theirs transformations and conversions (Duval, 1995). Under the OSA these levels can be characterized by the presence of different types of onto-semiotic configurations (Godino, Font, Wilhelmi, & Lurduy, 2011) which involve practices, objects and processes implying new levels of generality or syntactic calculus, supported by symbolic representations of the corresponding objects. Furthermore, they imply unitization, materialization and reification processes involved in generalization and representation (Godino et al., 2014).

Considering algebraization levels of mathematical activity can help raise awareness of gaps or discontinuities in didactical trajectories. These gaps involve the use of different registers of semiotic representation, their treatment and conversion, as well as the establishment of relations between conceptual, propositional, procedural and argumentative objects of higher generality. In other words, these gaps can be explained by analyzing how the numerical-iconic and analytical – algebraic onto-semiotic configurations involved are articulated, and not only by the treatment or conversion of RSR. Strømskag (2015) referring several studies emphasizes that it is not generalization tasks that are difficult for students but they are related to the way tasks are designed. We think that taking into account the levels of algebraization could help in selecting and design tasks that increase students' opportunities to learn algebra.

SYNTHESIS AND IMPLICATIONS FOR TEACHER EDUCATION

In this work we complemented the work by Ake and colleagues (2013) and Godino and colleagues (2014) on the identification of algebraization levels of mathematical activity in primary education, including three new levels that characterize secondary mathematics. As a summary we propose the following six levels of algebraic thinking in primary and secondary education (along with level 0, indicating absence of algebraization):

Level 0: Operations with particular objects using natural, numerical, iconic, gestural languages are carried out.

Level 1: Use of intensive objects (generic entities), the algebraic structure properties of N and the algebraic equality (equivalence).

Level 2: Use of symbolic – alphanumeric representations to refer the intensive recognized, although linked to the spatial, temporal and contextual information; solving equations of the form $Ax \pm B = C$.

Level 3: Symbols are used analytically, without referring to contextual information. Operations with indeterminate quantities or variables are carried out.

Level 4: Studying families of equations and functions using parameters and coefficients.

Level 5: Analytical (syntactic) calculations are carried out involving one or more parameters.

Level 6: Study of algebraic structures themselves, their definitions and structural properties.

These algebraic reasoning levels have implications for teacher training, both in primary and secondary education. In addition to develop curricular proposals (NCTM, 2000) including algebra from the earliest levels of education, the teacher need to act as the main agent of change in the introduction and development of algebraic reasoning in elementary classrooms, and its progression in secondary education. Reflecting on the recognition of algebraic thinking objects and processes can help identify the features of mathematical practices on which the teachers can intervene to gradually increase the algebraization levels of students' mathematical activity.

Consequently, recognizing the algebraization levels 4, 5 and 6 by secondary school teachers, along with its articulation with the previous levels, can help raise their awareness of the gaps or onto-semiotic discontinuities which may appear when carrying out tasks proposed to their students.

ACKNOWLEDGEMENT

The research reported in this article was carried out as part of the following projects: EDU2012-31869 and EDU2013-41141-P (Ministry of Economy and Competitiveness, Spain)

Using variation theory to design tasks to support students' understanding of logarithms

AnnMarie H. O'Neil and Helen M. Doerr

Syracuse University, Syracuse, USA, ahoneil@syr.edu

In this paper, we discuss three implementations of a task in which students were asked to generate examples of logarithm expressions equal to a given value. We situate the design of the task in variation theory and in research on learner generated examples, which describe learning as developing students' ways of seeing, particularly in regards to the dimensions of variation and the range of permissible change. The analysis of the three implementations reveals students' understanding of logarithms, as well as what is possible to learn given the task-as-implemented, or the enacted object of learning. We claim that using variation theory in task design can support students in developing important capabilities for reasoning about logarithms in powerful ways.

Keywords: Logarithms, variation theory, learner generated examples.

While exponential functions have been emphasized as a key mathematical understanding in secondary school (Confrey & Smith, 1995), their inverses, logarithmic functions, have received very little attention in the research literature. Besides the significance of logarithms for their relationship to exponential functions, the applications of logarithms to various phenomena, such as sound, earthquakes, and human growth (Wood, 2005), are important in their own right.

According to the Common Core State Standards (National Governors Association Center for Best Practices & Council of Chief State School Officers, 2010), recently adopted in the United States, the emphasis on the algebra of logarithms in a typical Algebra II course, as well as subsequent courses in mathematics (e.g., precalculus), means that upwards of 2.5 million American students will be expected to engage with and develop an understanding of these ideas each year (National Center for Education Statistics, 2014; National Science Board, 2010). Despite this, there is a dearth of research literature involving student learning of logarithmic functions, in general, and the algebra of logarithms, in particular. Of the literature available, much of the focus is on suggested mathematical and pedagogical approaches to logarithms with no empirical data related to students' learning using these approaches. Weber (2002) concluded that many students do not have a process understanding of exponentiation and logarithms and suggested numerical approaches to encourage the development of these understandings, but not for logarithms directly. Wood (2005) suggested verbal explanations from students about the meaning of logarithmic expressions such as in order to build an understanding of this expression as a numerical value. Confrey and Smith (1995) and Panagiotou (2011) both suggest drawing on the historical development of logarithms as a basis for teaching about logarithms. Confrey and Smith further claim that building the isomorphism between the *counting*, or additive, world and the *splitting*, or multiplicative, world is building the rules of logarithms. The purpose of this study is to address this research gap by exploring a task design that develops students' understanding of logarithms. In the recent ICMI 22 Study, Margolinas (2013) indicated the importance of tasks for generating mathematical activity that afford students the opportunity to encounter concepts and strategies. This study focuses on three iterations of a task designed to elicit students' current understanding of logarithms, as well as lead them to generalizations related to the properties of logarithms.

The task design and analysis is situated within both variation theory, developed by Marton and colleagues (Marton, Runesson, & Tsui, 2004), and research related to learner generated examples, LGEs, (e.g. Watson & Mason, 2005). Variation theory is most concerned with the object of learning, comprised of three aspects: (1) the intended, (2) the enacted, and (3) the lived (Marton et al., 2004). The intended object of learning is what the teacher intends the students to learn at the outset or in the planning of a lesson. The enacted object of learning is what was actually made possible for students to learn in the implementation of a lesson. The lived object of learning is what the students actually did learn at the completion of the lesson, and beyond. Marton and colleagues (2004) defines learning as the development of capabilities, where a capability is described as seeing, experiencing, or understanding something in a certain way. In order to develop a particular capability (way of seeing, experiencing, or understanding), one must simultaneously focus on the critical features of the particular object of learning. A variation theory perspective claims that we can only focus on that which we discern; we can only discern what we experience to vary; we can only experience variation if we have experienced different instances previously and can juxtapose our previous experiences with our current experience simultaneously.

Marton and colleagues (2004) contend that we can only learn that which we experience to vary. In order to ascertain the enacted object of learning, it is necessary to be concerned with what varies and what remains invariant in a learning situation. Marton et al. describe what varies and what remains invariant as a pattern of variation and identify four of these: (1) contrast, (2) generalization, (3) separation, and (4) fusion. The first pattern of variation, contrast, refers to the comparison between what something is and what it is not. For example, in the context of logarithms, $\log 100 = 2$ can be contrasted with $\log_2 8 = 3$ in order to discern which aspects of a logarithm statement can vary. In order to understand what it means for a logarithm to have base ten, students need to experience logarithms that are not base ten. The second pattern of variation is generalization, which refers to experiencing the varying appearances of an object of learning in order to separate it from irrelevant features. For instance, seeing $\log_2 8$, $\log 1000$, $\log_3 27$, and $\ln e^3$ as equivalent log expressions that all equal three, can help students to generalize what it means for a logarithm to be equal to three. The base of the logarithm is an irrelevant aspect here; but the power of the input in terms of the base is significant. The third pattern of variation, separation, involves varying a particular aspect of an object of learning while holding the other aspects invariant. This draws attention to the particular aspect that is allowed to change. The example above held the value of the logarithm invariant while changing the base, which then determined the input. Marton et al. contend that systematically varying certain aspects, while keeping other aspects invariant, can prepare students for various other situations related to the capability in question. Fusion, the last pattern of variation, is the experiencing of all of the critical aspects simultaneously. Through fusion, learners develop the ability to make generalizations that link the critical aspects of an object of learning (Holmqvist, 2011). For instance, discerning the relationship between the base of a logarithm and the input, in order to hold the value of the logarithm invariant, is a result of fusion and experiencing simultaneous changes in both the base and the input of the logarithm.

Drawing on Marton's work, Watson and Mason (2005) suggest that LGEs are an appropriate way to introduce new concepts in mathematics. The use of LGEs, however, may appear to be in conflict with variation theory, as the task designer/instructor concedes control of the presentation of specific examples to the students. Variation theory, however, does not suggest particular ways of arranging for learning, only that variation must be present for discernment. Rather, Marton and colleagues (2004) claim that the particular way of arranging for learning is dependent upon the thing to be learned, and research can be undertaken to determine the most conducive arrangement for student learning of that particular thing. In this sense, then, there is no tension between variation theory and the use of LGEs, as LGEs, when used in conjunction with collaboration, can create the variation in features necessary for discernment.

Watson and Shipman (2008) found that the use of LGEs, in a supportive classroom atmosphere, can successfully introduce new concepts for both advanced and low-achieving learners. Watson and Shipman suggest that while the discernment of critical features of a concept (Marton's *dimensions of variation*) through a set of examples may reveal the structure of the concept, learning through exemplification occurs through discerning the generalization of relationships across the dimensions of variation. Drawing on this work, the task used in this study was developed with the intended object of learning as generalizations related to the properties of logarithms, such as $\log_b(xy) = \log_b x + \log_b y$, $\log_b(\frac{x}{y}) = \log_b x - \log_b y$, and $\log_b x^n = n \cdot \log_b x$, as well $\log_b b^x = x$, which proceeds from the equivalence relationship between logarithmic and exponential statements: $\log_b a = x \leftrightarrow b^x = a$. As will be discussed in the analysis below, over the course of the three implementations of this task, the intended object of learning was shifted based on the insights gained in the first two implementations of the task.

METHODOLOGY

A task that involved learner-generation of examples of logarithm statements was enacted by the first author as the teacher/researcher with three groups of students: two sections of pre-freshman engineering students enrolled in a summer mathematics course, one of which was composed of students who had previously studied calculus (n=13) and the other of which was composed of students who had previously studied precalculus (n=12), and a small problem-solving session comprised of two pre-freshman students who were recruited from a summer precalculus course. The task was enacted with groups of students of varying achievement levels in order to expand on the teacher/researcher's understanding of the variation in students' reasoning about logarithms as revealed by the task. The first enactment was with the group of engineering students who had previously studied calculus; the second enactment was in a problem-solving session with two pre-calculus students; the third enactment was with the group of engineering students who had previously studied precalculus. Each enactment of the task was carried out by the teacher/researcher, and each of the enactments was video-recorded. Students' written work was also collected.

By the time students encounter logarithms in a typical precalculus course in the United States, students have already been introduced to logarithmic functions, the properties of logarithms, and have used logarithms to solve exponential equations (in a typical Algebra II course). Hence, logarithms were not a new concept for these students, but rather a concept that many of the students still struggled with in terms of recalling, applying, and reasoning with and about the properties of logarithms. Prior research also suggests that students tend to struggle with the relationship between logarithms and exponents, as well as the properties of logarithms (Weber, 2002; Wood, 2005). This study, then, expands on previous work related to the use of LGEs to introduce new concepts (Watson & Shipman, 2008) by using LGEs to deepen students' understanding of and reasoning about a previously introduced concept. This research study addressed the following questions:

1) What does the task, as implemented, reveal about students' understanding of logarithms?

2) What is the *enacted object of learning*, or what is possible to learn, given the task-as-implemented?

Task design and data analysis

As the task itself cannot be separated from its enactment, the way in which the task was implemented in each iteration varied. The variation in the task-as-implemented was influenced by the teacher/researcher's insights garnered from the previous implementation(s), as well as the particular *space of variation* opened in that implementation. Despite the differences in the implementation of the task among the three groups of students, commonalities between the *spaces of variation* opened in each of the implementations revealed much about students' understanding of logarithms and served to focus the teacher/researcher's *intended object of learning* for later implementations, as well as to refine the task.

The basic structure of the task in all three implementations involved (1) individual student generated examples, (2) group assessment and group generation of examples, (3) collective class organization/categorization of the student generated examples, and (4) generalization. In each iteration of the task, the teacher asked the students to write a log expression that was equal to three. Then the students were asked to write another. The student generation of examples was meant to draw on students' prior knowledge of logarithms and elicit students' understanding of logarithms, in general, and the value of a logarithm, in particular. The students were then arranged into groups of two to four students to share what they wrote with each other. The teacher distributed a set of index cards to each group, asking them to write a different log expression that equalled three on each card. This potentially required that the group generate additional examples as their original examples may have been duplicative. As groups of students finished writing their examples on the cards, the teacher asked them to tape their cards on the board. The teacher then gathered the students around the cards on the board and asked them to collectively categorize the cards. The collective student sorting of the log statements allowed the teacher to gain insight into what critical features of logarithms the students were attending to, as well as the structure of logarithms, as perceived collectively by the students. A discussion of the students' categories followed, along with additional student generation of examples of logarithm expressions equal to two and five, and finally, student generalizations.

Each of the three implementations were analysed using the framework of variation theory in an attempt to understand *the intended object of learning* and *the enacted object of learning* (or *the space of variation*). While this framework served to answer the second research question most directly, the analysis also addressed what was revealed about students' understanding of logarithms. The variation in the student generated examples, as well as what was revealed about students' prior understanding of logarithms, served to answer the first research question.

RESULTS

This section describes the insights garnered by the teacher/researcher primarily during the first two implementations of the task and the refinement of the task through the third implementation. The intended object of learning shifted from the properties of logarithms to the equivalence relationship between logarithms and exponents and the generalization $\log_b b^x = x$ to generate additional examples, equal to any given number, x. In all three implementations of the task, the categorization of the LGEs, largely by the base, showed that the base of the logarithm and the input of the logarithm, were brought to the fore as aspects of a logarithm that were possible to change, and the range of permissible change for each of these aspects was explored, to some extent. While all students were able to generalize the process of writing a log statement equal to a given number, higher achieving students were more readily able to recognize a generalization comprised of a single statement, such as $\log_b b^x = x$. Extending the task to include combinations of logarithm expressions may create an opportunity for students to verify the properties of logarithms and explore the relationship between the properties of logarithms and the properties of exponents.

The intended object of learning

The intended object of learning in the first implementation of this task was the generalizations related to the properties of logarithms, such as $\log_b(xy) = \log_b x + \log_b y$, $\log_b(\frac{x}{y}) = \log_b x - \log_b y$, and $\log_b x^n = n \cdot \log_b x$, as well as the equivalence relation: $\log_b a = x \leftrightarrow b^x = a$. We had anticipated LGEs of the form $\log_2 8 = 3$, but had also anticipated that some students would extend their thinking to include an example such as $\log_{10} 10 + \log_{10} 100 = 3$. Goldenberg and Mason (2008) discuss how example generation is not just a memory lookup, but rather found that students often start with some known example(s) and through combinatorial approaches can construct new examples. As students began generating examples in the first part of the task, the teacher/researcher quickly realized that while the combinatorial approach was not appearing, other examples that had not been anticipated were being generated by the students, such as examples with fractional bases.

In the second implementation the generalization $\log_b b^x = x$ was the intended object of learning, with b and x as the *dimensions of variation*. We were also interested in how to extend the task in such a way that allowed students to gain access to examples that included a combinatorial approach, as they did not appear in either the first implementation, or in the first portion of this problem solving session. The students were asked to use the logarithm statements that they had already generated and combine them in some ways (using addition, subtraction, multiplication, or division) to generate other logarithm statements equal to three. While this allowed students to recall and verify the properties of logarithms that they had previously learned, students could not discern why these properties were valid and they were unclear about the relationship between the properties of logarithms and the properties of exponents.

The third implementation of the task was a refined version, based upon our insights from the first two implementations of the task. In this implementation, the intended object of learning focused on the equivalence relationship between logarithmic and exponential statements: $\log_b a = x \leftrightarrow b^x = a$, as well as the general logarithm statement $\log_b b^x = x$ for generating logarithm statements equal to a given value, x. Students were not asked to combine logarithm expressions to generate new statements equal to a given value in this task. Rather, the combination of logarithms was separated into a distinct, but linked task, for the sake of time and depth.

Categorization of LGEs

After students shared their generated examples in a small group and on the board, the whole class categorized the examples they had generated. The first class separated the examples into four categories, determined largely by the base of the logarithm: (1) whole number, (2) base 10, (3) fractional bases, (4) special, and (5) wrong. The students in the third implementation were not able to use graphing calculators (that can calculate logarithm expressions with various bases), but rather used simple four-function calculators to calculate a larger power of a number. As suspected, perhaps due to the change in the type of calculator available for a tool, fractional bases for the logarithm expressions did not appear in the third implementation of the task. In the first portion of the second implementation, the students still organized their examples according to the base, first separating them into even and odd categories, then deciding to list them out from statements with base two up to statements with base ten. In the second part of the session, the students were asked to generate combinations of logarithm expressions equal to three and reorganize the examples, in consideration of the additional examples. The students chose, then, to categorize the LGEs by operation. The students in the third implementation also categorized the LGEs according to the base of the statement, however, they included four subdivisions or "branches": (1) Odd, (2) Even, (3) Base 10, and (4) Fractional, under the "big tree" of the equivalence relationship $\log_b a = x \leftrightarrow b^x = a$. This is similar to the students in the first implementation who also explained how all of their correct examples "followed the same rule," after they had determined a generalization for logarithms with whole number bases. The students in the third implementation also included a "wrong" category, a "natural log" category, which were actually exponential statements that included natural log in the exponent (e.g. $e^{\ln 3} = 3$), and a "unique" category, which included only the statement $\log_3 (\frac{729}{27}) = 3$.

In all three implementations of the task, the students' categorization of the LGEs showed that the base of the logarithm, as well as the input of the logarithm, was brought to the fore as aspects of a logarithm that were possible to change. The combinatorial approach did not spontaneously appear. In terms of revealing student understanding, however, Watson and Goldenberg (2008), point out that, "the fact that [students] don't display an example does not imply that it is not within their accessible [example] space, just that they have not perceived a reason to express it" (p. 189). As such, it appears that the task as enacted did not cue or trigger students to think of examples using the combinatorial approach. The *enacted object of learning*, in the first and third implementation, as well as the first portion of the second implementation, was restricted to the generalization $\log_b a = x \leftrightarrow b^x = a$, the equivalence relationship between logarithm and exponential statements, and the generalization $\log_b b^x = x$, which expresses the structure of the correct logarithm statements.

Range of permissible change

The LGEs served to reveal students' understanding of the *range of permissible change*, particularly in the base of the logarithm statement. As mentioned above, the combination of logarithm statements did not arise spontaneously, indicating that students did not, in that instance, recognize combinations of statements as within the *range of permissible change* for the structure of a logarithm expression equal to three. Without this range of LGEs, students tended to categorize the examples of logarithm statements according to the value of the base, despite the common structural form. Their choice to separate logarithm statements with a whole number base from those with base ten was perhaps indicative of their greater familiarity with base ten, or their understanding of the common log as somehow more important than logs in other bases. We did not anticipate the use of fractional bases students' generated examples; this may have been related to students' graphing calculator usage while generating their examples, particularly since this did not occur in the subsequent implementations when students were restricted to four function calculators. Students' choice of separating base e and base π logarithm statements as "special" could perhaps be indicative of students' sense of e and π as symbols that represent something other than a specific number. Students' recognition, however, of $\log_1 1 = 3$, $\log_0 0 = 3$, and $\log_{-1} -1 = 3$ as "wrong" logarithm statements served to restrict the *range of permissible change*. Student attempts at both justifying these statements and explaining why these logarithm statements were incorrect created an opportunity to deepen students' understanding of both exponents and logarithms.

Only a single example began to directly confront the *range of permissible change* for the input of the logarithm. The students seemed to recognize that the input of the logarithm would change, dependent on the base of the logarithm, but failed to see the range of possibilities in writing the input. In the third implementation, the example $\log_3\left(\frac{729}{27}\right) = 3$ was placed in the "unique" category. The statement $\log_3\left(\frac{729}{27}\right) = 3$ is equivalent to the statement $\log_3 27 = 3$. Therefore, it has the same structure as the other LGEs, but the students did not recognize it as such. This indicates that students could use more exposure to variation in the input of the logarithm. This was also the only instance when combinations of logarithm statements arose spontaneously. Two students in the third implementation insisted that the way that you would deal with this statement is to rewrite it as $\log_3 729 - \log_3 27 = 6 - 3 = 3$. Thus, students recalled the logarithm property $\log_b\left(\frac{x}{y}\right) = \log_b x - \log_b y$, and applied it, but this appeared to overshadow a more flexible and efficient means of simplifying the statement to show its equivalence to three.

Generalizations

In the last part of the task, the teacher/researcher asked the students to write a logarithm statement that was equal to any number. Some students generated two separate statements that was often a restatement of the equivalence relation: $\log_b a = x \leftrightarrow b^x = a$. Others were able to succinctly describe the generalization as $\log_b b^x = x$. Being able to symbolically write down a generalization did not indicate that students would be successful at verbalizing the generalization. For instance, Evette, in the third class, wrote the symbolic statement $\log_b a = x \leftrightarrow b^x = a$, and the verbal statement: "That 'any number' that you want it to equal, must be raised to the base value." While Evette correctly wrote the symbolic statement, she incorrectly stated that the exponent would be the base value. It is also ambiguous what she is referring to with the use of "it". This is perhaps related to a lack of opportunities to explain and communicate verbally in the mathematics classroom.

Lower achieving students had more difficulty than higher achieving students in discerning a generalization comprised of a single statement, such as $\log_b b^x = x$. This is perhaps related to an underdeveloped sense of variable and equality, and the failure to recognize the substitution of equivalent expressions. This could also be related to a preference of seeing each "part" of the logarithm statement (the base, the input, and the output) as distinct and a failure to fuse these critical aspects together.

Combinations of logarithm expressions

The expansion of the example space to include combinations of logarithm expressions in the second implementation served to broaden the *space of variation* when compared to the first and third implementations. Through opening up the variation of the statement to include combinations of logarithm expressions, it becomes possible to discern both *how* the logarithm expressions can be combined and the ways in which the *dimensions of variation* are related within a given statement. Watson (2000) described these two ways of seeing pattern as 'going with the grain,' indicating a recursive continuation of pattern to generate more instances that may not indicate structure (in this case, *how* the logarithm can be combined), and 'going across the grain', a metaphor that indicates the revelation of the internal structure itself (here, the relationship between the *dimensions of variation*). Thus, this opening of the *space of variation* has the potential to provide students with the opportunity to "see" the relationship between logarithms and exponents in ways that they had, perhaps, not experienced before. One of the students wrote about what he had learned during the problem solving session:

> The exponents in exponential equations are used as the values for logarithmic functions. For example:
>
> $$5^{2} + 5^{1} = 5^{3}$$
>
> $$\log_5(25) + \log_5(5) = 3$$
>
> $$2 + 1 = 3$$

While the exponential statement is erroneous, this student is beginning to discern variation 'across the grain', and we would argue, is on his way to developing a certain way of seeing logarithms, and hence developing important capabilities for reasoning about logarithms in powerful ways.

CONCLUSION

Based on the three iterations of this task, using LGEs with students who have had previous exposure to a concept can serve to reveal students' understanding of the *dimensions of variation* of a concept, as well as the *range of permissible change* in those aspects. The use of LGEs, in this particular task, revealed students' understanding of the *range of permissible change* in the base of the logarithm and led to opportunities to connect exponential and logarithmic functions. Holding the value of the logarithm statement invariant (for a time) created an opportunity for students to explore what happens when a single aspect, namely – the base of the logarithm, is varied.

While this task draws students' attention to the relationship among the *dimensions of variation* in a logarithm statement, as well as the *range of permissible change* of those dimensions, further consideration of how tasks can be designed to generate and develop an understanding of the relationship between combinatorial properties of exponents and logarithms is needed to more fully develop students' facility with logarithms.

2 University of Cyprus, Department of Education, Nicosia, Cyprus, pmicha@ucy.ac.cy, andreas.philippou@cytanet.com.cy

The present study investigates students' abilities to understand the concept of function. Secondary education students were asked to (i) define the concept of function and present examples of functions, (ii) translate between different representations of a function and (iii) solve function problems. Findings revealed students' great difficulties in proposing a definition of function, in solving tasks of conversions between different modes of representation, and in solving function problems. Based on the students' abilities and misconceptions about functions, teaching practices for improving the students' understanding of functions are discussed.

Keywords: Function, definition, use of representations, teaching methodology.

INTRODUCTION

For more than twenty years, the concept of function has been internationally considered as a unifying theme in mathematics curricula (Steele, Hillen, & Smith, 2013). Students face many instructional obstacles when developing an understanding of functions (Sajka, 2003; Sierpinska, 1992). Kieran (1992) questions whether students' inability of conceptually understanding functions is related to its teaching or is due to students' inappropriate way of approaching function tasks. Sajka (2003) indicates that students' abilities in solving tasks involving functions are influenced by the typical nature of school tasks, leading to the use of standard procedures. According to a standard didactic sequence, students are asked to infer the properties of a function using the given graph, by following a specific procedure.

In relation to the above, our study examines students' conceptions of function, as it is one of the most important topics of the curriculum and it is related to other subjects, such as physics (Sanchez & Llinares, 2003). In fact, the results we present in this paper are a part of a large scale cross-sectional study examining the use of different modes of representations in functions at the secondary school level. Adopting a developmental perspective at different grades of secondary education, we aim to trace students' abilities in defining functions, recognizing and manipulating them across representations and in problem solving, emphasizing the approach used (algebraic or geometric). Thus, our main questions are: (i) What abilities do students have to define and flexibly manipulate functions and solve function problems?, and (ii) What are the differences in students' performance at the 3rd, 4th and 5th grades of secondary education? Based on our results, we provide suggestions for teaching practices that can facilitate students' understanding of functions.

THEORETICAL FRAMEWORK

The role of multiple representations in the understanding of functions

There is strong support in the mathematics education community that students can grasp the meaning of a mathematical concept by experiencing multiple mathematical representations of that concept (Sierpinska, 1992). One of the main characteristics of the concept of functions is that they can be represented in a variety of ways (tables, graphs, symbolic equations, verbally) and an important aspect of its understanding is the ability to use those multiple representations and translate the necessary features from one form to another (Lin & Cooney, 2011). In order to be able to use the different forms of representations as tools in order to construct a proof, students have to understand the basic features of each representation and the limitations of using each form of representation.

According to Steele and colleagues (2013), it is typical in the U.S. for the definition of a function and a connection to the graphic mode of the function concept to occur in the late middle grades, while the formal study of function with an emphasis on symbolic and graphical forms occurs in high school. According to Bardini, Pierce and Stacey (2004), in their brief overview of Australian school mathematics textbooks, symbolic equation solving follows graphical work. A proper understanding of algebra, however, requires that students be comfortable with both of these aspects of functions (Schwartz & Yerushalmy, 1992). It is thus evident that the influence of teaching is extremely strong, and the promotion of specific tools or processes enforces the development of specific cognitive processes and structures. For example, it has been suggested that one way to improve learners' understanding of some mathematical concepts might be the use of graphic and symbolic technologies (Yerushalmy, 1991).

The role of definition in the understanding of functions

In mathematics definitions have a predominant role in the construction of mathematical thinking and conceptions. Vinner and Dreyfus (1989) focus on the influence of concept images over concept definitions. Over time, the images coordinate even more with an accepted concept definition, which in turn, enhances intuition to strengthen reasoning. A balance between definitions and images, however, is not achieved by all students (Thompson, 1994). Actually, pupils' definitions of function can be seen as an indication of their understanding of the notion and as valuable evidence of their mistakes and misconceptions. Elia, Panaoura, Eracleous and Gagatsis (2007) examined secondary pupils' conceptions of function based on three indicators: (1) pupils' ideas of what function is, (2) their ability to recognize functions in different forms of representations, and (3) problem solving that involved the conversion of a function from one representation to another. Findings revealed pupils' difficulties in giving a proper definition for the concept of function. Even those pupils who could give a correct definition of function were not necessarily able to successfully solve function problems.

METHODOLOGY

Participants

The participants were 756 secondary school students from eight schools in Cyprus. There were 315 students at 3rd grade of gymnasium (15 years old), 258 students at 4th grade of lyceum (16 years old) and 183 students at 5th grade of lyceum (17 years old). The students at 5th grade follow a scientific orientation and attend more advanced levels of mathematics courses. Students' participation was due to the voluntarily participation of their teachers, thus our sampling procedure was not randomized.

Procedure

Two tests including different types of tasks were developed. The tests were developed by the researchers and secondary mathematics teachers. The tasks were mainly aligned to the level of the 3rd graders and the tests were piloted to almost 100 students at each grade. At the middle of the school year, each test was administered to students by a researcher or by a teacher who had been instructed on how to correctly administer the test. The testing period was 40 minutes. The tests were scored by the researchers, using 1 and 0 for correct and wrong answers, respectively.

The tasks focused on (a) defining and explaining the concept of function, (b) recognizing, manipulating and translating functions from one representation to another (algebraic, verbal and graphical), (c) solving problems.

Costas has €20 and spends €1 per day. His sister has €15 and spends €0,5 per day.

i. Find the function expressing the amount of money (y) each person will have in relation to the number of days (x).
ii. Design the graph showing this function for each person.
iii. In how many days will the two brothers have the same amount of money? What will this amount of money be?

Figure 1: Example of a problem solving task

The first test asked students to (i) present a definition of function and an example, (ii) explain their procedure for recognizing that a graph does not represent a function and present a non-example of function, (iii) write the symbolic representation of six verbal expressions (e.g. "the area E of a square in relation to its side"), (iv) draw a graph to solve a problem, (v) recognize graphs of functions, (vi) explain a graph in terms of the context, and (vii) examine whether symbolic expressions and graphs represent functions. In the second test students had to (i) present their procedure for examining whether a graph represents a function, (ii) draw graphs of given functions, (iii) recognize graphs of given verbal or symbolic expressions, and (iv) write the symbolic equations of given graphs. The reliability for the total of the items on both tests was high (Cronbach's alpha=0.868).

RESULTS

According to our research questions, we first present the results of students' performance on defining the concept of function and their ability to present an example in order to explain the definition. Then, we concentrate our attention on the procedure students follow in order to justify whether a verbal expression or an equation is a function. A crosstabs analysis gives further insight into the performance of students in defining and recognizing functions. Finally, differences between students in the three grade levels are presented.

Based on the results of our descriptive analysis, 159 students were able to present a correct definition, 242 presented a wrong definition, and 358 students did not give any answer. Most of the students who presented a correct definition (Table 1) were at the 4th and 5th grade. The results were similar to the task that asked students to present an example for explaining the definition of function. Only 401 of the students presented an example, and of these, 323 were correct. The highest percentages of correct examples (Table 1) were at the 4th and 5th grade. This result is the first indication that students are perhaps more capable of providing an example in order to explain a mathematical concept than of defining it verbally by using formal language and/or symbolization.

In the first test students were asked to explain their procedure for identifying a graph that does not represent a function and provide a relation that does not represent function. In the second test, students were asked to explain their procedure for identifying a graph that represents a function and to provide an example of a function. Table 2 indicates the percentages of correct answers for the specific tasks. In all cases, the results were higher in the 5th grade, as was expected, but there were especially negative results for students in the 3rd grade. The majority of the 3rd graders did not give an answer and many of those who answered presented a wrong procedure.

	Correct definition	Correct example
Grade 3 (N=315)	8.2%	23.0%
Grade 4 (N=258)	58.5%	57.0%
Grade 5 (N=183)	32.7%	55.7%

Table 1: Students' correct definitions and examples for each grade

Tasks	3rd (%)	4th (%)	5th (%)	Total (%)
Procedure indicating that a verbal expression or an equation is not function	2.2	38.4	42.0	24.3
Procedure indicating that an expression is function	2.5	32.6	47.5	23.7
An example of a function	19.4	50.4	55.7	38.6
A non-example of a function	3.8	38.4	38.3	23.9

Table 2: Percentages of students' correct answers at specific tasks

We analysed, by using crosstabs analysis (Table 3), the performance of students who correctly described a procedure for determining whether a graph represents a function in relation to their ability to correctly identify functions presented graphically. Results indicated that less than half of the students, who correctly described a procedure, correctly recognized the graph that represented a function (44.1%).

We further analysed, by using crosstabs analysis (Table 3), the characteristics of students who were able to correctly define function. Consequently, these students seemed to have a more conceptual understanding of function. Results indicated that 89.4% of the students presented both a correct definition of function and a correct example, showing that they likely have a strong theoretical understanding of the concept. At the same time, of the students that provided a correct definition of function, 74.2% also succeeded in describing a procedure for determining whether a graph did not represent a function, and 62.7% also succeeded in describing the procedure for recognizing whether a graph did represent a function. These initial results permit us to assume that the students who are able to define function and explain by providing an example are the students with the highest conceptual understanding.

In the second test, students who were able to correctly describe a procedure for determining whether a graph represented a function were generally able to present an example of function (90.4%). Of the students who were able to correctly describe a procedure for determining whether a graph did not represent a function, 83.7% were also able to present a symbolic non-example of a function. It is important to note, however, that of the total sample, only 153 students correctly presented a procedure for recognizing a graph that represented a function, while only 135 students correctly presented a procedure for recognizing a graph that did not represent a function. Similarly, only 241 students correctly presented an example of a function, and only 165 students correctly presented a non-example.

	Example for definition	Describing a procedure for determining whether a graph represents a function	Describing a procedure for determining whether a graph does not represent a function
Recognition of function	–	44.1%	–
Correct definition	89.4%	62.7%	74.2%
Function Example	–	90.4%	–
Function Non-example	–	–	83.7%

Table 3: Crosstabs analysis for students' (total sample) understanding of functions

The second objective of the study was to identify statistically significant differences ($p<0.05$) concerning the concept of function in respect to students' grade level in order to investigate the developmental aspect of a conceptual understanding of function. ANOVA analysis was used for comparing students' means in presenting the definition of the concept and giving an example of a function in respect to the categorical variable of their grade. In the first case, Scheffé analysis indicated that there was a statistically significant difference ($F_{2,397}=33.396$, $p<0.01$) between the students at the 3rd grade with the students at the 4th and 5th grade ($\bar{x}_3=0.11$, $\bar{x}_4=0.53$, $\bar{x}_5=0.48$). Although the highest mean was at the 4th grade, there was not any statistically significant difference between the two grades at the lyceum. Concerning the presentation of an example in order to explain the definition of the concept, the difference was statistically significant ($F_{2,398}=5.896$, $p<0.01$) only between the 3rd and the 4th grade ($\bar{x}_3=0.72$, $\bar{x}_4=0.88$, $\bar{x}_5=0.78$). The same analysis was conducted concerning students' ability to describe a procedure for recognizing an equation which did not represent a function, in respect to grade level. There were statistically significant differences between the 3rd grade and the two other grades ($F_{2,292}=33.510$, $p<0.01$) with a large difference between the means ($\bar{x}_3=0.12$, $\bar{x}_4=0.47$, $\bar{x}_5=0.55$).

Items from both tests were grouped in order to be able to further analyse students' performance concerning the specific aspects which were the main interest of this study: (i) Propose definition, (ii) present examples to explain a concept or a procedure, (iii) recognition of the concept, (iv) translation of the concept from one representation to another, (v) construction of graphs which represent functions, as an indication of manipulating the concept and (vi) problem solving tasks. Table 4 presents the means and standard deviations of students' performance on these specific dimensions.

	$\bar{X}$	SD
Definition	0.718	0.261
Examples	0.837	0.231
Recognition	0.449	0.152
Translation	0.619	0.212
Construction	0.648	0.354
Problem solving	0.393	0.169

Table 4: Means and standard deviations of students' performance

ANOVA analysis was conducted for examining the statistically significant differences for each of the above aspects of a conceptual understanding of function in respect to the three grade levels. Statistically significant differences ($p<0.05$) were found only concerning three of the dimensions. There was a statistically significant difference ($F_{2,182}=7.678$, $p<0.01$) concerning the proposed definition of the concept. The Scheffé analysis indicated that the difference was between the 3rd grade with the 4th and the 5th grade ($\bar{x}_3=0.33$, $\bar{x}_4=0.75$, $\bar{x}_5=0.71$). The second statistically significant difference was for the students' ability to recognize functions presented in different forms of representations ($F_{2,570}=18.926$, $p<0.01$). The difference was between the students at the 3rd grade in comparison to the students at the 4th and 5th grade ($\bar{x}_3=0.48$, $\bar{x}_4=0.41$, $\bar{x}_5=0.40$). It was unexpected that in this case the performance at the 3rd grade was higher than the two other grades. The third statistically significant difference was for the students' ability to translate the functions from one type of representation to another ($F_{2,165}=11.077, p<0.01$). The students at the 3rd grade had a lower performance than the older students ($\bar{x}_3=0.343$, $\bar{x}_4=0.547$, $\bar{x}_5=0.702$).

DISCUSSION

We have concentrated on students' ability to define the concept of function and on their ability to handle flexibly the different modes of representation of function. The results of the present study confirm previous findings that students face many difficulties in understanding function at different ages of secondary education (Sajka, 2003; Tall, 1991). Findings revealed serious student difficulties in proposing a proper definition for function or a tendency to avoid proposing a definition due to their possible belief that the intuitive and informal presentations of their conceptions cannot be part of the mathematical learning. Those difficulties are consistent with Elia and colleagues' (2007) findings. Although formal definitions of mathematical concepts are included in the mathematics textbooks for secondary education, mathematics teachers do not focus on definitions. Instead they promote the use of algorithmic procedures for solving tasks, as actions and processes (Cottrill et al., 1996), and underestimate the word and meaning (Morgan, 2013) as interrelated dimensions of the concept.

Secondly, it seems easier for students to present an example for explaining a mathematical concept, rather than using a non-example in order to explain the respective negative statement. At the same time, it is easier for them to use an example for explaining the concept of function rather than explaining the procedure they follow for determining whether a graph represents a function. This is probably a consequence of the teachers' method of using examples in order to explain an abstract mathematical concept. Thirdly, students had a higher performance on manipulating the concept in graphical form and translating from one type of representation to another, than on recognizing functions in algebraic and graphical forms. Symbolic equation solving follows the graphical work (Llinares, 2000), and probably for this reason, the performance on graphical functions was higher. Finally, the results of the students at the 3rd grade of secondary education were especially negative, thus we have to further examine whether their processing efficiency and cognitive maturity prevent us from teaching the specific concept at that age. Despite the tendency to use the spiral development of concept in the teaching process and the curriculum (Ministry of Education and Culture, 2010), we have to rethink the teaching methods we use at the different ages and the cognitive demands of tasks at each age.

We believe that it is not adequate just to describe the students' knowledge of a concept, but it is interesting to design and implement didactic activities and examine their effectiveness. Brown (2009) suggests that the construction of concept maps will enable teachers to have in mind all the necessary dimensions of the understanding of the concept. The distinction of the procedural understanding and the conceptual understanding and the lack of interrelations between aspects such as the definition of the concept, the manipulation of the concept and problem solving related to a concept have as a possible result the phenomenon of compartmentalization (Elia, Gagatsis, & Gras, 2005). Thus, the use of multiple representations, the connection, coordination and comparison with each other and the relation with the definition of the concept should not be left to chance, but should be taught and learned systematically.

The verification of the interrelations between the different aspects of understanding functions are within our next steps, which include the confirmatory factor analysis (CFA), for confirming the theory about the structural organization of the conceptual understanding of functions. We are going to examine whether the students' abilities in defining the concept, in recognizing and manipulating the concept and in translating the concept from one representation to another are important dimensions of the conceptual understanding of functions. Specifically we will focus on the interrelationship between these dimensions. Special emphasis will be given to the role and influence of the definition on the remaining dimensions of the conceptual understanding of functions, as our results revealed students' great difficulties in this particular aspect of the concept.

Concluding, the present study enables us to know and understand how students conceptualize the notion of function and to realize the students' obstacles and misunderstandings. Teaching processes and teaching materials need to be enriched with problem solving situations. The given examples presented by students were mathematically structured by using a formalistic way and there was not any reference to a daily experience. In the context of the interdisciplinary social reality, the concept of function has to be related to other relevant domains such as physics, engineering, and technology.

Limitations

A limitation of our study concerns the administration of the tests. In cases where the administration was not performed by the researchers, there is no certainty that the proper amount of time was given to the students. Thus we cannot be sure that the same conditions held in every classroom during the administration of the tests, and this may have affected the reliability of the tests. The teachers who administered the tests, however, were provided with all the necessary instructions. A further limitation of the study was our inability to control the teaching method which was used for the specific concept. In Cyprus, however, teachers receive the same instructions by the Ministry of Education for the teaching methods they have to use in their classes and the same in-service training. There is also a common curriculum and a common textbook for students.

The development of student's early number sense

Marios Pittalis, Demetra Pitta-Pantazi and Constantinos Christou

University of Cyprus, Nicosia, Cyprus

The present study adopted a theoretical model, suggesting that number sense consists of elementary number sense, conventional arithmetic and algebraic arithmetic, to trace the development of students' early number sense. Two hundred and four 1st grade students were individually tested on five time-points. Data analysis suggested that number sense follows a linear growth rate and six groups of students were identified that follow different growth patterns. Two of the groups had a low initial value, two had a moderate initial value and two had high initial value. Systematically, one of the two groups with the same initial value exhibited a greater growth rate. The gap of the groups with same initial value in algebraic arithmetic progressively increased across the five time-points of the study.

Keywords: Early number sense, arithmetic, algebraic arithmetic.

INTRODUCTION

The development of students' number sense is considered as an important outcome and key ingredient of school curricula and a foundation for developing formal mathematical concepts and skills in elementary school (Yang, 2005). Research findings support that number sense is a powerful predictor of mathematics outcomes and a vital prerequisite to success in mathematics (Malofeeva, Day, Saco, Young, & Ciancio, 2004). Recent longitudinal studies documented that number sense skills developed in pre-K and kindergarten are not only foundational, but also correlate with first grade mathematics achievement (Jordan et al., 2006). It was found that the mastery of counting principles correlates significantly with arithmetic abilities. Moreover, Jordan, Glutting, Ramineni and Watkins (2010) showed that core number competences in kindergarten have strong predictive validity on mathematics computation and problem solving even at third grade.

The present study capitalizes on previous studies asserting that early number sense consists of three distinct, but interrelated components (Pittalis, Pitta-Pantazi, & Christou, 2013, 2014). Our adopted model hypothesizes that student's early number sense consists of (a) elementary number sense, (b) conventional arithmetic and (c) algebraic arithmetic. The innovative aspect of this model lies on the inclusion of algebraic arithmetic as a component of number sense and builds on the theoretical premise that the artificial separation of arithmetic and algebra deprives students of powerful ways of thinking about mathematics in early grades and makes it more difficult for them to learn algebra in later grades. Algebraic arithmetic adopts Drijvers and his colleagues (2011) description of algebra as a synthesis of (a) patterns and formulas, (b) restrictions and (c) functions. This conceptualization of algebraic arithmetic leads to a broader, more dynamic and flexible construct that underlies the importance of grasping the relations among numbers and manipulating numbers and number relations with flexibility.

In this study, we extend the work presented in PME 38 and present the results of a longitudinal study that traced student's number sense in grade 1 and at the beginning of grade 2. In particular the aims of the study were to: (a) to trace the development of six year old students' number sense and (b) to identify different growth patterns.

LITERATURE REVIEW

Number sense is one of the most important concepts to be developed in early mathematics (Baroody et al., 2009; McGuire & Wiggins, 2009). Children's number sense is a key predictor of later mathematical success, both in the short (Aunio & Niemivirta, 2010) and the longer term. For instance, research findings suggest that early number sense development contributes in learning more complex mathematics concepts, it promotes numerical fluency and it is foundational to all aspects of early mathematical skills (Baroody et al., 2009; Jordan et al., 2010). Inadequate development of number sense in early grades may be related to mathematics learning difficulties. In addition, it is widely supported that students who enter school with strong number sense are more likely to benefit from mathematics teaching in the elementary grades and that the effect of weak number sense may be cumulative (Jordan et al., 2010).

Number sense develops gradually and matures with experience and knowledge (Reys & Yang, 1998). It develops as a result of exploring numbers in a variety of contexts and relating them in ways not limited to traditional algorithms (Sood & Jitendtra, 2007). Moreover, number sense is highly personal and is a by-product of teaching for understanding. Longitudinal studies provided evidence regarding the growth of students' early number sense in kindergarten and in elementary early grades. For instance, Jordan and her colleagues (2010) traced empirically three growth trajectories: (a) children who started with low number competence and stayed low, (b) children who started with high number competence and stayed high, and (c) those who started with low number sense but made relatively good growth. A growing body of research with converging data (Gersten et al., 2005; Jordan et al., 2010) assert that the identification of growth groups is extremely important to trace students that need early intervention.

A number of researchers proposed that number sense is difficult to define, while different research studies identified different conceptual understandings and components of number sense (Malofeeva, Day, Saco, Young, & Ciancio, 2004).A well-accepted and broad definition of number sense refers to a coherent understanding of what numbers mean, numerical relationships and the ability to handle daily life situations which involve numbers (Yang, 2005). In the present study we define early number sense as a synthesis of elementary number sense, conventional arithmetic and algebraic arithmetic (see Pittalis, Pitta-Pantazi, & Christou, 2013, 2014). Elementary number sense refers to key elements of numbers sense. It consists of counting, number identification, number knowledge, quantity discrimination, enumeration and non-verbal calculations (Jordan, et al., 2006). Counting relates to grasping one to one correspondence, knowing the count sequence and mastering counting principles, such as stable order and cardinality (Jordan, et al., 2006). Number knowledge refers to discriminating and coordinating quantities and making numerical magnitude comparisons. Enumeration relates to the ability of enumerating sets, irrespectively of the orientation of the objects. Number identification refers to the ability of naming written symbols. Non-verbal calculations refer to the ability of manipulating non-verbal addition-subtraction situations with objects, while quantity discrimination relates to the ability of recognizing the relative magnitude size (Reys, & Yang, 1998). Conventional arithmetic includes students' ability to calculate number combinations, conceptualize the effect of operations (Yang, 2005) and solve story problems. Number combinations relates to students' ability of executing calculations with no object referents (Jordan et al., 2007). Understanding the effect of operations involves students' ability to conceptualize, judge and interpret the meaning of operations. Story problems conceptualize the ability to solve simple word problems, without using manipulative.

Algebraic arithmetic refers to the dimension of early number sense that moves beyond conventional arithmetic. It encompasses the development of a more sustainable and abstract understanding of the relations among numbers. Thus, the inclusion of algebraic arithmetic as a component of number sense could be considered as a move from particular numbers and measures towards relations among sets of numbers and measures. It can be conceived as a generalized arithmetic of numbers and quantities in which the concept of function assumes a major role. The inclusion of algebraic arithmetic as a factor of number sense results in reconceptualising the conception of number sense. The proposed nature of number sense defines a more dynamic and flexible construct that could facilitate students' advancements and transition to a more abstract and relational system of thinking. In particular, algebraic arithmetic encompasses the general cognitive ability of relational thinking, since it focuses on relations than on calculating answers (Carpenter, Levi, Franke, & Zeringue, 2005). In particular, algebraic arithmetic refers to number patterns, functions and restrictions (equations and balance scale restrictions), as proposed by Drijvers and his colleagues (2011). The parameter of number patterns involves searching for regularity and patterns to recognize a common algebraic structure. The dimension of restrictions describes students' ability in finding what value(s) of the unknown satisfies the required conditions in various situations; balance scale tasks or in more formal setting, such as equations. The function component involves students' ability to investigate arithmetic relations between quantities/variables.

METHODOLOGY

Subjects

The subjects of the study were 204 first grade students from 7 urban primary schools in Cyprus. The school sample is representative of a broad spectrum of socioeconomic background. Students were assessed on the number sense measures four times during the period October to June (approximately one administration per two months). A fifth measure took place at the beginning of the following year, when students attended grade 2. During each measurement students were interviewed in two sessions of approximately 30 minutes each. Students had a time restriction for each type of task (one minute for the majority of tasks). Students were individually tested in all five occasions. The order of the parts was rotated in the five time series.

Measures

The majority of the test items were adopted from the Curriculum Based Measurement (Fernstrom & Powell, 2007) and the rest ones were developed based on the theoretical considerations of the study. Six types of tasks were used to measure elementary number sense: (a) counting tasks, (b) number recognition, (c) quantity discrimination, (d) number knowledge, (e) enumeration, and (f) non-verbal calculation. In the counting tasks, students were asked to enumerate objects, in the number recognition tasks, students had to read numbers, in the quantity discrimination tasks students were asked to decide which was the largest number, in the number knowledge tasks, students were asked to find smaller and bigger numbers of a given one and in the non-verbal calculation tasks students had to add or delete objects in a given set so the number of objects corresponds to a given number. Conventional arithmetic was measured by three types of tasks: (a) story problems, (b) understanding of operations and (b) number combinations. In story problems tasks, students had to select the appropriate number sentence for a list of story problems. In the understanding of operations tasks, students were presented with simple word problems and were asked to select out of 4 mathematical sentences, the one that fitted the problem. In number combinations tasks students had to find mentally the result of addition, subtraction, multiplication and division combinations. Finally, algebraic arithmetic was measured by four types of tasks: (a) number patterns, (b) restrictions-equations, (c) restrictions-balance scale and (d) functions. In number patterns tasks, students had to extend or complete number patterns, such as 5, 8, 11, ... The ability to solve number patterns implies that a student can conceptualize the relations among numbers to fill in or extend a number pattern. For the assessment of students' abilities in number restrictions two types of tasks were used, number equations and balance scales. In the number equations, students were asked to complete the missing terms of equations, such as 3+5=4+□. Solving number equations encompasses conceptualizing the equal sign as equity of two quantities and the relations among all its components. In addition, estimating the missing term by analysing the relations among the components of the equation, instead of executing calculations, indicates students' flexibility and it is less time consuming. The other restriction task appeared in the form of a balance scale. Students had to identify the value of two or three shapes which balanced in the balance scale with a given number. Finally, regarding student's abilities with functions, students were presented with function machines and a table which showed the input and output values. Students were requested to provide the input or output numbers which were missing. The task was an adaptation of a task presented by Drijvers and his colleagues (2011). Students had to identify the relation between the input and the output value, identify the effect of change and examine whether their hypothesized rule was valid in all cases.

Data Analysis

To trace the development of number sense we used latent growth models. Growth models examine the development of individuals on one or more outcome variables over time. In order to evaluate model fit, three widely accepted fit indices were computed (Muthén & Muthén, 2007): The chi-square to its degree of freedom ratio (x^2/df should be <2); the comparative fit index (CFI should be >.9); and the root mean-square error of approximation (RMSEA should be close to or lower than .08). Latent class analysis was used to trace categories of students reflecting different developmental patterns in number sense; this is a statistical method for finding sub-types of related cases from multivariate data. To make the extraction of an average score for each dimension of number sense feasible, it was thought appropriate to set the highest score in each test across the five time-points as 1 and then make the necessary adaptations. That was necessary because all the tasks were equivalent and the time restriction did not allow the setting of an ultimate maximum score. The same procedure was followed for the extraction of an average number sense score.

RESULTS

Student's early number sense development

To evaluate change in students' number sense components, the repeated measures longitudinal date were analysed using latent growth curve analysis. The latent intercept of number sense was defined by fixing all loadings at 1, whereas the loadings for the latent slope of number sense were set to the values of each time-point (i.e, t_1=beginning of Year 1, t_2=January, t_3=March, t_4=June, t_5=beginning of Year 2). It was assumed that t_1=0, indicating that the intercept of each component can be interpreted as the individual initial value and the slope as the individual rate of change over time. The hypothesized latent growth model assumed that student's early number sense followed a linear growth rate across the five time-points. Alternative models hypothesizing (a) a quadratic trend in the slope and (b) a logarithmic trend were examined. Figure 1 presents the way in which the factors of the model relate to each other.

The results of the study showed that the hypothesized linear growth model had an excellent fit to the data (χ^2/df=1.94, CFI=.99, RMSEA=.07). The fit of the two alternative models was extremely poor (χ^2/df>10, CFI<.70, RMSEA>1). Thus, it was concluded that student's early number sense followed a linear growth rate. Two latent factors were estimated for number sense, the intercept (or initial value) of the latent number sense and the slope (or growth rate). Each contains a latent growth factor mean and variance, with the covariance being allowed between them. Both the mean intercept and mean slope of number sense were significantly greater than zero. The results of the model fit and significant slope mean and variance supported the proposed growth model regarding the linear development of the parameters of number sense. The analysis showed that the mean value of student's number sense intercept was 0.20 and the mean value of the slope across the five time-points was 0.07. The $M_{N.S.}$ value of 0.07 can be interpreted as the increase in performance per unit of time (i.e., 0.07 × 4 = 0.28), which corresponds to the actual increase of the mean value of number sense from time-point 1 to time-point 5. The amounts of variation of the intercept factor and slope factor were significant larger than zero. This finding is extremely important because we could conclude that there is variability. The correlation between the intercept and the slope was positively strong ($\underline{r}$=.55, $\underline{z}$>1.96), indicating that students entering first grade with a strong number sense may exhibit greater growth rate.

Figure 1: The hypothesized growth model

Tracing growth patterns

To trace categories of students that follow different growth behaviour, latent class analysis was used. To do so, we first examined whether students varied at entering grade 1. Thus, we applied a stepwise method to validate the model under the assumption that there were one, two, three, four or five categories of students at time 1 (first measurement). The best fitting model with the smallest AIC and BIC indices and the largest entropy was the one involving three categories of students. The mean value of the three categories were 0.13 (n_1=62), 0.20 (n_2=99) and 0.30 (n_3=36), respectively. Then, we repeated the same procedure for each category of students, using the data of the four remaining measurements. The results of the three latent class analysis showed that each of the three initial categories of students could be more accurately modelled by two sub-categories of students. Thus, in total we traced six groups of students that varied across the five time-points. Figure 2 presents the development rate of the six groups.

	Group 1	Group 2	Group 3	Group 4	Group 5	Group 6	Total
N.S.T_1	0.12	0.13	0.20	0.22	0.29	0.31	0.20
N.S.T_2	0.18	0.21	0.27	0.30	0.36	0.40	0.27
N.S.T_3	0.22	0.27	0.31	0.38	0.41	0.49	0.32
N.S.T_4	0.28	0.35	0.40	0.52	0.48	0.59	0.40
N.S.T_5	0.35	0.41	0.46	0.62	0.56	0.68	0.47

Table 1: Means of the six groups

Groups 1 ($n_{Gr.1}$=32) and 2 ($n_{Gr.2}$=30) represent the two subgroups of the first initial category. Groups 1 and 2 had almost the same initial value, but progressively Group 2 adopted a greater growth rate. Groups 3 ($n_{Gr.3}$=70) and 4 ($n_{Gr.4}$=21) represent students entering grade 1with moderate initial value. However, Group 4 exhibited a remarkable growth rate, overtaking after the third measurement a group that had a greater initial value (Group 5). Groups 5 ($n_{Gr.5}$=19) and 6 ($n_{Gr.6}$=17) exhibited the greatest initial value. Overall, the mean value of Group 5 increased from 0.29 to 0.56 (see Table 1), while the mean value of Group 6 increased from 0.31 to 0.68, indicating a significantly greater growth rate.

Summing up, we traced six groups of students that followed different growth patterns. Two groups with low initial value, with the one following a moderate growth rate and the other one adopting a remarkable growth rate, two groups with moderate initial value, with the first adopting a moderate growth rate and the second exhibiting an amazing progress, and two groups with high initial value, with the one adopting a constant greater increasing rate. To get a better insight of the reasons that may explain the different developmental trends of the six groups of students, we examined their growth rate in the three dimensions of number sense.

Figure 3 presents the development of the six groups of students in the three dimensions of number sense. Comparing groups 1 and 2 (with low intercept), it could be concluded that in the first four time-points the gap between the two groups in elementary arithmetic got constantly bigger and it was reduced in the last measurement (beginning of grade 2). The gap between the two groups in conventional arithmetic increased until the third measurement and then it stabilized. However, the gap between the two groups in algebraic arithmetic increased systematically, especially after the third measurement. It should be noted that the gap between the two groups with moderate initial value (Groups 3 and 4) got impressively larger every successive time-point in all number sense components. On the contrary, the gaps of the three components between the two groups with high initial number sense (Groups 5 and 6) followed three different patterns. Their gap in elementary number sense increased until the third time point and then

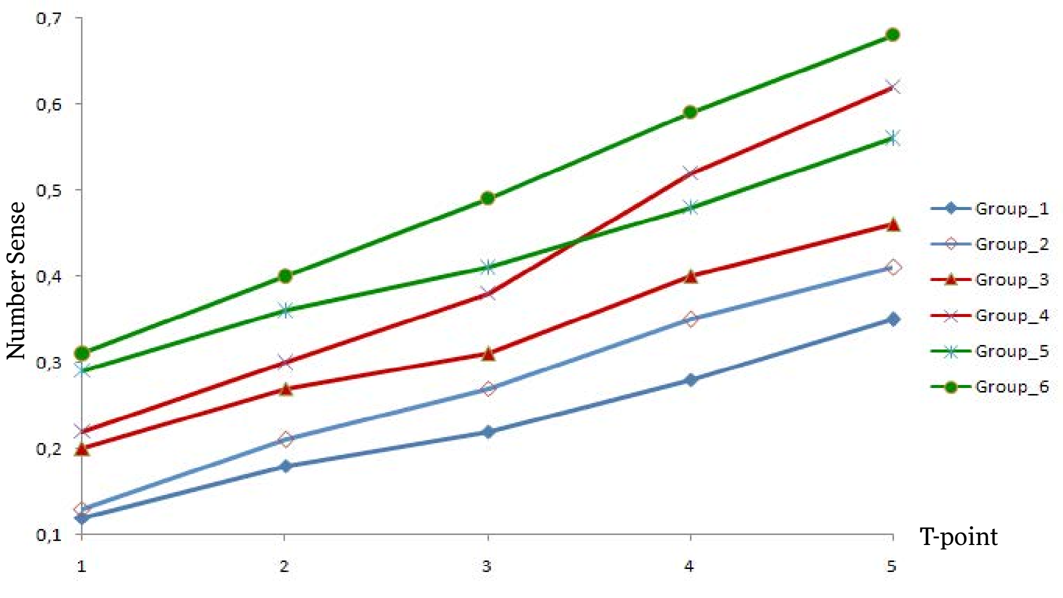

Figure 2: The development rate of the six groups

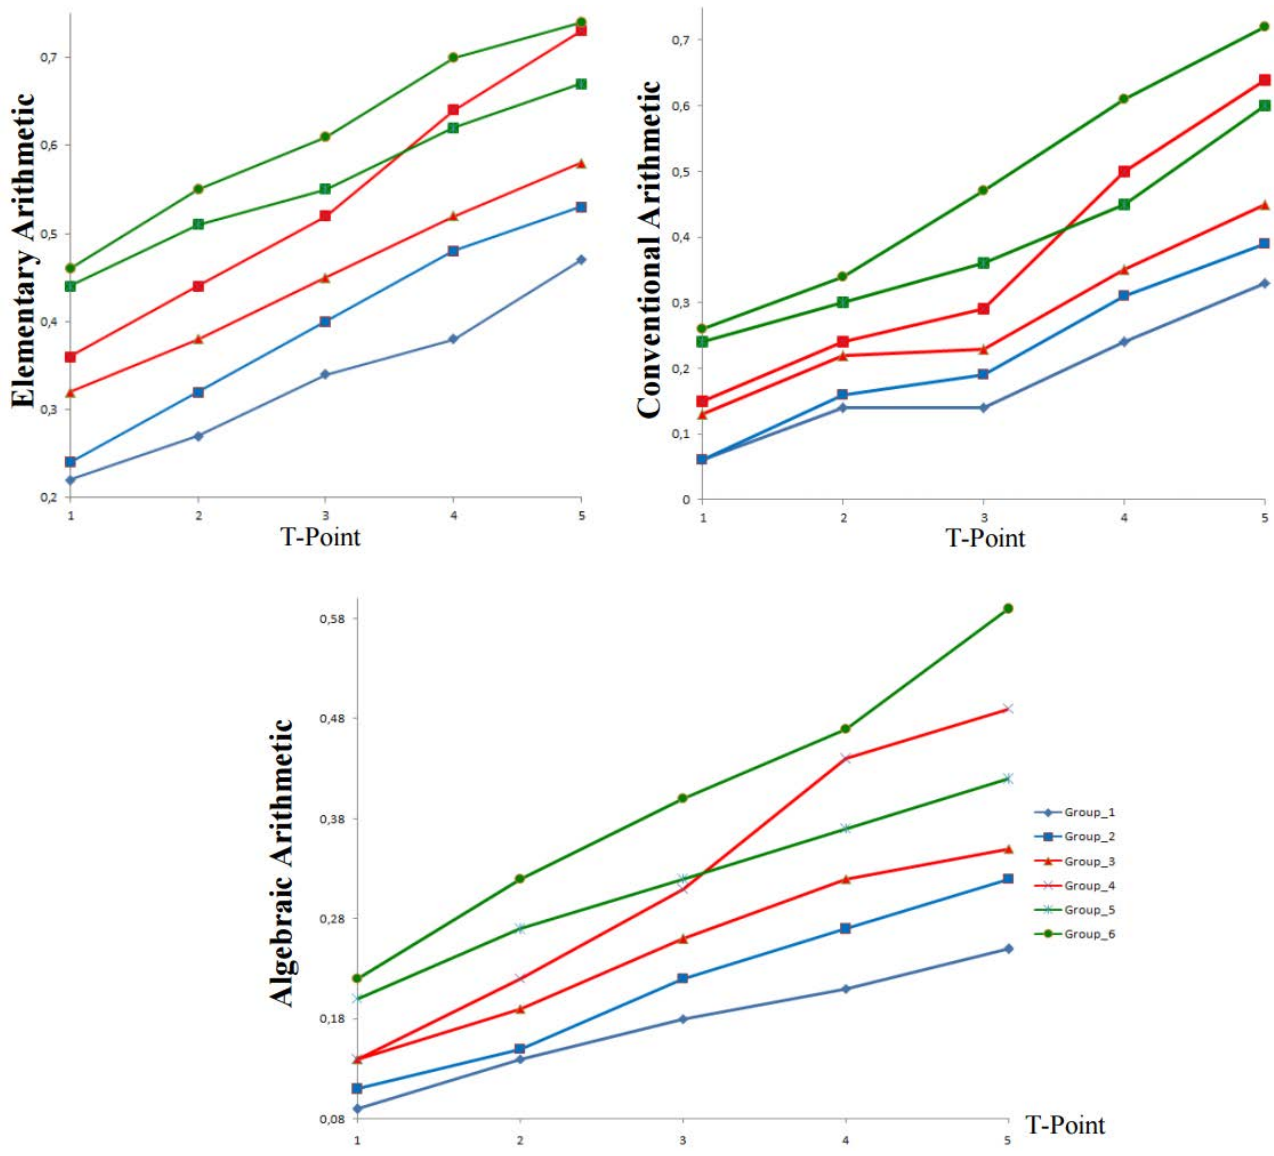

Figure 3: Development of the six groups in the dimensions of number sense

stabilized. The gap in conventional arithmetic got systematically bigger until the fourth time point and then reduced, while their gap in algebraic arithmetic progressively increased.

DISCUSSION

The present study utilized the model proposed by Pittalis, Pitta-Pantazi and Christou (2013, 2014), suggesting that students' early number sense consists of elementary, conventional and algebraic arithmetic, to trace six year old student's development in number sense. The results of the study showed that student's early number sense followed a linear growth rate from the beginning of grade 1 to the beginning of grade 2, suggesting a constant increase across the five time-points. However, the variation in the intercept and slope factors suggest that there are individual trajectories in the development of number sense. In addition, mixture growth analysis showed that six groups of students could model more accurately student's variances in the five time-points. We identified two groups of students with low initial number sense, two groups with moderate initial value and two groups with high initial value. Systematically, the one of the two groups with the same initial value adopted a greater growth rate in all the dimensions of number sense.

We might suggest that the gap between the groups with same initial value could be explained by their progress in algebraic arithmetic. This could be concluded by the fact that the gap between the groups with the same initial value progressively increased across all the five time-points only for algebraic arithmetic. Thus, we might suggest that algebraic arithmetic might be the source of large individual differences in number sense development. In addition, it might be assumed that the development of students' algebraic arithmetic might positively affect the development of the other number sense components. For instance, Group 4 every major improvement in algebraic arithmetic was followed by a corresponding huge improvement in conventional arithmetic in the following time point. These findings highlight the dynamic nature of algebraic arithmetic and underlie the significance of studying (a) more extensively the factors that may enhance or prohibit the development of algebraic arithmetic and consequently the development of student's early number sense, (b) the interaction among the growth of the three components of number sense and (c) the effect of instruction and teaching material on their growth rate.

College students' understanding of parameters in algebra

Valentina Postelnicu[1] *and Florin Postelnicu*[2]

1 Texas A&M University-Corpus Christi, Corpus Christi, USA, Valentina.Postelnicu@tamucc.edu

2 Alhambra High School, Phoenix, USA

A study was conducted with 26 college students with the purpose of gaining insight into students' conceptual understanding of parameters in algebra. Participants contributed to a whole-class discussion, solved problems with parameters, and identified the parameters in each problem. About one third of the students had difficulty identifying parameters. Even when successful at identifying parameters, students had great difficulty solving the problems with parameters. The difficulty was even greater when the mathematical object was a family of quadratic equations. This suggests that the true difficulty lies not with identifying parameters, but with parameters in action, that is to say when solving problems with parameters.

Keywords: Parameter, algebra, college students.

INTRODUCTION

At the time Šedivý (1976) wrote "A note on the role of parameters in mathematics teaching," the New Math era in the United States was replaced by the Back-to-Basic movement. The New Math secondary algebra curriculum, characterized by a structural approach and deductive reasoning, was replaced by a collection of "basic" algorithms to solve simple equations (Kilpatrick & Izsák, 2008). Solving equations with parameters like, $x + \sqrt{x^2 - 2ax} = b$ (Šedivý, 1976), using symbolic manipulation, disappeared from the secondary algebra curriculum. During the Back-to-Basic movement, the research on parameters was very scarce (Bloedy-Vinner, 1994). According to Furinghetti and Paola (1994), in the journals *For the Learning of Mathematics*, and *Educational Studies in Mathematics* only one article with the word "parameter" in the title was published, the one written by Šedivý (1976). The secondary algebra curriculum of the standards-based era that followed the Back-to-Basic movement departed from the static equation solving and gradually introduced the dynamic functional approach and the use of graphing technologies (Kilpatrick, Mesa, & Sloane, 2007). The research on parameters remained scarce (Ursini & Trigueros, 2004) and only in the last decade gained some momentum by focusing on ways in which graphing technologies may contribute to student understanding of parameters (Abramovich & Norton, 2006; Green, 2008). The purpose of the study reported here is to revisit the students' conceptual understanding of parameters in algebra, given the curriculum shifts from the past five decades.

THE CONCEPT OF PARAMETER

There is a consensus that the concept of variable is multi-facetted and context-dependent (Kuchemann, 1978; Philipp, 1992; Schoenfeld & Arcavi, 1988; Usiskin, 1988). Variables as parameters have the role to stand for values or numbers "on which other numbers depend" (Usiskin, 1988). Parameters are "general constants" (Philipp, 1992) or "general numbers, but of second order, that is, required when generalizing first order general statements." (Ursini & Trigueros, 2004) Discriminating between parameters and other variables implies both a variable hierarchy (Bloedy-Vinner, 1994; Philipp, 1992; Šedivý, 1976), and a reification of the mathematical objects defined with the help of parameters (Sfard & Linchevski, 1994). With respect to the mathematical objects with parameters, in the secondary algebra curriculum in the United States, the students encounter mostly families of linear and quadratic equations and functions in which one particular value of the parameter generates one specific equation or function.

One example given by Philipp (1992) is conceiving of the parameter k in the family of linear functions

$C = kg$, where C is the cost per gas (in \$), k is the price of gas per gallon (in \$ per gallon), and g is the quantity of gas (in gallons). First, one has to imagine selecting the price of gas, i.e., instantiating k with posible values (e.g., \$2.49, \$2.69, \$2.99), and only then can one construct the specific mathematical object, i.e., the specific linear function that describes the quantitity of gas, g, and the cost, C, varying together with a constant rate of change, k. Thus, discriminating between the parameter k, the dependent variable C, and the independent variable g, implies both a variable hierarchy and a reification of the family of linear functions. With respect to the family of functions $C = kg$ or $C(k, g) = kg$, from the student point of view, it may be difficult to conceive of k as the literal coefficient of the variable g and instantiate it with one value at a time to obtain particular linear functions $C(g) = kg$. If we use the subscript notation for the parameter k in the family of functions $C_k(g) = kg$ as suggested by Šedivý (1976), we fulfill the need to specify explicitly which variable is considered a parameter, and which ones are considered the independent and dependent variables. As well, it may be even more difficult for students to conceive of k as a variable with a specific domain, attend to all its values simultaneously, and conceive of the whole family of linear functions $C(k, g) = kg$ as a mathematical object.

Another example used in this study (see Problem 1, in the Method chapter) is conceiving of the parameter m in the family of quadratic functions $E_m(x) = mx^2 + 2x + 3$. Within this context, we can pose the problem:

> Find the values of m, where $m \in R - \{0\}$, such that the equation $E_m(x) = 0$ has only real solutions.

Unfortunately, in our secondary algebra curriculum we rarely use the subscript notation. Therefore we formulate Problem 1 this way:

> Find the values of m, where $m \in R - \{0\}$, such that the equation $mx^2 + 2x + 3$ has only real solutions.

Assuming that a student with "symbol sense" – a "feel for symbols," "at the heart of competency in algebra", as described by Arcavi (1994), identifies the parameter m, and conceives of the quadratic equation $mx^2 + 2x + 3$, there remains the hardest part yet, requiring both "symbol sense" and knowledge of quadratic equations, linear inequalites, and intersection of sets. The student should interpret the paramenter m as a literal constant, impose the condition of positivity for the discriminant of the quadratic equation, accept the role change for the symbol m (now a variable for the linear inequality), solve the linear inequality $4 - 12m \geq 0$, and intersect the solution set with the domain of the parameter m. The final solution, $A = (-\infty, \frac{1}{3}) - \{0\}$, should have meaning for the student – every value of the parameter m from A instantiates a quadratic equation $E_m(x) = 0$ that has two real solutions. In short, the student should conceive of the family of quadratic equations $E_m(x) = 0$ ($m \in R - \{0\}$) as a mathematical object (Sfard, 1991) at the beginning of the problem, unpack the mathematical processes the mathematical object entails, and reify the new mathematical object $E_m(x) = 0$ ($m \in (-\infty, \frac{1}{3}) - \{0\}$) that satifies the condition imposed by the problem.

The literature on student understanding of parameters points to student difficulty to discriminate between parameters and other variables, reify mathematical objects (Sfard, 1991), and succefully solve problems with parameters especially when the context is unfamiliar (Bloedy-Vinner, 1994; Furinghetti & Paola, 1994; Šedivý, 1976; Ursini & Trigueros, 2004).

The theoretical framework we propose for analyzing student understanding of the concept of parameter has two levels: I) *identifying parameters*; and II) *parameters in action*.

Each level has three categories, corresponding to student actions as observed. When asked to *identify parameters*, students: i) correctly identify parameters; ii) identify "actual" parameters; or iii) identify other variables as parameters, like the independent and dependent variable in a function.

The term "actual" is borrowed from computer science and represents constants or expressions used in places where parameters might have been used in another context. For example, a student may reason this way: a, b, c are parameters in $ax^2 + ax + c = 0$, therefore "m, 2, and 3 are all parameters in $mx^2 + 2x + 3 = 0$."

Across the level *parameters in action*, we have three categories for student actions. When asked to solve the problem with parameters, students: i) solve the problem and check/discuss the solution given the constraints of the problem; ii) apply the right algorithm to solve the problem without considering the constraints of the problem; or iii) cannot solve the problem.

This theoretical framework is a departure from the dichotomy "algebraic-analgebraic" used by Bloedy-Vinner (1994) to analyze students' difficulties with parameters. By treating all the incorrect answers as "analgebraic" we lose access to valuable information with respect to students' difficulties and concequently to ways of overcoming those difficulties. In our framework, the two levels capture those two reifications needed to solve problems with mathematical objects defined with the help of parameters, the second level posing more difficulties to students than the first one. Morevoer, the intermediate categories capture the students' over-reliance on pseudo-empirical abstractions (Piaget, 2001). Piaget (2001) discriminates between pseudo-empirical knowledge abstracted from individual actions on objects, and reflective knowledge abstracted from coordinated actions on objects. For example, in Problem 1, when the student identifies "m, 2, and 3 are all parameters in $mx^2 + 2x + 3 = 0$," we may infer that the parameters are recognized as the coefficients of x^2, x, and x^0 in the mathematical object $ax^2 + ax + c = 0$. As such, the student performs individual actions on the quadratic equation $mx^2 + 2x + 3 = 0$, and therefore relies on pseudo-empirical abstractions. Reflective knowledge may be inferred if the student identifies m as the parameter after conceiving of the family of quadratic equations $mx^2 + 2x + 3 = 0$, where $m \in \mathrm{R} - \{0\}$, poses the condition of positivity of the discriminant to ensure real solutions for quadratic equation, solves the inequality that results from posing the condition of positivity, and intersects its solution with the domain of the parameter. Thus, the student performs coordinated actions on the family of quadratic equations. Moreover, after solving Problem 1, the student conceives of a new mathematical object-the family of quadratic equations with real solutions only, $mx^2 + 2x + 3 = 0$, where $m \in (-\infty, \frac{1}{3}) - \{0\}$. The coordination of actions can be interrupted at any time, for example if a student stops solving Problem 1 after substituting m, 2 and 3 the quadratic formula for solving $mx^2 + 2x + 3 = 0$. We may consider this latter case as another example of generalization via pseudo-empirical abstractions, as the student fails to link it to a new action, at a higher level (Piaget, 2001), in this case the reification of the family of quadratic equations with real solutions only.

METHOD

This study is part of an ongoing study on student understanding of parameters. We report here only the exploratory phase, used to inform our teaching intervention. Participants in this study were 26 college students, enrolled in an Introduction to Proofs class at a university in the United States. All students completed at least the Calculus I course, and at the time of the study they have just began an introduction to logical quantifiers and elementary methods of proof. There was no lesson taught on the topic of parameters, therefore students' knowledge on parameters was acquired prior to this study. To answer the question "What is a parameter?" all students were asked to come prepared to class with written examples of problems with parameters. The task was to identify the parameters, and justify the choice. A whole-class discussion on the concept of parameter was conducted, and every student attempted to answer the question "What is a parameter?" and commented on the other students' previous answers. The instructor (the first author) wrote the students' examples and comments on the whiteboard, took pictures for analysis (see Figure 1, in the Analysis chapter), and collected the students' written answers for analysis. The discussion lasted the whole class period, 50 minutes. The consensus was reached by the students, without the instructor's validation. The next day, a 30-minute questionnaire was administered to all students. Students were asked to solve four problems, and identify the parameters in those problems. We report here on only two of those problems. Problem 1 was inspired from the research literature on parameters (Šedivý, 1976), and Problem 2 from the current mathematics curriculum at the secondary level. We wanted to minimize the role of context in students' difficulties with parameters, therefore we proposed only problems with familiar contexts (e.g., linear and quadratic equations and functions) and familiar tasks (e.g., solving a quadratic equation, graphing a linear function). At the same time, we wanted to compare our students' difficulties with those reported in literature (Problem 1), and to gain insight into our students' understanding of parameters, given their exposure to graphing technologies (Problem 2):

> Problem 1. Find the values of m, where $m \in \mathrm{R} - \{0\}$, such that the equation $mx^2 + 2x + 3 = 0$ has only real solutions.

> Problem 2. Graph the function $f\colon \mathrm{R} \to \mathrm{R}$, $f(x) = kx$, where $k \in \mathrm{R}$.

Students' answers were scored, first using two rubrics ("0" for correct, "1" for incorrect, and re-scored using three rubrics ("0" for correct, "1" for partial correct, "-1" for "incorrect") by two raters, with high inter-rater agreement, measured using Cohen's k statistic (Cohen, 1960), $k = .90$ ($p < .05$). Open coding techniques and procedures described by Strauss and Corbin (1998) were used to develop the theoretical framework used for analysis. A conceptual analysis (Postelnicu & Postelnicu, 2013; Steffe & Thompson, 2000) of the data was performed, with the goal of answering the following research question: What is the students' conceptual understanding of parameters? We tried to infer students' conceptual understanding of parameters by analysing their constructions and actions. The data collected was subjected to repeated linkage processes, and systematic inferences, both inductive and deductive. We adjusted our working hypothesis. i.e., our proposed models to account for students' conceptual understanding of parameters, until the data no longer contradicted our hypothesis. The last viable hypothesis was reported as the students' conceptual understanding of parameters.

ANALYSIS AND RESULTS

Identifying parameters

During the whole-class discussion, the students seemed to agree that parameters are some sort of

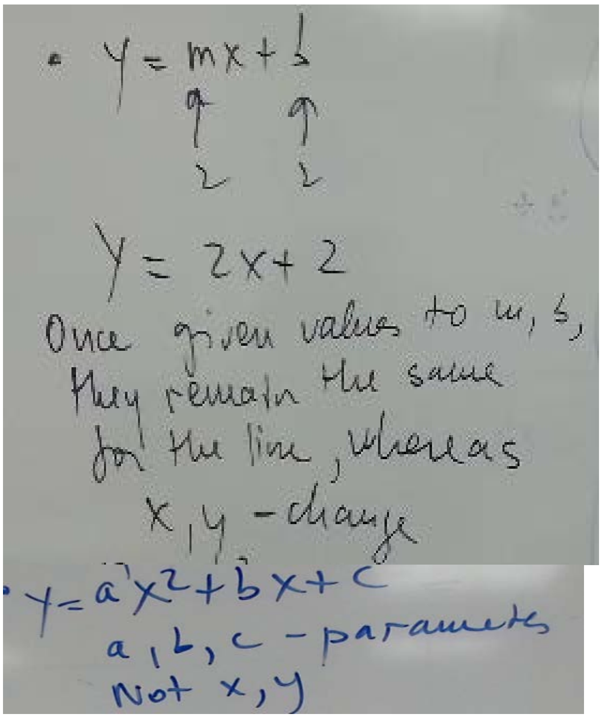

Figure 1: Identifying parameters in families of linear and quadratic functions

"general constants" (Philipp, 1992) or variables that appear in the definition of a mathematical object, but do not affect the structure of the mathematical object. When parameters change their values, the specific mathematical object changes, but keeps its structure (see Figure 1).

As can be seen from Figure 1, during the whole-class discussion, the students could discriminate between parameters and other variables, in the context of linear and quadratic functions.

There was some debate if parameters are variables or constants, illustrated by the following comments:

> "Parameter is the quantity that influences the output of a function and is usually constant. Example 1: m and b are parameters in $y = mx + b$ because they're constants in this case that affect what the function looks like. This is a linear function so it'll always look like a line."

> "[A parameter is] a constant or variable that determines the specific form of the function but not the general nature. E.g., $y = ax^2 + ax + c$ where a, b, and c are all parameters."

> "Parameters are variables that have fixed number. An example is the equation of a line $y = mx + b$, [where] m is a parameter that is equal to the slope of the line, and b is a parameter that is equal to the y-intercept of the line."

The idea of variable hierarchy (i.e., first parameters are instantiated, and only then the mathematical object becomes specific) did not appear explicitly in students' discussions.

After the whole-class discussion, our working hypothesis was that our students conceived of parameters as "general numbers of the second order" (Ursini & Trigueros, 2004), and they could identify parameters in the context of linear and quadratic functions and equations. It was not clear if our students considered the parameters variables or constants. Students' answers on the questionnaires showed that the issue of the nature of parameter – variable or constant that appeared during the whole-class discussion was more problematic (see Table 1).

	Identifies parameters	Identifies "actual" parameters	Identifies other variables as parameters
Problem 1	(N=18) m is the parameter in $mx^2 + 2x + 3 = 0$	(N=3) m, 2, and 3 are all parameters in $mx^2 + 2x + 3 = 0$	(N=5) x is the parameter in $mx^2 + 2x + 3 = 0$
Problem 2	(N=21) k is the parameter in $f(x) = kx$	(N=2) the parameter depends on what value takes k in $f(x) = kx$	(N=3) x is the parameter in $f(x) = kx$

Table 1: Identifying parameters

In Table 1, we present the frequencies of student answers per problem and category across the level *identifying parameters,* accompanied by corresponding examples of student answers. We have already commented on students' answers to Problem 1 from the mid-column, when the students rely on pseudo-empirical abstractions, and identify the parameters based on their places in the symbolic representation of the quadratic equation. With respect to students' answers to Problem 2 from the mid-column, we can infer pseudo-empirical knowledge, too. We interpret the observation that the parameter depends of the value taken by k as the students' need for instantiation. We infer that the students operate with instances of the mathematical object defined with the help of parameters, i.e., one specific linear function instantiated by a specific value of k, and not with the whole family of linear functions. Looking at the students' answers from the last column, when the other variables, x or y were identified as parameters that can affect the mathematical object, equation or function, we infer that the parameters might have been considered variables by students if they attended to the domain of the variable x (at least in the linear function in Problem 2), or might have been considered constants by students if they attended to particular instances or values of x, one at a time. In both situations, a failure to identify the parameters implies that the student operates with a particular instance of the mathematical object defined with the help of parameters. This raises the question whether, in the absence of the reification of the mathematical object, one can perform any operations on the object. The obvious answer is no, and the analysis across the second level, *parameters in action,* supports this answer.

Parameters in action

The students who could not identify the parameters in Problem 1 could not solve the problem. Most students (N=21) tried unsuccessfully to solve it by manipulating it symbolically in various ways (e.g., solving the quadratic equation by factoring, completing the square, using the quadratic formula). All students exhibited a weak competency in algebra (Arcavi, 1994), when they tried to solve the equation and write the solutions explicitly, instead of just posing the condition of positivity of the discriminant and solving the linear inequality obtained. From those 18 students who identified the parameter m in Problem 1, none solved the problem completely. Five students almost solved the problem, without completing the last necessary step – checking that the solution they found ($m < \frac{1}{3}$, sometimes $m < \frac{1}{3}$) fulfils the constraints of the problem ($m \neq 0$). In this case, when $m = 0$, we obtain a degenerated equation. Considering the students' schemes of operations (Piaget, 2001), we may infer that their reifications of the family of quadratic equations from Problem 1 are structurally weak (Sfard, 1991). Indeed, when solving Problem 1, about one third of the students failed the first reification the family of equations $mx^2 + 2x + 3 = 0$, where $m \in \mathrm{R} - \{0\}$ and there is no evidence of a successful second reification of the family of equations $mx^2 + 2x + 3 = 0$, where $m \in (-\infty, \frac{1}{3}) - \{0\}$.

Under the assumption that our students have been exposed to graphing technologies, we did not anticipate difficulties with Problem 2, which required graphing a family of linear functions. In Problem 2, only one student provided the correct graphic representation and highlighted the fact that the line $x = 0$ is not part of the solution, fifteen students graphed several lines, while all the other students graphed only one line. We can infer that the students who graphed only one or several lines conceived only of an instance or several instances of the family of linear functions, respectively. With the exception of one student, all the students failed to represent graphically the family of linear functions as the geometric locus of all the lines passing through the origin, except the line with the equation $x = 0$.

DISCUSSION

In retrospect, during the past five decades, the concept of parameter has remained an elusive one, even for college students. Our study supports previous findings with respect to student difficulty identifying parameters. We believe that this difficulty can be addressed by using subscript notation or logical quantifiers when using mathematical objects defined with the help of parameters. This means that the curriculum ought to be augmented by special topics, like connecting symbolic representations and logical quantifiers with ways of defining mathematical objects with the help of parameters. Identifying parameters is only the tip of the iceberg, the true difficulty lies with *parameters in action*. Of note, Godino, Neto, Wilhelmi, Aké, Etchegaray, & Lasa (2015) also proposed two levels of algebraic thinking involving parameters, the superior level referring to the "treatment of parameters" in problems requiring higher algebraic competency. Indeed, the real issue seems to be the weak algebraic competency (Arcavi, 1994; Sfard, 1991) inferred from the students' pseudo-empirical knowledge that hinders the reification of mathematical objects, or from the lack of active knowledge, like the knowledge about the role the discriminant of a quadratic equation in Problem 1. Our findings suggest that in spite of the use of graphing technologies, students continue to have difficulty connecting symbolic and graphic representations of mathematical objects defined with the help of parameters, and thus they have difficulty conceiving of those mathematical objects as geometric loci, like in the case of the family of linear functions (family of lines passing through the origin, except the line $x = 0$) in Problem 2. To conclude, the students' difficulty when solving problems with parameters – is the reification of the mathematical objects, reification that is dependent on the students' fluency in unpacking and packing the mathematical processes behind the mathematical objects.

Analysing Ireland’s Algebra Problem

Mark Prendergast[1] and Paraic Treacy[2]

1 Trinity College Dublin, Dublin, Ireland, Mark.Prendergast@tcd.ie

2 University of Derby, Derby, United Kingdom

In recent years, there has been concern regarding the performance of Irish second level students in mathematics and in particular algebra. In response, the Irish Government have introduced ‘Project Maths’ which is a major reform of second level mathematics. It was introduced on a phased basis in 2008 and involves changes to what students learn, how they learn it and how it is assessed. One of the main changes is the promotion of a functions based approach to teaching algebra. This is much different from the transformational rule based approach which had dominated Irish classrooms. The new algebra strand and functions based approach was introduced in second level schools in September 2011. This paper aims to investigate the immediate effect, if any, of such an approach on student’s transformational algebraic ability. This will be done by analysing the mathematics diagnostic scores of incoming third level students at an Irish University.

Keywords: Algebra, curriculum change, teaching approaches.

THE STUDY

This paper aims to investigate the immediate effect (if any) of the functions based approach to teaching algebra that has been implemented in Irish schools instead of the transformational (rule and procedure) based approach which was previously used. The paper will do this through analysing the results of a diagnostic test taken by incoming first year students at an Irish University. There are eight algebra based questions on the diagnostic test and all of them are transformational based in nature. Hence this paper will compare student’s algebraic ability from a technical perspective in aspects such as manipulating terms and solving equations.

BACKGROUND TO THE STUDY

Irelands ‘Algebra Problem’

Algebra has long been identified as an area of difficulty in the teaching and learning of mathematics. In the introductory note to his monumental *Arithmetica*, written ca. 250 AC, Diophantus of Alexandria mentions the discouragement that students usually feel when learning what we now term ‘algebraic techniques’ to solve word-problems. Fast forwarding to 1982, Cockcroft identified algebra as a source of considerable confusion and negative attitudes among students. This was followed by Herscovics and Linchevski (1994, p. 62) who reported that many students consider algebra an unpleasant, even alienating experience and find it difficult to understand.*”How can we multiply by x when we don’t know what x is?”* (12 year old student). Furthermore Artigue and Assude (2000) posit that many students see algebra as the area where mathematics abruptly becomes a non-understandable world.

Evidence of this confusion is common in Irish classrooms. Chief Examiners’ Reports have identified algebra as an area of weakness over the past number of years. According to these reports, Irish student performance in algebra has shown little or no progress in the last fifteen years. In the 1999 Junior Certificate (JC) Higher Level paper, there were two questions based primarily on algebra, while other parts of questions also involved algebra. The long questions on algebra were both low scoring and unpopular choices. Question 3, yielding an average mark of 24.3 out of 50, was the lowest scoring on the paper thus reflecting the extent of candidates’ difficulties with algebra. Furthermore, candidates often ignored parts of other questions which involved the topic. In the 2003 JC Higher Level paper, the Chief Examiner Report (2003) concluded that while there was some improvement in relation to algebraic skills, further improvement was still needed. Questions 3 and 4 relating to algebra demonstrated that the algebraic skills of candidates need to be enhanced so that they can handle with ease topics such as manipulation of formulae, quadratic equations, solving inequalities and setting up equations. Again the lowest scoring question on the paper (Question 4, yielding an average mark of 29.1 out of 50), was based on algebra (Chief Examiners Report, 2003). This was also the case in the most recent Chief Examiners Report (2006). On this occasion Question 4 yielded an average mark of 27.1 out of 50. This report noted that improvements were required in areas such as simplifying and removing brackets from algebraic expressions, particularly expressions containing minuses and also simplifying algebraic fractions. Hence on the evidence of these reports it is clear that although algebra has long enjoyed a place of distinction in the mathematics curriculum, many students have difficulty in understanding and applying even its most basic concepts. *"Algebra means hours of instruction that you don't even come close to understanding"* (seventh-grade student as cited in House, 1988, p. 1).

Reasons for such poor performance in algebra

In Ireland, research has suggested that there has been an over reliance on traditional methods when teaching algebra. Transformational based activities have dominated lessons. Algebra was a paper and pencil activity involving the following of rules and procedures. A minimalist approach to algebraic sense making took place. Each day of instruction was textbook led and focused on a particular type of manipulation. For example, the textbook started by introducing the concept of a variable, followed by the notion of algebraic expressions and then equations (Kieran, 1992). This structure ensured that algebra was considered as a series of skills to be mastered (Chazan, 1996). Success in the subject was determined by the ability to memorise procedures by rote, nothing else (Bracey, 1992).

Research has found that many mathematics teachers felt there was no alternative to teaching mathematics through the traditional chalk and talk or the common method of following sections through a textbook (Lyons et al., 2003). Using such a method with algebra forced students to memorise procedures and solve artificial problems that had no meaning to their lives. They were drilled on the possession of mathematical rules and manipulations and they were graded not on their understanding of the mathematical concepts, but on producing the right symbol series. As a result what students learned was a collection of procedures and skills to be performed, having no logical coherence, very little connection with previously learned arithmetic, and no applications in other school subjects or in the outside world (MacGregor, 2004). Although such procedures and skills are important outcomes of learning algebra, what students need even more is a sound understanding of algebraic concepts and the ability to use knowledge in new and often unexpected ways. Students need to be given the opportunity to construct their own mathematical knowledge along with understanding its importance and usefulness in every day applications.

The 'Solution'

As a result of Irish students' poor performance in mathematics and indeed algebra, the Irish Government have introduced 'Project Maths' [1]. This is an ambitious reform of Irish second level education [2] which has an overall aim to teach mathematics in a way which leads to real understanding (Department of Education and Skills (DES), 2010). It involves changes to what students learn in mathematics, how they learn it and how they will be assessed. The initiative is designed to ensure an appropriate balance between understanding mathematical theory and concepts and developing practical applications skills. There is a much greater emphasis placed on student understanding of mathematical concepts, with increased use of contexts and applications. The focus is on students understanding the concepts involved, building from the concrete to the abstract, from the informal to the formal and learning to apply their knowledge in familiar and unfamiliar contexts (DES, 2010). Changes have being phased in over a number of years covering 5 strands of mathematics (Number, Algebra, Statistics and Probability, Geometry and Trigonometry, Functions), with assessment in the examinations being adapted as each strand of mathematics comes on stream. The assessment reflects the different emphasis on problem solving and applications in the teaching and learning of the subject.

Changes to the teaching, learning and assessment of algebra

Although the initiative first began in 24 pilot schools in 2008, it was not rolled out nationally until 2010 and the new algebra strand was not introduced to all schools until September 2011. In a major shift from the transformational based approach which had dominated Irish classrooms, the new strand advocates a functions based approach to teaching algebra. The functions based approached envisages that students may be able to work with variables and the rules of arithmetic and learn to use algebraic notation and techniques themselves. There is an opportunity for students to see algebraic notation arising as a natural and useful consequence of expressing generality (Pegg & Redden, 1990).

Through Project Maths, the new approach reflects inquiry methods through which students take responsibility when dealing with new problems rather than rehearsing known procedures. Students examine functions derived from some kind of context, e.g., familiar everyday situations, imaginary contexts or arrangements of tiles or blocks. They express generalisations mathematically using algebraic symbolism, interpret expressions as rules for functions and use the Cartesian plane as a space to display and consider a variety of meanings of the results (Chazan & Yerushalmy, 2003). Therefore students represent the problem using words, numbers, symbols, tables and graphs. This approach builds on the learner's prior knowledge and allows them to see different representations which should enable a deeper understanding of the topic.

The change in teaching approach to algebra has also led to a change in the assessment approach for the strand. The Project Maths assessment reflects the changes in emphasis of a functions based approach in which students are required to take an everyday problem, solve it mathematically using tables, functions and graphs and then interpret their results in the context of the problem.

Success of Project Maths and the Functions Based Approach?

The phased implementation of Project Maths means that 2014 was the first year in which all strands of the revised syllabi were examined. Indeed it will be 2017 before a first cohort of students who have experienced all 5 strands of Project Maths from 1st to 6th year [3] will be examined. Thus it is very early to make any conclusions regarding the successes / failures of the initiative. However, an interim report commissioned by the NCCA and conducted by the National Foundation for Educational Research (NFER, UK) has been published and includes findings on students' attitudes and achievements. Overall this report found that there is emerging evidence of the positive impacts of Project Maths on students' experiences of, and attitudes towards, mathematics (Jeffes et al., 2013). Furthermore, students' are achieving more at individual strand level, and in some instances students appear to be successfully drawing together their knowledge across different mathematics topics (Jeffes et al., 2013). This suggests that students are beginning to acquire a deeper understanding of mathematics and how it can be applied (Jeffes et al., 2013).

With a specific reference to algebra, the revised strand was first examined at LC level in June 2012. The NFER report found that out of the five strands, algebra is in the lowest two strands, both in terms of student confidence and student achievement (Jeffes et al., 2013). Furthermore although students' performance in other strands is similar to international students who participated in TIMSS 2007, students appear to find algebra especially difficult when compared to international standards (Jeffes et al., 2013). However on a positive note for the functions based approach, the report found that students feel more motivated to learn algebra when it is taught in a way that makes it seem more relevant to everyday life and when they can see that it interlinks with other mathematics topics.

METHODOLOGY

The methodology of this study involves comparing student's results on a number of transformational based algebra questions from a university diagnostic test. The results will be compared between two cohorts, 2011 in which students were taught using traditional methods, and 2013 in which students were taught using a functions based approach.

The instrument

The diagnostic test from which the data is compared was designed and implemented in the University of Limerick (UL) in 1997. It was designed to help identify students who may be at risk of failing service mathematics examinations (O'Donoghue, 1999; Gill, 2006). Within the design process, a team of experienced service mathematics lecturers analysed and adjusted an initial list of 70 questions, reducing this to the final 40 question version. Thirty four of these questions are set at a LC Ordinary Level standard or below, with the other six questions set at a LC Higher Level standard. To ensure the validity of this test, it was then piloted in Irish second level schools and compared with the SEFI Core Level Zero syllabus for engineers, the Irish

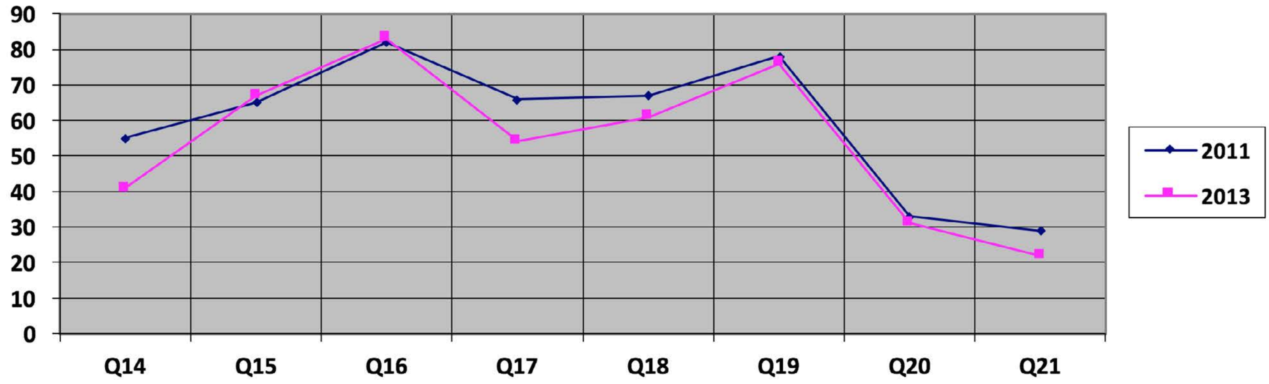

Figure 1: Student results in eight algebra questions

JC mathematics syllabus, the Irish LC mathematics syllabus and further diagnostic tests (Gill et al., 2010).

The test was intended specifically to suit the mathematical level of the students in each of the targeted service mathematics modules in UL, namely Science Mathematics 1 and Technological Mathematics 1. Since 1998 students from these cohorts have been assigned the 40 question diagnostic test which assesses basic skills and procedures in various mathematical topics. These topics include arithmetic (13 questions), algebra (8 questions), geometry (4 questions), trigonometry (3 questions), co-ordinate geometry (4 questions), complex numbers (2 questions), differentiation (3 questions), integration (2 questions), and modelling (1 question). The test is presented to students in their first mathematics lecture of each year since and they are not informed beforehand that they are required to take it.

The layout of the test and each of the 40 questions have remained unchanged over the years to ensure reliability. The UL database which contains data from these diagnostic tests dating from 1998 to 2013 currently holds information on over 10,100 students.

THE STUDY

This paper will focus on the results of students from the 8 algebra questions (see appendix 1) in the year 2011 in comparison to the results from 2013. It is important to note that the algebra questions included in the test are transformational based in nature and hence do not reflect a student's overall algebraic ability. The years 2011 and 2013 were selected as the algebra strand of Project Maths was first phased into Irish schools in September 2011. Hence the students who took the 2011 UL diagnostic test would have been taught algebra using the transformational based approach. The students who took the 2013 UL diagnostics test would have been taught algebra using the functions based approach. 685 students took the diagnostic test in 2011 and 645 took it in 2013. Analysis of this data will aid the authors is answering the following research question:

Is there a difference in the transformational algebraic ability of incoming third level students who have been taught using different approaches?

RESULTS

Descriptive analysis of the data found that there was a statistically significant difference ($t=4.463$, $p=.000$) between the mean algebra scores of the students in 2011 (M: 59.01; SD: 24.07) compared to the mean scores in 2013 (M: 53.16; SD: 23.74). In order to get a more in-depth analysis of this finding, the results of each of the eight algebra questions from both years were compared (see Figure 1).

Students who had been taught using the transformational based approach scored higher in six out of the eight algebra questions. There was a statistically significant difference in the mean scores of students in four of the eight algebra questions (Q14, 17, 18, 21) in 2011 when compared to 2013 (see Table 1).

A closer inspection of the four questions (See Appendix 1 Q14, 17, 18, 21) in which there were statistically significant differences between the cohorts does not reveal any correlation between the questions. Question 14 involves the rearrangement of formula, Question 17 and 18 involve solving equations (quadratic and simultaneous respectively) and Question 21 concerns the subtraction of algebraic fractions. Similarly, no correlation appears to exist between

Question	Mean and SD 2011	Mean and SD 2013	Independent T-test
14	.54 (.499)	.40 (.490)	t=5.390, p =.000
15	.65 (.478)	.66 (.475)	t=-3.52, p =.725
16	.82 (.383)	.82 (.386)	t=0.156, p =.876
17	.66 (.476)	.52 (.500)	t=5.087, p =.000
18	.66 (.474)	.59 (.492)	t=2.551, p =.011
19	.77 (.420)	.75 (.436)	t=1.131, p =.258
20	.33 (.471)	.30 (.460)	t=1.138, p =.255
21	.29 (.453)	.22 (.414)	t=2.895, p =.004

Table 1: Mean Score, Standard Deviation and Independent T-tests

the questions in which there were no statistically significant differences (See Appendix 1 – Q15, 16, 19, 20). Question 15 involves substitution, Question 16 involves solving a linear equation, Question 19 is the expansion of brackets while Question 20 concerns solving inequalities. Each of the eight questions are JC Higher Level / LC Ordinary Level standard and would have been on the traditional syllabus, in addition to being on the current Project maths syllabus.

DISCUSSION AND CONLCUSION

Despite the perceived success of Project Maths and the functions based approach to teaching algebra (Jeffes et al., 2013), the analysis of the UL diagnostic test results shows that there is statistically significant differences in the 2013 mean algebra scores of students when compared to 2011. Analysis of the LC grades shows that both cohorts had very similar grades in mathematics upon completing second level. The mean number of LC points achieved by these students through mathematics in 2011 was 54.27 while, in 2013 this cohort produced a mean number of 53.64 points. However the performance of the 2013 cohort in the algebra section of the diagnostic test is significantly lower than the 2011 cohort. This would suggest that the introduction of the new algebra strand in Project Maths and the change in teaching approach has had a detrimental effect on student's transformational algebraic ability.

The findings of the study are hardly surprising given that diagnostic test used to gather the data focuses solely on transformational activities and the emphasis on such activities has been diminished under the new curriculum. However the eight algebra questions contained in the test (See Appendix 1) are of a very basic standard and all Irish students would have encountered such concepts at Junior Cycle / Senior Cycle level in both syllabuses. Thus the results of this study, in this regard are surprising. Whatever the approach to teaching algebra at second level, it is expected that students entering third level on degree programmes with a mathematics component, should be competent in rearranging basic formula, expanding brackets, substitution and solving basic equations. The authors argue that such skills should be acquired by second level students regardless of whether they are being taught algebra using a transformational, a functions based or indeed any other approach.

Thus the challenge for Irish mathematics educators on the basis of this study is to ensure that the transition to the functions based approach does not result in a neglect of teaching the technique and rule-bound aspects of the algebraic language (Prendergast & O'Donoghue, 2014). While the transition to the functions based activities of Project Maths is a welcome move, it is also important that the algebraic purpose behind such activities is not lost. This results with students not knowing how to move from their informal constructions to a formal and algebraic relationship (Stacey & MacGregor, 1997).This was evidenced in the UK where the search for meaning and the consequent suppression of symbolism led to a situation in the early 1990s where students were doing hardly any symbol manipulation (Sutherland, 1997). Problem solving by whatever means had all but replaced algebra (Kieran, 2004). The hope was that, in focusing on algebraic understanding, the techniques would take care of themselves. However, a study carried out by Artigue in France in the mid 1990's on the use of DERIVE in French classrooms found that the techniques did not take care of themselves (Kieran, 2004). As anticipated, the researchers found that the teachers were emphasising the conceptual elements while neglecting the role of the procedural work in algebra learning. However, this emphasis on conceptual work was producing neither a clear understanding of the procedural aspects, nor a definite enhancement of students' conceptual understanding, "easier calculation did not automatically enhance students reflections and understanding" (Lagrange, 2003, as cited in Kieran, 2004, p. 28). Thus traditional exposition and practice must be retained alongside more opportunities for practical work, problem solving, investigations and discussion and providing purpose to the activities (Sutherland, 1997). The work of 'Project Maths' in Ireland must facilitate the curriculum and teachers in making such an evolution. While the new curriculum is having many positive benefits it is important that techniques and conceptual understanding are taught together rather than in opposition.

How much space for communication is there for a low achieving student in a heterogeneous group?

Anita Movik Simensen, Anne Berit Fuglestad and Pauline Vos

University of Agder, Kristiansand, Norway, anita.m.simensen@uia.no

This paper reports on a case study aiming to deepen our understanding of low achieving students' learning of algebra, in particular when they work with pattern problems. We observed one low achieving student, May, who participated and worked in three different heterogeneous settings. Data were analysed from a multimodal perspective on key and regulating activities in the groups. The analysis revealed that May's contribution varied, depending on the composition of the groups, and that her contributions were influenced by regulating activities by peers and access to physical artefacts. The findings show that a low achieving student is able to generalise beyond her arithmetic knowledge, but the environment in a heterogeneous group did not offer her the space to do so.

Keywords: Regulating activities, low achieving, pattern problems, heterogeneous groups.

INTRODUCTION

Pattern problems have been studied extensively in classroom situations, particularly in group work (Radford, 2009; Ryve, Larsson, & Nilsson, 2013). Pattern problems can be tackled using different strategies, including arithmetic strategies (counting) and grouping strategies, before advancing to generalised explicit formulae (Lannin, Barker, & Townsend, 2006). Radford (2012) has explained that generalising is central in algebraic thinking, not symbolising. With pattern problems, students can reason informally, yet algebraically, they can even generalise their answers, without immediate need to symbolise.

To supplement the studies of students working on pattern problems, we are interested in how to facilitate low achieving students' learning of algebra within heterogeneous groups. We define low achieving students as students following regular mathematics lessons, but achieving low on tests compared to their peers. Many studies have demonstrated that these students are able to reason algebraically, but their potential is often not captured by standard tests (Karsenty, Arcavi, & Hadas, 2007; Watson, 2002).

The rationale for our study of low achieving students within heterogeneous groups is that in Norway, the official policy is an inclusive school system: it is not allowed to teach in fixed ability groups over time (The Educational Act, 1998). Research on learning in group settings has identified that heterogeneous groups are beneficial to students' learning and invite all students to become active participants (Dekker & Elshout-Mohr, 1998; Webb, 1991).

In the current paper we present a case study of May, who is considered as a low achieving student by her teacher and based on test results. We observed her work with pattern problems in three different groups.

THEORETICAL FRAMEWORK

Algebra learning is defined to involve both symbolic expressions and reasoning about generalisation (Caspi & Sfard, 2011; Måsøval, 2011). In our study, we focus on the algebraic reasoning and generalising, and to a lesser extent on symbolising. Strømskag (2015) emphasises the importance of natural language as a basis for symbolic expressions which might be even more crucial for low achieving students. According to Karsenty and colleagues (2007), low achieving students do have a potential to think algebraically, yet they are not always capable of working with symbols. Therefore, low achieving students' algebraic potential might be more visible in natural language than in symbolic expressions.

A relation between students' communication and algebraic thinking is emphasised by Caspi and Sfard (2011) when they define algebra as a discourse. This definition is promising for researching low achieving students' algebra learning because it "transfers algebra from the category of passive tools to that of human activities" (p. 470). In their study, students' communication is analysed according to verbal interaction and written products, not focusing on gestures. However, research on low achieving students has identified gestures to be crucial for students' active participation in meaning making processes (Simensen, Fuglestad, & Vos, 2014).

Radford (2009) demonstrates how students' written products from generalisation processes can be traced back to their use of speech, gestures and actions (such as using physical artefacts) during the solution process. He also argues that gestures in isolation do not tell much; it is when all three actions work together that observing communication can give insight into students' meaning making. Radford refers to activities where students combine speech, gestures, and actions as *multimodal activities* (2009, p. 120). Multimodal activities are not only local products of the situation in which they take place; they have roots in previous situations and contribute to future communication (Civil & Planas, 2004). Therefore, facilitating all students to become active participants is not only about an individual's empowerment to become an active contributor by offering appropriate tasks and physical artefacts; it is also about previous communication, and mutual encouragement of communication.

Dekker and Elshout-Mohr (1998) have defined two categories that can be used to analyse multimodal activities: *regulating activities* and *key activities*. Regulating activities are activities that encourage students to communicate about their work, namely by questioning or critisising it, for instance: *"What are you doing? Why are you doing that?"* (Pijls, Dekker, & van Hout-Wolters, 2007, p. 312). Regulating activities can be practiced by other students, the teacher, or by the student herself.

Regulating activities do not only encourage communication, they can also be used to define students' *key activities*. Four key activities have been identified as indicators for level raising in mathematics (Dekker & Elshout-Mohr, 1998) and they can be observed in students' communication. The four key activities are: showing one's work; explaining one's work; justifying one's work; and, reconstructing one's work.

Pijls and colleagues (2007) have carefully demonstrated how to classify utterances according to regulating and key activities. They emphasise particularly the key activities' dependence on regulating activities, because the regulating activities are crucial to categorise key activities. For instance, Pijls and colleagues (2007) claim that it can be difficult to decide whether a student is showing or justifying her work. The decision should then be based on the regulating activity that initiated the actual key activity. For example, justifying one's work is always a response to critique, while showing is not (p. 313). For further explanations of regulating and key activities, we refer to work by Dekker and Elshout-Mohr (1998) and Pijls and colleagues (2007). Heterogeneous groups in which all four key activities were identified showed to be the most beneficial for attaining mathematical level raising (Pijls et al., 2007). Nevertheless, students who demonstrate fewer key activities, like showing and justifying, can attain a certain degree of level raising. We build on these studies, but extend the analysis beyond utterances, and also analyse other multimodal activities.

Despite the large amount of research concerning algebraic thinking and communication, not much of it relates to low achieving students' communication and their algebraic learning potential. For this reason, we want to investigate: *How do regulating activities encourage or hinder a low achieving student's communication about pattern problems in heterogeneous groups?*

METHODS

To answer our research question, we designed tasks on hexagon patterns in such a way that the questions should be easy to understand and such that they could be solved by multiple methods. Motivated by Radford's (2009) claim that students' use of gestures and artefacts is crucial for communication on pattern problems, we made hexagon tiles and sheets with hexagon patterns available for the students. We assumed that these factors (questions that were easy to understand, multiple methods for solving, availability of physical artefacts) would invite all students to become

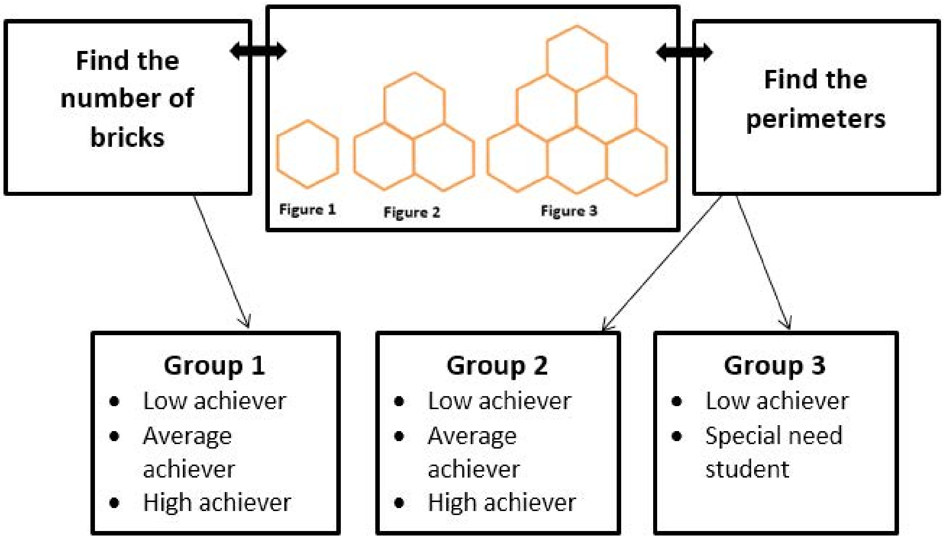

Figure 1: Tasks and organisation of heterogeneous groups

active participants. Based on these problems, we carried out a task-based intervention on three different days during one week in a Grade 8 class.

For this case study, we will focus on one student, May, who performed low on a National Test for Grade 8. Before the intervention, we had communicated with the teacher, and created a group in which we assumed that May would become an active participant: May (low achieving), Tom (average achieving) and Bo (high achieving). But Bo was sick when our intervention started and we had to reorganise the groups, replacing Bo with Eva (high achieving). After that first session, Bo was back and May could work with Bo and Tom in the ensuing session. This accidental change in our study enabled us to observe May in two heterogeneous settings, which turned out to be very different. Because of the different outcomes, we became interested in learning more about what encouraged or hindered May's communication in heterogeneous settings. Therefore, we carried out an additional, third session in which we asked May to work together with Siv. Siv is not only May's friend, but she has special educational needs as well. We assumed that these two factors, working with a friend and being the most knowledgeable, might empower May to take an active role in the work. A third choice we made to strengthen May's role as the most knowledgeable peer, was to give May and Siv a task with which May was familiar from the work in Group 2 (see Figure 1).

All the sessions were video recorded and transcribed. We then counted the number of utterances made by May in each group, and this gave us a quantification of her participation in the communication between the group members. However, counting the number of utterances does not give insight into the nature of utterances nor the chain of activities that the utterances are part of. We therefore analysed the communication according to key and regulating activities, as developed by Dekker and Elshout-Mohr (1998). In this analysis, the four key activities can be identified independently, one activity is not dependent on others, and they are incremental in the sense that we can see attempts to carry out key activities, partly or strongly. Because of this, we consider key and regulating activities as suitable to identify both students' actual level raising and their potential level raising. In previous studies (Dekker & Elshout-Mohr, 1998; Pijls et al., 2007), key activities and regulating activities are only observed in students' speech, and not in their gestures and actions. However, we decided to analyse communication according to key and regulating activities from a multimodal perspective, following Radford (2009).

RESULTS

We carried out a frequency count of May's utterances in the three groups. In the first group she hardly said a word (3 % of the group's utterances are from May), in the second group her contribution raised to 16% of the groups' utterances, while in the third group she contributed with 53 % of the utterances. Below we will report exemplar episodes from the three groups.

Group 1

On the first day of the intervention, May sat with Tom and Eva. They discussed pattern problems on finding

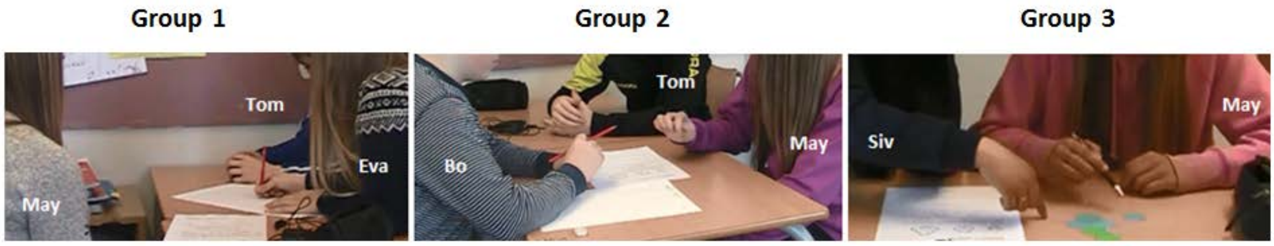

Figure 2: Organisation of the three groups

the number of hexagon tiles required to build various figures. In their discussions, Tom and Eva agreed about how to find this number, reasoning from a recursive approach, namely by adding the next figure number to the number of tiles in the present figure. May said little and her utterances were in general short, consisting of one or two words.

Tom asked May several times if she understood how he and Eva had found the number of hexagon tiles in the figures without counting. Every time May nodded, but except for the nodding, she did not move her arms or body. As can be observed in Figure 2 she was sitting further away from the other group participants, as if she was not part of the group (see Figure 2). There were a few moments, when May's nodding was followed by Tom asking if she really understood. This could indicate that he did not accept May's nodding as sufficient confirmation that she understood.

Eventually, Tom asked May to explain it to him:

122 Tom: Ok, explain it for me. I need an explanation. [Looks at May and moves the hexagons in her direction]
123 Eva: You know the explanation. [Looks at Tom and gathers the hexagons]
124 Tom: Yes, but I want her to understand. [Points to May]
125 Eva: To get the next figure number, you have to add the next figure number. [Looks at Tom]

In utterance122 Tom extended his attempt to invite May to contribute. Here he asked her explicitly to explain her understanding and he offered her artefacts (hexagon tiles) that could have supported her explanation. However, the invitation was not answered by May but by Eva, both verbally and physically (123). May did not give any explanation.

We interpret Tom's question about May's understanding to be a regulating activity, aiming at inviting May to contribute. However, we do not interpret the nodding to be a key activity, because we cannot learn about May's ideas from the nodding. In utterance 122, Tom makes a verbal regulating activity, and he strengthens it by physically offering the hexagon tiles to May. Eva's subsequent contribution (123) can be interpreted as a barrier to May's acceptance of the invitation. Eva is hindering at two levels: by taking the hexagons physically and by verbally answering. We therefore consider both contributions from Tom as examples of regulating activities, asking May to explain. However, they do not result in May using key activities.

Group 2

On the second day of the intervention the groups were reorganised and May's group was joined by Bo (high achieving) instead of Eva. Therefore, Group 2 consisted of May, Tom, and Bo. Their work was still related to the hexagon patterns, but now the question was to find the perimeter of the figures.

The discussion started similarly to what happened on the previous day, with Bo asking May if she understood. She responded in exactly the same way as she did in Group 1, by nodding. However, Bo did not repeat the question like Tom did in Group 1. Bo rephrased it into "May, do you want to count how many sides the second figure has?", at the same time as he pointed at the illustrations on the worksheet. Later on Bo initiated an invitation to May to give an explanation:

691 Bo: Why is it multiplied by 6?
692 May: Because it is 6 more each time.
...
722 May: You take the number of sides on one brick.
[Teacher nods]
723 May: And multiply by the figure number.

...

738 Bo: Instead of writing it in words, can you write it like you would have written it in your notebook? What do you write if you want to do a calculation?

739 May: N multiplied by 6.

The excerpt shows how Bo acted like a teacher, guiding May to make explanations without using artefacts. In utterance 691 he asked May to justify *why* the perimeters can be found by multiplying by six. In utterance 692 May indicates that this is about the multiplication table of six continuing by adding 6. Further, in utterances 722 and 723 May explained in words how to find the number of tiles in a random figure, and in utterance 739 she showed how it can be generalised with symbols.

We interpret Bo's explicit questions at the beginning of the discussion in Group 2 as regulating activities, inviting May to contribute with speech, gestures, and use of artefacts. May shows her ideas by pointing at the physical artefacts and we interpret it as key activities demonstrated with multimodal expressions. In the episodes given above, we identified key activities such as: justify (692), explain (722 and 723), and show (739) one's ideas.

To sum up, in the heterogeneous setting of Group 2 we first observed how Bo asked May to explain her understanding, which did not evoke May's use of key activities. When he asked her explicitly to show her ideas ("do you want to count?"), this was followed by May demonstrating the key activities of showing her ideas. Finally, when Bo asked May again to explain her ideas (691), she demonstrated the key activity explanation by offering the generalised formula "N multiplied by 6".

Group 3

The third setting in which May participated was different from the previous ones in several ways: (1) only two students were involved, Siv and May; (2) Siv is identified to be in need of special education and, therefore, May was the relatively high achieving student in this setting; (3) the students were given the task from Group 2, so May was knowledgeable about the task, while Siv was not.

First May demonstrated that the perimeter could be found by counting the physical sides one by one. We interpret this as the key activity 'showing one's idea'. May then carried out a regulating activity by asking Siv to count the sides. Thereafter May initiated other strategies to find the perimeters:

51 May: Do you know what we can do instead of counting one by one?

52 Siv: Hm?

53 May: We can, or it is fine to just count. We only have to add these. 23, 24, 25, 26, 27, 28, 29, 30, 31, 32, 33, 34, 35, 36, 37. [Points on the "new" sides in Figure 5] Then we know that it is 37 sides around. Do you see a pattern?

54 Siv: Where?

55 May: Here. [Points on the diagram in the task]

56 Siv: No.

57 May: It is the times six table. 6, 12, 18, 23, 37. For example: 6 plus 6 equals 12. It is 6 twice. If we have 6 three times, then we have 18. 12, 13, 14, 15, 16, 17, 18. [Counts on her fingers]

In the above episode (53) May suggested that the perimeter can be found by counting on from the previous figure's perimeter, which is a recursive strategy. Thereafter, she claimed that the perimeters are equal to numbers in the "times six table" (57), which is an explicit formula for the perimeter of the triangular hexagon pattern.

We interpret the utterance "Do you know what we can do instead of counting..." (51) as a regulating activity. This regulating activity is followed by May showing her idea (53). Within that very same utterance (53), we also observe a regulating activity: asking for a pattern. Finally, when May showed her idea (57), she demonstrated another key activity. In utterances 53 and 57 she scrutinises the counting process, which we interpret as searching for generalisation. She did not detect that the numbers she found were incorrect, which illustrates how her willingness and potential to generalise goes beyond her skills in mathematics.

May's contributions in Group 3 differed from the other groups, because her contributions did not depend much on others' regulating activities directed at her. May's contributions in Group 3 demonstrated both regulating activities and key activities. In Group 3 we observe that May's contributions relate little to the other participant (Siv gives little feedback), and more to the nature of the tasks, use of gestures, and access to physical artefacts.

DISCUSSION AND CONCLUSION

The empirical material presented in this paper shows how differently a low achieving student can contribute in various heterogeneous settings. When working with higher achieving students, May's communication was strongly affected by the regulating activities from the other students. She was mostly awaiting and only answering when others invited her to contribute. In contrast, when working with a special needs student, May was the leader; she was the one initiating and regulating the communication. Our findings are consistent with work by Civil and Planas (2004), and it indicates that being categorised as a low achieving student might position a student into a similar position as students who are marginalised because of social inequality. Therefore, we assume that regulating activities are crucial for the lowest achieving student's contribution in heterogeneous groups.

Although May's contributions in both Group 1 and Group 2 were strongly related to the regulating activities by the other students, her contributions in these two groups were different. In the first group we observed how regulating activities can fail to encourage low achieving students' contribution. Tom asked May several times about her ideas but May just nodded and did not answer in words. Pijls and colleagues (2007) reported similar observations and claim that two main factors are crucial for students' use of key activities. First, the use of key activities depends on whether someone asks you about your work. Second, students should think their contribution makes sense to other students. In our study we observed that there was no communication space for May's response because the regulating activities by Tom were blocked by Eva.

Further, in Group 2 we observed how Bo's attempts to encourage May to carry out key activities, did not become successful until May had access to artefacts. This suggests that access to artefacts might be another important factor for low achieving students to be able to carry out key activities. Therefore, our findings indicate that regulating activities can encourage low achieving students' communication about pattern problems, but it is crucial that they have access to combine speech, gestures, and use of artefacts in order to communicate their ideas. A new finding is that regulating activities can also hinder low achieving students' active participation in communication. We observed how artefacts were moved away, and speech blocked the regulating activities that were originally aiming to invite for contributions. This is in line with Radford (2009) who advocates that thinking happens not only as a mental process, but in and through the use of speech, gestures, and actions (like use of artefacts). In our study we observed that these multimodal expressions were important for May in showing her ideas, specifically when she used counting (relying on arithmetic) to communicate about the pattern problem. Later on, when she demonstrated more abstract strategies like recursive reasoning and how to express the problem explicitly in a formula, in Group 2, she did not use gestures and artefacts. This may indicate a development: in the first session gestures and artefacts were important for the key activities, and May needed them to express ideas that were not yet completely her own. But at the end of the session in Group 2 she expressed her ideas verbally without use of gestures and artefacts, which was possible because Bo encouraged her. In Group 3 she could confidently claim that the pattern of the perimeters is equal to the multiplication table of six. This indication of development needs more research addressing low achieving students' use of multimodal expressions when generalising beyond their arithmetic knowledge.

Our results show the complexity of how to empower low achieving students' in order to become active contributors in heterogeneous groups. We observed in Group 2 that a regulating activity for a low achieving student can be an explicit invitation to combine speech, gestures, and artefacts for showing one's ideas. The key activity of 'showing one's ideas' is a prerequisite which enables low achieving students to demonstrate other key activities. Therefore, teachers can empower the students to use key activities by giving access to artefacts and by designing tasks inviting all students to show their ideas. While further work is required to explore low achieving students' learning and their ability to generalise, our findings also indicate that further research is needed on low achieving students in heterogeneous settings where the low achieving student is relatively high achieving, for instance when they work with younger students.

A pattern-based approach to elementary algebra

Heidi Strømskag[1]

Sør-Trøndelag University College, Faculty of Teacher and Interpreter Education, Trondheim, Norway, heidi.stromskag@hist.no

With a focus on epistemology, this paper discusses what pattern generalisation as an algebraic activity involves. Further, it presents a review of empirical studies where a pattern-based approach is used to teach algebra. This shows that students' problems with establishing algebraic rules from patterns and tables can be explained by: 1) difficulties caused by students' use of invalid methods to identify explicit formulae; 2) difficulties caused by students' tendency to focus on recurrence relations; and 3) institutional constraints. As an alternative to a traditional task on a shape pattern, the paper presents an epistemological model designed to implement the equivalence statement: $1 + 3 + 5 + L + 2n - 1 = n^2$.

Keywords: Algebraic activity, pattern generalisation, epistemological model, milieu.

INTRODUCTION

According to Reed (1972), humans have a natural inclination to observe patterns, and to impose patterns on different experiences. Inspired by Steen (1988), Devlin (1994), and others, I consider mathematics as the science of patterns. Mathematicians seek patterns in different areas, including numbers (arithmetic and number theory), form (geometry), motion (calculus), reasoning (logic), possibilities (probability theory), and position (topology). In the development of mathematical knowledge, generalisation is an essential process. This is asserted by for instance Krutetskii (1976), who classifies generalisation as one of the higher cognitive abilities demonstrated by mathematics learners.

Generalisation of shape patterns and numerical sequences is part of the elementary and secondary curriculum in many countries, for example England (Department for Education, 2014); the United States (National Council of Teachers of Mathematics, 2000); Canada (Ontario Ministry of Education and Training, 2005); and, Norway (Directorate for Education and Training, 2013). A purpose of students' engagement with patterns is to provide a reference context (physical, iconic or numerical) for generalisation and algebraic thinking.

A shape pattern is usually instantiated by some consecutive geometrical configurations in an alignment imagined as continuing until infinity. In this paper, geometrical configurations will be referred to as *elements*, and the constituents of an element will be referred to as *components*. Generalising a pattern algebraically rests on noticing a commonality (a structure) of the components of some elements of the pattern, and using it to provide an expression of an arbitrary member of the number sequence mapped from the pattern. This will be explained in more detail below.

PATTERN GENERALISATION AS AN ALGEBRAIC ACTIVITY

A model for conceptualising algebraic activity is proposed by Kieran (2004), where she introduces three interrelated principal activities of school algebra: generational activity, transformational activity, and global/meta-level activity. The *generational activities* involve the creation of algebraic expressions and equations like (i) equations that represent quantitive problem situations; (ii) expressions of generality arising from shape patterns or numerical sequences; and (iii) expressions of the rules that determine numerical relationships (Kieran, 2004). I interpret the letters used in the three examples as having the role as unknowns, variables and parameters, respectively. The *transformational activities* involve syntactically-guided manipulation of formalisms including: collecting like terms; factoring; expanding brackets; simplifying expressions; exponentiation with polynomials; and, solving equations (Kieran, 2004). These are the activities with which school algebra has traditionally been associated. The *global/meta-level activities* involve activities for which algebra is used as a tool, and include:

1 The author has earlier published under the name

problem solving; modelling and predicting; studying structure and change; analysing relationships; and, generalising and proving (Kieran, 2004).

The elements of a shape pattern are carriers of multiple structures which have to be interpreted by the students. The process of interpreting and representing these structures algebraically, involves generalisation of arithmetical relationships in members of the sequence mapped from the shape pattern. A shape pattern can be generalised either through an indirect approach, where the result is a recursive formula (a relationship between consecutive elements), or through a direct approach, where the result is an explicit formula (a functional relationship between position and numerical value of an element).

Måsøval (2011) distinguishes between two types of shape patterns: *arbitrary patterns* (Figure 1), and *conjectural patterns* (Figure 2).

These patterns correspond respectively to two different mathematical objects aimed at in the process of generalising: *formula* (for the general member of the sequence mapped from the shape pattern; e.g., $a_n = 3n + 1$ in Figure 1), and *theorem* (in terms of a general numerical statement; e.g., $1 + 3 + 5 + ... + 2n - 1 = n^2$ in Figure 2). Institutionalisation of the knowledge in the case when algebraic generalisation aims at a formula (for an *arbitrary* pattern) is not institutionalisation of the formula *per se*. It is institutionalisation of how the formula can be derived through identification of an invariant structure in the elements of the pattern. Further, it is institutionalisation of how the invariant structure is interpreted into arithmetical relationships and how these in turn are generalised algebraically in terms of a formula. The cultural, reusable knowledge in this case is the nature of the relationship between the algebraic expression and its referent (a generic element of the pattern). On the other hand, institutionalisation of the knowledge in the case when algebraic generalisation aims at a theorem (illustrated by a *conjectural* pattern) involves decontextualisation of the general numerical statement from the shape pattern on the basis of which it is developed. The cultural, reusable knowledge in this case is a general relationship between sequences of numbers (in Figure 2, between odd and square numbers).

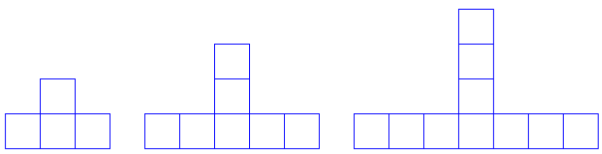

Figure 1: Example of the first three elements of an arbitrary pattern

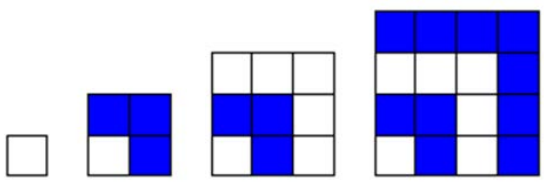

Figure 2: Example of the first four elements of a conjectural pattern

In the following, I illustrate briefly a strategy for generalisation of an *arbitrary pattern*, where I focus on the connection between the iconic, the arithmetical, and the algebraic representation of the pattern. For a detailed epistemological analysis of shape pattern generalisation, see (Måsøval, 2011, Chapter 5). The target knowledge is the nature of the relationship between the sought generalisation (an algebraic expression) and its referent (a generic element of the pattern). A direct approach to generality is employed. The invariant structure of a shape pattern provides the possibility to decompose the elements into different repetitive parts. Decomposition refers to diagrammatic isolation (encircling, painting with different colours, or other techniques) of various parts of the elements in order to visualise the invariant structure of the pattern. The point is to express the number of components of each partition of an element as a *function* of the element's position in the shape pattern. These arithmetical expressions are used to express the total number of components of the element. Generalisation of the sequence of arithmetical expressions will lead to a formula where letters are placeholders for positions. An example of the first three elements of a quadratic pattern is presented in Figure 3.

Figure 4 presents a possible decomposition of this pattern, with corresponding arithmetical expressions

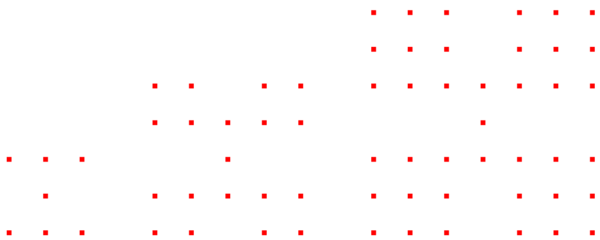

Figure 3: The first three elements of a shape pattern

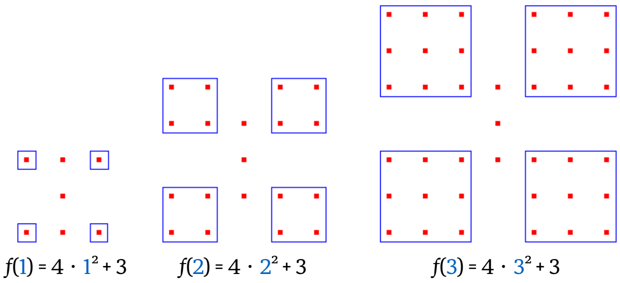

Figure 4: A possible decomposition of elements of the pattern in Figure 3

representing the number of components in the partitions of the first three elements.

The decomposition shown in Figure 4 corresponds to an interpretation which means that each element consists of three components plus four times the square of the position of the element. The corresponding arithmetical expressions suggest a generalisation in terms of the formula, $f(n) = 4n^2 + 3$. An alternative decomposition (discussed without illustration) involves filling in components at "empty places" to make each element into a square; this is compensated by subtraction in the arithmetical expression. In order to build a square, the n-th element would need to get an extra of $4n - 2$ components. The resulting formula would then be given by $g(n) = (2n + 1)^2 - (4n - 2)$.

The example in Figure 3 conceptualised through Kieran's (2004) framework

The process of interpreting and decomposing the pattern is a *global/meta-level activity*. It is a modelling process that involves studying and representing the quadratic relationship between the position and the corresponding member of the number sequence mapped from the pattern. Establishment of a formula (here, a function) is a *generational activity*, where the variable n is a placeholder for an element in the domain (natural numbers). The two different decompositions presented above result in different formulae, where *transformational activity* can be used to justify that they are equivalent.

Justification of the new knowledge (the formula), which is a global/meta-level activity, can be done through decomposition of a *generic example*. This is done to illustrate references between the partitions of the generic element, on the one hand, and the mathematical symbols of the formula, on the other.

EMPIRICAL STUDIES OF STUDENTS' PATTERN GENERALISATION

Students' difficulties in establishing algebraic rules from patterns and tables

Several studies have documented students' difficulties in establishing algebraic rules from patterns and tables. Stacey (1989) reports responses to linear generalising problems of 140 students aged between 9 and 13. Generalisation of the given problems was of the type $f(x) = ax + b$ with $b \neq 0$. It turned out that mainly two ideas were used. Stacey refers to these as the *difference method* and the *whole-object method*. The difference method involves multiplying the common difference between members of a sequence by the rank of a member to calculate its numerical value. The whole-object method involves taking a multiple of the numerical value of a member of a sequence to calculate the numerical value of a member with a higher rank; that is, implicitly assuming that $f(mn) = mf(n)$. The two methods will be applicable only when the linear problems are direct proportionalities. Because the problems used in Stacey's study were not of this type, the difference method and the whole-object method were invalid. The erroneous generalisations were not discovered by the students because they failed to check the validity of the rules they produced.

Another finding from Stacey's (1989) study was that students showed a tendency to focus on recurrence relations in one variable rather than on functional relationships between two variables. The same conclusion about students' tendency to focus on recurrence relations was reached by MacGregor and Stacey (1995). They tested approximately 1200 students in Years 7 to 10 in ten schools on recognising, using, and describing rules relating two variables; 14 students were interviewed. The results showed that the students had difficulties in perceiving functional relationships and expressing them in words and as equations. The students' tendency to find recurrence relations in patterns and tables were in most cases counter-productive to identification of a relationship between two variables. Hence, MacGregor and Stacey recommend teachers to use examples where it is not possible to find differences between consecutive members of a sequence.

Orton and Orton (1996) conducted a study in which 1040 students from Years 6, 7 and 8 (ages 10 to 13) completed a written test on different pattern questions;

30 of the students were interviewed about their responses. Results from this study are consistent with findings from Stacey (1989) and MacGregor and Stacey (1995): students have a clear tendency to use *differencing methods* and identify a recursive pattern.

Lannin, Barker and Townsend (2006) explored students' use of recursive and explicit relationships by examining the reasoning of 25 sixth-grade students, including a focus on four target students, as they approached three generalisation tasks while using computer spreadsheets as an instructional tool. Their results demonstrate students' difficulty in moving from successful recursive formulae towards explicit formulae. One obstacle to students' ability to connect recursive and explicit formulae was their limited understanding of connections between mathematical operations, such as addition and multiplication.

Måsøval (2011) reports from a case study of six (two groups of three) student teachers' collaborative engagement with four tasks on shape pattern generalisation (with some teacher involvement). Three categories of constraints to students' generalisation processes emerged from a process of open coding of transcripts of video recordings, conceptualised through the theory of didactical situations (Brousseau, 1997). The constraints are explained in terms of: 1) an inadequate *adidactical milieu*, in particular caused by unfavourable design of tasks (where the focus is on number of components rather than on the multiple structures inherent in the pattern); 2) complexity of transforming observations and conjectures represented in informal language into algebraic symbolism (from *action* to *formulation*); and 3) complexity of justifying proposed generalisations (*validation*), in particular caused by students' use of empirical reasoning instead of rigorous mathematical reasoning (Måsøval, 2011).

The foregoing discussion of students' difficulties in establishing algebraic rules from patterns and tables can be summarised in three points. First, there are difficulties caused by students' use of invalid or unsuccessful methods to identify explicit formulae (the *difference method* and *differencing*, and the *whole-object method*). Second, there are difficulties caused by students' tendency to focus on recurrence relations which are not easily transformed into explicit formulae. Third, there is an institutional constraint caused by the use of stereotype tasks (focusing on "How many?") and further, by the way pattern generalisation is taught.

Components of a successful pattern-based approach to elementary algebra

Results from Redden's (1996) study demonstrate a significant correlation between natural language descriptions and symbolic notation used by students. On the basis of investigation of how 1435 children aged 10 to 13 responded on requests to generalise shape patterns, he found that natural language descriptions exclusively in terms of functional relationships appear to lead to students' successful use of algebraic notation. This finding points at the importance of relating the independent variable (the position of a member) to the dependent variable (the member itself).

Warren (2000) demonstrates significant correlation between students' ability to reason visually (identify, analyse, and describe patterns) and successful algebraic generalisations from shape patterns and tables of values. Warren's finding is based on responses on two written tests administered to 379 students (aged between 12 and 15 years); 16 of the students were interviewed in groups of four. Warren, Cooper and Lamb (2006) examined the development of students' functional thinking during a teaching experiment that was conducted in two classrooms with a total of 45 Year 4 students (average age nine and a half years). They found that tables with input values not increasing in equal steps assisted students to search for a relationship between two data sets instead of focusing on variation within one. Randomness of the input values encouraged students to think relationally instead of sequentially, a finding consistent with MacGregor and Stacey's (1995) recommendation referred to above.

The results referred to above can be combined to provide a recommendation for students' engagement with shape patterns: Students' should be encouraged to *express functional relationships in natural language*, because this is important for the ability to use symbolic notation. It is relevant here that students remain connected to the iconic representation and *reason visually*, which is a condition for successful algebraic generalisations. Further, visual reasoning can potentially prevent students from senseless pattern spotting in numerical sequences without connection to the original mathematical situation. The strategy presented above (exemplified by the pattern in Figure 3) for generalising a pattern algebraically is favourable in that it has the recommended features: first, it involves analysis of geometrical configurations (decomposition); and second, it involves identification of functional relationships between two sets (position and numerical value of element, respectively).

Several studies suggest that it is not generalisation tasks in themselves that are difficult; the problems that students encounter are rather due to the way tasks are designed and limitations of the teaching approaches employed (Moss & Beatty, 2006; Måsøval, 2011, 2013; Noss, Healy, & Hoyles, 1997). Motivated by this, I designed an epistemological model – a *situation* (Brousseau, 1997) – that involves a problem that can be solved in an optimal manner by using the knowledge aimed at. In the concluding section of the paper, I explain this epistemological model and its devolution to a class of twenty student teachers enrolled on a master programme for primary and lower secondary education. The data from the experiment are students' notes and solutions in addition to my field notes.

AN EPISTEMOLOGICAL MODEL OF A PIECE OF KNOWLEDGE

Inspired by TDS, the theory of didactical situations (Brousseau, 1997), I created an epistemological model of the general numerical statement that "the sum of the first n odd numbers is equal to the n-th square number". The choice of this piece of knowledge was motivated by Måsøval (2011) who reports from students' (less successful) engagement with this equivalence statement through a traditional task, based on a shape pattern similar to the one in Figure 2.

Devolution

I had cut out sets of twelve paper forms, consisting of from 1 to 25 unit squares (a selection of which is shown below). In the classroom I presented the context (below), and gave each pair of students an envelope with a set of cut-outs.

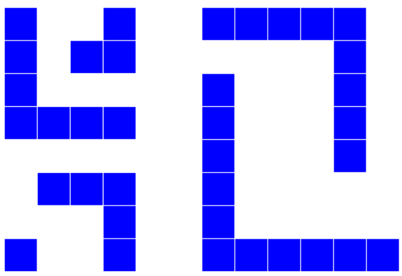
"The company TILEL (in class, represented by the envelopes) sells a special kind of tile formations that can be used to cover *squares*. The tile formations have shapes as Ls, and consist of an *odd number* of unit squares. There is also a degenerated L-form which consists of only one unit square. You and your partner are supposed to construct a quadratic area of tiles, using L-forms from TILEL. You decide on the *size of a square*, and the task is for your partner to go and get a selection of L-forms which *precisely covers* the chosen square. There is a restriction on the L-forms: they shall all be of *different size*.

When your partner returns with the L-forms he/she has bought, the two of you shall arrange them into a square. If you lack some L-forms, or have anyone left over, your partner will have to go back to TILEL for supplements or returns. Each time this is necessary, a *charge* must be paid, so buying the right L-forms at once is important."

Some of the features of the milieu were, due to time constraints, hypothetical (e.g., purchase of tile formations and the fee charged for supplements and returns). The adidactical situation might have been designed as a game, where the winner would be the group that solved the task with least costs, and/or had the best recipe, etc. Figure 5 shows the task given to the students for work in pairs, after the context was presented.

Features of the milieu derived from the knowledge at stake

The target knowledge in this case is the equivalence statement: "the sum of the first n odd numbers is equal to the n-th square number", potentially represented by $1 + 3 + 5 + L + 2n - 1 = n^2$. A model of the target knowledge is created using a dissection of a square into L-forms consisting of consecutive odd numbers



1. One of you chooses the size of a square; the other one gets L-forms to cover it. Collaborate to arrange the L-forms into the chosen square. (ACTION)
2. On the basis of the work you have done, make a recipe for how to cover a square of random size with L-forms of different sizes, without having to go back for supplements or returns. Let another group try your recipe and see if it works. (FORMULATION)
3. Explain why your recipe will always work (for a random square). (VALIDATION)

Figure 5: The task given to the students for work in pairs

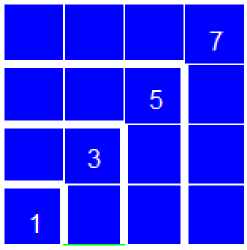


Figure 6: Dissection of the fourth square into the first four odd numbers

of unit squares (1 is represented by one unit square, hence a degenerated L). A generic example is given in Figure 6, illustrating that $1 + 3 + 5 + 7 = 4^2$.

It is important that the L-forms given to the students are of different size; this is what guarantees that the square is made of a sum of *consecutive* odd numbers. The fee charged for not getting the correct L-forms is intended to motivate students' (in the situation of action) to develop a model that relates odd numbers and square numbers. It is expected that the students (in the situation of formulation) express in natural language that it is necessary to add as many odd numbers (from 1 and upward) as the rank of the chosen square number. The situation of validation is intended to motivate reasoning based on the nature of the knowledge at stake, even if algebraic notation might not be used. For this to happen, it is necessary that the students have a technique (prior knowledge) for representing odd numbers in terms of $2 \cdot 1 - 1$, $2 \cdot 2 - 1$, $2 \cdot 3 - 1$, and so on.

Due to limited space, I comment only on the validation phase (in whole class). Two approaches were used to justify the conjecture: One was a visual proof (cf. Figure 6), where students argued by a generic example that the next square is reached by adding the next odd number $(2(n+1)-1)$ to the current square. The other approach started with the statement in algebraic notation, $1 + 3 + 5 + L + 2n - 1 = n^2$; students showed that the sum on the left hand side is equal to n^2 by using the Gaussian method (adding the first and last terms, then the second and last but one term, etc.). There was a discussion of implementation of the model in different grades in school.

The adequacy of an epistemological model is based on the quality of the underlying epistemological analysis (EA). An EA should provide a rationale that would make the students' engagement in the problem situation sensible. An EA is however "work in progress"; experiments feed back to, and might strengthen, the EA and hence the model based on it. A relevant direction for future research on pattern generalisation is therefore the design and study of implementation of epistemological models of pieces of algebraic knowledge – in order to improve the models. Due to its epistemological focus, TDS would be a favourable framework to use in this kind of research.

A study of the preparation of the function concept

Gyöngyi Szanyi

University of Debrecen, Institute of Mathematics, Debrecen, Hungary, szanyi.gyongyi@science.unideb.hu

Function is a basic concept of mathematics, in particular, mathematical analysis. With an appropriate development of a function approach, it becomes possible for students to use function models to describe mathematical and non-mathematical problems. After an analysis of the function concept development process, I propose a model of rule following and rule recognition skills development that combines features of the van Hiele levels and the levels of language about function (Isoda, 1996). Using this model I investigate students' rule following and rule recognition skills from the viewpoint of the preparation for the function concept of sixth grade students (11–12 years old) in the Ukrainian education system.

Keywords: Function concept, Ukrainian secondary education, features of van Hiele levels, rule following and rule recognition skills.

INTRODUCTION

The function concept interweaves the whole teaching of mathematics. Functions are incorporated in the concepts of numbers, equations, inequalities, ratio, proportionality, geometrical transformations, etc. Through the teaching of functions, it is also possible for students to develop creativity, functional thinking, and other cognitive strategies (Czeglédy, Orosz, Szalontai, & Szilák, 1994).

In her study, Sierpinska (1992) sets out the conditions of understanding the notion of function. These conditions illustrate that it takes time to reach a thorough understanding of the function concept. There is a long journey between beginning to develop an understanding of the links between the elements of sets to the robust function concept. In this study I examined the portion of this journey that happens during the fifth – sixth grade, which is the period before learning the definition of the function (preparation period). The study was based on the analyses of the Ukrainian curriculum framework. The study revealed that the development of rule following and rule recognition (hereafter referred to as RF and RR) skills are missing from the curriculum. Dreyfus and Vinner (1989), however, point out that a function can also be defined as a rule, and the rule is an element of the function concept (Kwari, 2007). The present study examines RF and RR skills that are necessary in the formation of the function concept and in the construction of function tables, which help children to figure out the relationship between quantities (Blanton & Kaput, 2011). The participants were a class of sixth grade (11–12 years old) students, studying in the Ukrainian education system.

THEORETICAL BACKGROUND

Definition plays an important role in mathematics. According to Skemp (1987), definitions have their specific places in mathematical concept development. Concepts of a higher order than those which people already have an understanding of, cannot be communicated to them by a definition, but rather by presenting to them a suitable connection of examples. Since in mathematics these examples are almost invariably other concepts, it must first be ensured that these are already formed in the mind of the learner (Skemp, 1987).

The modern definition of function that frames this study is the Dirichlet-Bourbaki definition, which is "a correspondence between two nonempty sets that assigns to every element in the first set (the domain) exactly one element in the second set (the codomain)" (Vinner & Dreyfus, 1989, p. 357). So in order to develop a concept of function, the knowledge of both simple and higher level concepts is necessary, and this formation is a long process.

Vinner and Dreyfus (1989) discuss the notions of function put forth by secondary school students after being given the definition of function. The authors, drawing on Vinner (1983), categorized students' definitions of function into six categories: (A) correspondence (the Dirichlet-Bourbaki definition); (B) dependence relation (dependence between two variables); (C) rule (a function is a rule; a rule is expected to have some regularity, whereas a correspondence may be "arbitrary"); (D) operation (a function is an operation or manipulation); (E) formula (a function is a formula, an algebric expression, or an equation); and, (F) representation (graphical or symbolic representation) (Vinner & Dreyfus, 1989, p. 360).

Taking into account these categories and the above mentioned studies, it can be highlighted that the function concept has many elements. Sierpinska (1992) described the "worlds" that the study of functions should focus on: the world of changes or changing objects; the world of relationships or processes; and, the world of rules, patterns, and laws. Likewise, Kwari (2007) showed the constitutive elements or aspects of the function concept that should be developed: change and what changes; relationships (attribute — builds rules to determine a unique y-value from any given x-value); rules (symbolically given by, e.g., $f(x) = ax + b$); representation; and, language/notation. Of the skills that could be linked to the above listed aspects, possession of the rule recognition and rule following skills are significant for the students in this study in order to recognise and express function-like relations. So, this study concentrates on the investigation of these skills and only touches upon the question of symbolisation (the articulation of rule by arithmetic operations), but does not intend to go further (to write function-like links with symbols, e.g., $f(x) = ax + b$).

As a *skill* is considered to be the psychic feature of an individual, that evolves by the practice of some kind of activity, and is manifested in the doing of that activity, then the mentioned skills can also be developed by cognitive operations. The recognition of a rule (regularity), the following of the rule, and in some cases, the appropriate application of the rule, presumes the execution of a series of cognitive operations (categorisation, selection, and link-recognition).

The information acquisition process is strongly influenced by the development of students' cognitive operations. Two Dutch didacticians, Pierre van Hiele and Dina van Hiele-Geldof developed a pedagogical theory in 1957 for the understanding of the process of geometric thinking, which differentiates between five levels of geometric thinking: visualization; analysis; informal deduction; deduction; and, rigor (as cited in Herendiné Kónya, 2003, p. 51).

Freudenthal (1973) and Isoda (1996) extend the van Hiele levels from geometry to other areas. Freudenthal viewed progressive mathematization as the main goal of school mathematics. For this ongoing task, he provided a framework by recursively defined levels: the activity of the lower level, that is the organizing activity by the means of this level, becomes an object of analysis on the higher level. Freudenthal's theoretical approach rests on the Van Hiele levels. Van Hiele, himself, has written about levels in arithmetic and algebra (van Hiele, 2002). He observed 'a change in level' from the act of counting to the concept of number. Isoda's paper (1996) points out features of van Hiele levels and shows that they are also characteristics of the proposed levels of language about function. These features include: (1) Language hierarchy. Each level has its own language and the levels are hierarchical; (2) The existence of untranslatable concepts. The corresponding contents of different levels sometimes conflict; (3) Duality of object and method. The thinking of each level has its own inquiring object (subject matter) and inquiring method (the way of learning); (4) Mathematical language and student thinking in context. While the levels are distinguished as sets of mathematical language, the actual thinking of each student varies depending on the teaching and learning context.

Isoda (1996) first discusses the levels of function from the point of view of language, and shows the duality between object and method in van Hiele's levels (the levels of geometry) and in the levels of function. These levels of language are: Level 1. Level of everyday language (students describe relation in phenomena using everyday language obscurely: students explore phenomena (object) using obscure relations or variation (method)); Level 2. Level of arithmetic (students describe the rules of relations using tables. They make and explore tables with arithmetic: students explore the relations using rules); Level 3. Level of algebra and geometry (students describe function using equations and graphs: students explore the rules using notations of function); Level 4. Level of calculus (students describe function using calculus); Level 5. Level of analysis (an example of language for description is functional analysis which is a metatheory of calculus).

The present study examines the preparatory part of the notion of function in the sixth grade in light of the state framework curriculum, using features (1) and (3) of van Hiele levels and the first three of the five levels of function described by Isoda (1996). I set out the levels of the cognitive operations that are crucial for the possession of RF and RR skills and the criteria for categorising activity forms into levels. Noticing an analogy between these levels and the van Hiele levels, I used the names of the van Hiele levels for the marking of the discussed levels. The levels which I created by joining the features of van Hiele levels and Isoda's levels and using them to develop a deeper understanding in (sixth grade) students' development of the function concept, are the following:

> Level 1 (visualization): Students recognise some kind of rule (functional relation) (method) between the element pairs (object) and follow the recognised rule *(level of everyday language).*
>
> Level 2 (analysis): Students are able to phrase the recognised rule (they can argue in favor of the recognised links between the cohesive element pairs) and follow the rule which is given by words or by simple formulas *(level of everyday language and level of arithmetic).*
>
> Level 3 (informal deduction): At this level the harmony of the simple (2–3 steps) rule-making and its description with formula develops *(level of arithmetic).*

METHODOLOGY

Sample

Participants were 26 sixth grade students (11–12 years old), with moderate abilities, in a school with Hungarian as the language of instruction in Ukraine. The students had four classes of mathematics a week, according to the state curriculum framework. The Hungarian version of the mathematics textbook is used at this level and is approved by the Ukrainian Ministry of Education and Science. As the research was carried out in March, during the second semester of the sixth grade, students were already familiar with the natural numbers, fractions (common fractions and decimals), and had learned arithmetic operations with rational numbers. The introduction of proportional amounts and linear relationships occurred during this period, with the practical application in the initial phase.

Background

In the Ukrainian education system, function as a mathematical concept is defined at the seventh grade of the secondary school. In the lower classes, students are prepared with the use of different materials for introduction of the function concept. Analysing the curriculum and the textbooks for the fifth and sixth grade from the point of view of topics and their content that are supposed to support the development of the function concept, major deficiencies come to the surface in the requirements for developing RF and RR skills (in the lower classes it does not exist at all). In the development requirements of the themes of the curriculum, rule recognition and rule following skills are not mentioned. Prior research (cf., studies cited above), however, suggest that they are neces-

Class	Themes	Development requirements
5.	Number line	The representation of natural numbers on the number line.
	Letter expressions	The recognition of number- and letter expressions and the illustration with examples.
6.	Linear relationship	Illustration of proportional amounts with examples, the definition of the concept of linear relationship, finding the unknown element of the proportion, defining the proportion between amounts.
	Diagrams	Editing column- and circle diagrams.
	Cartesian coordinate system	Finding the coordinate of the point in the coordinate plane and representing the given coordinate point.
	Graphs	Representing correlations between quantities by graphs and analysing these graphs. The student is able to read the data from the graphs.

Table 1: Themes preparing the function concept in the Ukrainian textbooks[1] and curricula[2]

sary for the development of the function concept. In Table 1, I summarized the textbook themes that could support the preparation of the function concept. It can clearly be seen in the table that RF and RR skills are not amongst the development requirements of the materials.

Based on these aspects, in this study I am looking for the answers to the following questions: *At the end of the 6th grade, what level do students reach in their RF and RR skills? What are the typical mistakes students make when carrying out activities at each level and what might explain these errors?*

The questionnaire

A written test was used in order to investigate the RF and RR skills of students. Students worked independently and had 30 minutes to complete the test. The test contained five tasks that were based on the recognition and application of the relationship between the cohesive elements (assignment rules), as well as on the expression of the recognised rule, including as a formula. I was interested in students' possession of the necessary skills for the preparation of the function concept. In some exercises, the cohesive element pairs did not clearly make a function, so more rules might be possible. In the direction to the test, however, I tried to make it clear that I wanted students to find only one adequate rule. When constructing the test, I included tasks for levels 1, 2 and 3. When choosing the tasks, I predominately relied on the literature and used some of them without any alterations.

1) *Find a rule between the first and second row of the table. Fill in the table according to the rule* (Level 1)*! Write down the recognised rule in words* (Level 2).

pék	*tér*	*ló*	*bál*	*görög*		
kép	*rét*	*ól*			*derék*	*savas*

Figure 1

2) *Find a rule for the numbers in the columns and fill in the blank places of the table according to that rule* (Level 1). *Write down the recognised rule in words* (Level 2).

40	80	12	60	44	100	160				
10	20	3					1	13	31	95

Figure 2

I indicate the level of the task, parenthetically, within the instructions (see figures below). The first two tasks (Figure 1 and Figure 2) targeted the recognition, application and verbal expression of the relationship between cohesive elements (words and numbers). The filling in of the blank places of the tables assessed the application of the rule. Although the correct solution of both tasks assumes the same level of cognitive operations and activity forms (level 1 and level 2), the difference can be found in the context of the tasks: While in the first task the cohesive element pairs are words, in the second they are numbers. Because function relationships do not only occur between numbers, it is crucial that students recognise this relationship, as well.

The aim of the third task (Figure 3) was to make students recognise the relationship between the elements, apply it, and to express it with both words and symbols. In order to reach the first level, it is necessary to recognise some kind of relationship between the cohesive elements (x and y), but unlike in the first two tasks, the table is extended by an extra (first) column which serves as a hint to record the recognised relationship in the language of arithmetic (2nd level). When asking students to express the relationship with a formula, I touch upon the question of symbolisation (3rd level), but I do not intend to examine it deeper in this study. The "end product" (y value) should be found with the help of the given "raw material" (x value) according to the recognised rule, while in the previous two tasks knowing the "end product" and using the recognised rule, the raw material should be found.

The fourth task (Figure 4) was aimed at the interpretation and following of a predefined rule. In order to solve the task, the student needed to possess the activity forms of the two levels in order to interpret (analyse) the given formula. A correct completion

3) *Find a relationship between the x and y values of the columns and based on it, complete the table with the missing elements* (Level 1)*! Write down the relationship with words* (Level 2) *and as an expression* (Level 3)*!*

x	1	10	7	0	9	20	38
y	5	23	17				

y=__________

Figure 3

x	-3	4	44	48	-20	0
y						

4) Fill in the table according to the following rule: y=2x+3. Write down the rule in words (Level 2).

Figure 4

5) 2 litres/second of water flows from a tap to a tank. How much water is in the tank at:

a) 1 s, c) 5 s, e) 16 s, (Level 2)
b) 2 s, d) 10 s, f) x s (Level 3)

later if the tank was empty at the beginning? Illustrate the relationship between the amounts in a table.

Figure 5

of the table indicated a correct interpretation of the symbolic rule.

In the fifth task (Figure 5) I examined rule recognition and its mode of illustration during the solution of a task given in context. In this case, the rule is given verbally, in context. I take students' correct responses for parts (a) through (e) (2nd level) as an indication that the student had correctly interpreted the rule. A correct response to part (f) indicated that students' understanding of function had reached the third level, since the student was able to generalise the task, i.e. write down the relationship using a formula.

RESULTS

Analysis of students' answers

All of the students filled in the table in Task 1 correctly. This indicated that the students could recognise some kind of regularity between the first and the second row of the table, and they could apply the recognised rule. This means that when the cohesive element pairs are words, students can recognise the relationship between them. Writing down the recognised rule in words, however, was difficult for eight students. Some students skipped this part of the task or gave a rule that was not supported by the completed table. Some examples of correct responses for recognised rules: "Words should be read backwards"; "If we change the first and the last letters we get another meaningful word".

In the second task, where the cohesive element pairs were numbers, only 18 students' gave a correct solution, while 14 students were able to give the recognised rule in words. The other students made one of the following mistakes: (1) they filled in the blank squares in the second row of the table according to a recognised rule, but in the first row they filled in the blank squares using another rule; that is, they did not apply the inverse of the recognised rule and interpreted this part of the table separately. From the point of view of the function concept, these mistakes indicated issues in recognising and differentiating between the basic set and the image set; (2) students tried to find different rules for each column and filled in the squares according to it. This could be the consequence of being unfamiliar with the table illustration of cohesive amounts. Here are some examples of correct responses for recognised rules:

> "If the square in the second row is empty the number above it has to be divided by four, and where the first row square is empty the second row number has to be multiplied by four" ; "Numbers of the first row are the fourfold of the lower row".

Only two students completed the third task, while other students did not give any indication of their thinking. This let me conclude that those students who possess the skill of one step rule recognition and rule creation may have difficulty with two step rule recognition.

In the fourth task, the rule was given symbolically. Students had to understand the symbolic rule and fill in the table accordingly. The given rule could have been familiar to the students, as letter expressions were from the fifth grade mathematics material, when they had to define the value of the letter expression along the certain values of the variable, but the values were not given in table form. Presumably, this new situation confused many students. Only twelve students could solve the task with only minor calculation mistakes.

Only ten students could answer all of the sub questions of the fifth task, including the last (f), so they could generalise the rule of calculating the amount of water in the tank if the elapsed time was unknown, and they could illustrate the relationship between the results with a table. Eight students could calculate with concrete numbers (parts (a) through (e)), but failed to complete the (f) question.

By analysing the responses of the students in the tasks according to the criteria of the set out levels it can be said that a student reached level 1 if he/she could complete at least one of Tasks 1, 2, or 3. I considered that a student had reached Level 2 when he/she correctly provided the rule in at least three tasks out of the five. The student reached Level 3 if he/she gave the correct answer to all of the questions of the third task. In some tasks students made calculation mistakes (such as in Tasks 4 and 5), but I did not take these into consideration if the student demonstrated the correct reasoning.

The students' answers were analysed based on the levels at which the various parts of the tasks were categorised. The results are summarised in Table 2.

Based on the analysis, the students were most successful at demonstrating a Level 1 understanding in the first task since every student correctly completed it. However, the part of the same task, which was categorised as Level 2, was completed by fewer students (18). It can be concluded, however, that in the case of each task, the highest results were reached on Level 2, as compared to the other levels. The third task was the most difficult. Only two students gave a complete solution.

Based on these aspects, out of 26 students, 14 are on the first level, ten are on the second level, and only two students are on the third level. So, most of the students can recognise some kind of rule between the element pairs and can follow it, but to write these rules down with words cause them difficulties. In addition, interpreting the rules given by symbols and making multistep rules also seems to be problematic. This study also confirmed the hierarchy of the levels. There was no student who could meet the requirements of Level 3, but not Level 1 or Level 2.

CONCLUSIONS

The goal of this paper was to investigate the RF and RR skills of sixth grade students studying in the Ukrainian education system, from the point of view of the development of the function concept. The results showed that students certainly reached level 1, indicating that they can recognise the relationship between simple elements. In many cases, however, I could see that some students fulfilled the requirements of level 1, but could not get to level 2 due to possible deficiencies in the area of communication in the language of mathematics. Many could also not successfully use the table as a tool for displaying cohesive elements. I suspect that students' deficiencies are not only age-specific, but are also related to the absence of tables from the curriculum requirements and from the textbook tasks. Students' lack of success in correctly completing Tasks 4 and 5, which entailed the use of already known concepts (letter expressions and linear relationship) in new situations (problem solving), indicated that this was also a problematic area for the students.

Finally, I would highlight a component of van Hiele's theory: that reaching a level does not only depend on the age of the student, but also on the teaching methods used and the quality of student learning. Based on this suggestion, with appropriate teaching methods and practical exercises integrated into the teaching/learning process, we can ensure that students possess the adequate skills for at least the first two levels in order to make the introduction of the abstract concepts easier in the seventh grade.

The development and arithmetic foundations of early functional thinking

Ulises Xolocotzin and Teresa Rojano

Research and Advanced Studies Centre, Ciudad de México, Mexico, uxolocotzine@cinvestav.mx

Functional reasoning is a key strand of early algebraization. This paper presents a cross-sectional study that analysed functional thinking in a sample of 94 elementary school students. Aspects such as following and identifying covariation rules showed dramatic differences between Grade 2, Grade 4, and Grade 6, whereas increases in the abilities to command verbal and symbolic representations were much smaller. After controlling for the influence of nonverbal reasoning, overall functional reasoning was found to be strongly associated with calculation skills, but not with skills such as counting, the understanding of numerals, and arithmetic problem solving. These results are discussed in terms of the nature of functional reasoning and its relationships to the arithmetical skills learnt during elementary education.

Keywords: Functional thinking, early algebra, arithmetic, quantitative methods.

INTRODUCTION

There is an increasing interest for understanding how algebraic ideas might be introduced during elementary education. Studies of early algebraization suggest that young children are capable of acquiring algebraic competences such as understanding the relationship between two quantities x and y, figuring out a co-variation rule (Carraher, Martinez, & Schliemann, 2008), and explaining and symbolically representing such rule (Cooper & Warren, 2007). However, the extent to what children's cognitive development permits their learning of algebraic notions remains to be fully understood (Carraher, Schliemann, Brizuela, & Earnest, 2006), and the interest for linking algebraic ideas with children's existing arithmetic knowledge are fairly recent (Russell, Schifter, & Bastable, 2011). This paper adds to the current literature by studying the acquisition of algebraic ideas such as that of function, by exploring the ways in which this might be linked to the arithmetical skills that children acquire during elementary education. This paper reports a cross-sectional study designed with two aims. First, the study aimed to identify the progression of a range of functional thinking aspects comparing children in Grade 2, Grade 4 and Grade 6. Second, the study analysed the extent to what overall functional thinking might be related to non-verbal reasoning and arithmetical skills, including counting, numerical understanding, calculation and problem solving.

Functional thinking in the early grades

The *functional approach* to teaching algebra is based on situations involving the simultaneous variation of two quantities and a rule governing such variation. Functional reasoning used to be absent in the elementary mathematics curriculum. However, during the last 15 years the development of the function concept gained recognition as a strand of early algebraization and, consequently, education programs addressing the mathematics of variation are increasingly common. For example, the Principles and Standards for School Mathematics introduce the subject 'Analyse change in various contexts' from Pre-K2 to Grade 12 (http://www.nctm.org/standards/content.aspx?id=26853). This is in part due to the recognition amongst researchers of the importance of introducing young pupils to mathematical representations of everyday situations (Blanton & Kaput, 2011), and responds to the evidence that technological environments effectively support the manipulation of dynamic mathematical representations of variation without algebraic representations (Rojano, 2008). The current study addressess two research questions.

How do functional thinking aspects progress across elementary grades?

Function tables are powerful tools for scaffolding and studying functional reasoning in the early grades (Martinez & Brizuela, 2006), since they help children to figure out relationships between quantities (Blanton & Kaput, 2011) and to elaborate algebraic conceptions such as co-variation and generalized correspondence (Tanışlı, 2011). Function tables are used in the current study for assessing a set of aspects of children's early understanding of functions, namely following explicit covariation rules, identifying and using such rules without an explicit definition, and understanding and generating verbal and symbolic representations of such rules (McEldoon & Rittle-Johnson, 2010).

What arithmetic skills are related to functional thinking?

It is well documented that children rely on their arithmetic knowledge to face their first encounters with algebraic problems (e.g., Van Amerom, 2003). Disregarding these intuitive arithmetical attempts and urging children to use formal algebraic methods might be misleading (Smith & Thompson, 2008). Therefore, there has been advocacy for grounding early algebraization on arithmetical knowledge (e.g., Russell, Schifter, & Bastable, 2011). This study adds to this research line by describing the relationship between functional thinking and a set of arithmetical skills that children usually learn during primary school.

METHOD

Design

This descriptive study relied on a cross-sectional design to compare aspects of functional reasoning across elementary school grades.

Participants and context of the study

The final sample for this study consisted of 94 students (58 girls) attending Grade 2 (n = 29, *Mean age* = 8.0 years, *SD* = 0.7), Grade 4 (n = 33, *Mean age* = 10.0 years, *SD* =0.5), and Grade 6 (n = 32, *Mean age* = 11.9 years, *SD* =0.5). The sample was randomly taken from the morning and evening shifts of a school located in a middle-size city in central Mexico. There are two considerations to make about the context of the study. First, at the moment of the study the mathematics performances of the two shifts in the participant school were fairly close to the national average in the nation-wide assessment ENLACE (SEP, 2014), which is similar to national standardized tests such as UK's SATs. This might be a helpful reference to understand how the participants in this study might compare to the rest of the Mexican population. Second, it is known that Mexico tends to rank at bottom positions in international mathematics assessments such as PISA (OECD, 2013). This is helpful to understand the relevance of this study for an international audience.

Measures

Functional Thinking Assessment

We wanted to link the progression of functional reasoning across elementary school grades with children's arithmetical knowledge. Therefore, we employed one instrument designed to do that, namely McEldoon & Rittle-Johnson's (2010) *Functional Thinking Assessment* (FTA). The items in the FTA are based on function tables that, as mentioned above, are adequate for approaching functional thinking. The FTA covers four aspects of functional reasoning:

— Apply rule: The student can use a given rule describing the relationship between the numbers in two table columns in order to determine new values of a table.

— Recognize rule: The student recognizes an $x - y$ correspondence rule in a table, and uses it to determine the next y value.

— Generate and use a verbal rule: The student writes a correspondence rule verbally, e.g., "*you add 4 to the number in the x column to get the number in the y column*".

— Generate an explicit symbolic rule: The student writes a correspondence rule using algebraic symbols, i.e., letters.

These aspects and their order were defined on the basis of both a review of existing educational materials involving function tables, and an empirical analysis of FTA validity and reliability. Item Response Theory measures showed that for all items, the probability of correct response implicated greater ability. Classical measures indicated high internal consistency (McEldoon & Rittle-Johnson, 2010). These properties suggest that the FTA possess adequate construct validity since it reliably identifies progression across ages, and the grouping of its items is consistent with the aspects that it is intended to assess.

A pilot study (Xolocotzin & Rojano, 2014) confirmed the appropriateness of the FTA, but it was also discovered that it might be beneficial to increase the number of items in the FTA, in order to give children a better opportunity to demonstrate their skills. Therefore, we added 4 items that required the generation of a verbal and a symbolic rule, without having to use it. These items added to the existing ones assessing the identification, generation, and usage of a covariation rule, which combination indexed the ability to command the verbal and symbolic representation of relationships between numbers. Other 4 items were added to balance the operations, for instance, to equalize the number of items involving additions and subtractions. Exploratory analyses (not reported) showed that these added items had similar difficulty and discrimination capacity as the original ones.

Non-verbal intelligence

Participants completed the *Matrix Reasoning* subtest of the Weschler Intelligence Scale for Children IV (Wechsler, 2007) according to the standard procedure. In order to have an age-standardized measure of non-verbal intelligence, the raw scores were converted to scaled scores for Mexican population.

Arithmetic ability

General arithmetic abilities were indexed with the raw scores obtained in the Arithmetic scale of the *Evaluación Neuropsicológica Infantil* (Neuropsychological Children Assessment, ENI) by Matute, Rosselli, & Ardila (2007). This is a battery for children aged 5 to 15. This instrument was selected because it assesses a comprehensive set of arithmetic abilities:

— Counting. This includes items that require numbering objects with and without interference, e.g., *"How many stars and bells are in this card?"*

— Numerical understanding. This includes items indexing abilities for commanding numerals, such as reading numbers, writing numbers, comparing numbers, and ordering numbers.

— Calculation. This subtest requires the making of numerical series, both forwards and backwards, as well as the verbal and written solution of arithmetic operations (e.g., 23 + 14).

— Arithmetical problems. This subtest requires the verbal solution of word-problems (e.g., "A second-hand motorcycle was sold in $ 8, 700, which is three-fourths of its original price. What is its original price?").

Procedure

After selecting the school, the corresponding authorities were contacted in order to explain the project intentions and requirements and obtain official permission for accessing the students. Parents of the selected groups were required to give informed consent for their children's participations. After this, complete groups of Grade 2, Grade 4 and Grade 6 were tested collectively with the FTA. Grade 4 and Grade 6 groups answered the FTA in one session lasting up to one hour, whereas children in Grade 2 groups were tested in two sessions of up to 30 minutes each. In total, 196 children were tested with the FTA. A sub-sample of 100 students was randomly selected for this study. Except for few children who required two sessions due to interruptions, the testing of arithmetic ability and non-verbal intelligence was made individually in one session lasting 45 minutes to one hour. Children were made to perform other tasks related to their cognitive development, the results of which are not reported here. The testing took place in a quiet room within the school, with presence of the researcher and the child only. Before each session, children were requested to verbally consent with the activities, after being clarified that their participation was anonymous, voluntary, and that they could stop at any moment. Three children did not complete the testing sessions because they decided to stop, and other three did not complete a second session, leaving a final sample of 94 children.

RESULTS

Comparisons by functional thinking aspect, grade and gender

The percentages of correct responses in each of the FTA aspects were analysed with a mixed ANOVA including the within-participants factor Aspect (Apply rule/Recognize rule/Verbal representation/ Symbolic representation) and the between-participants factors Grade (Grade 2/Grade 4/Grade 6) and Gender (male/female). None of the scores was weighted. The assumption of sphericity was violated, and although the results of the analysis with and without corrections were virtually equal, here we report the Greenhouse-Geisser corrected results. There was a significant main effect of Aspect [F (2.46, 217.037) = 118.323, p <.001, h^2 = .573], suggesting that children were more able to apply a rule than to recognize a rule, representing it

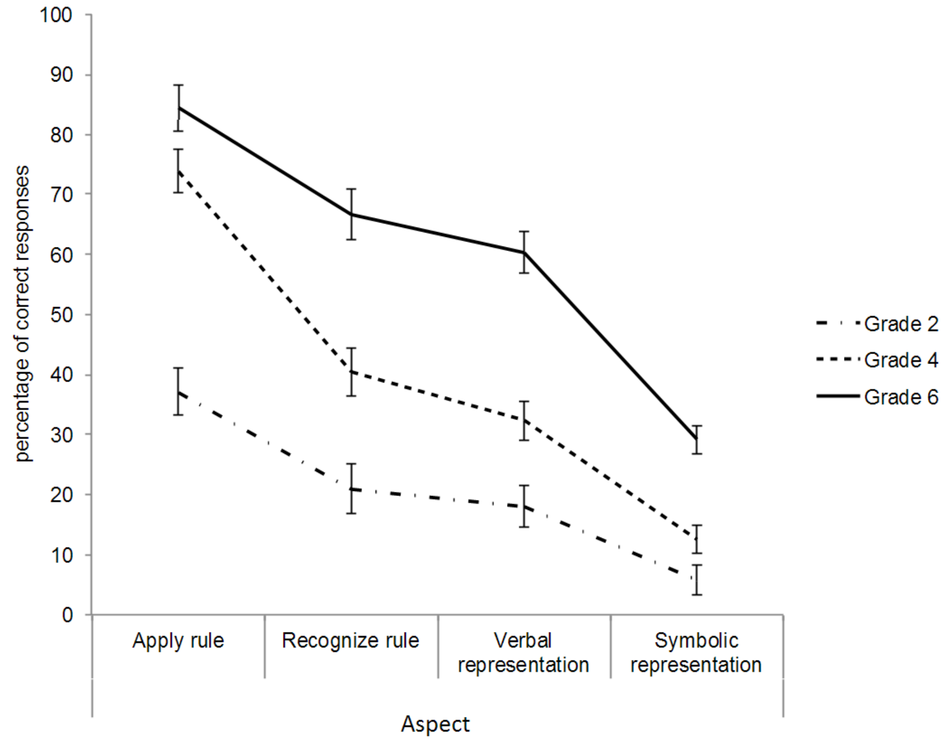

Figure 1: Percentage of correct responses by aspect and grade

verbally, or representing it symbolically, in that order. The significant main effect of Grade [F (1, 88) = 42.789, p <.001, h^2 = .493] indicated that the functional thinking aspects changed from one grade to another. There was also a significant aspect x grade interaction [F (6, 217.037) = 42.789, p < .001, h^2 = .493].

Post-hoc pairwise tests with Bonferroni adjustments revealed that the aspect apply rule increased significantly from Grade 2 to Grade 4, but not from Grade 4 to Grade 6. Also, the aspects verbal representation and symbolic representation increased only from Grade 4 to Grade 6, but not from Grade 2 to Grade 4. Neither the main effect of Gender [F (1, 88) = 0.57, ns] or the interactions aspect x gender [F (3, 217.037) = 0.93, ns], and aspect x grade x gender [F (6, 217.037) = 0.11, ns] resulted significant. Figure 1 illustrates these results.

Relationships between arithmetic and functional thinking

A multivariate regression analysis identified the arithmetic strands that might have been related to children's performance in the FTA. The dependent variable was a composite score indexing overall functional thinking, defined as the summed raw scores of the FTA indexes, namely apply rule, recognize rule, verbal representation and symbolic representation. Positive and significant correlations (not reported) were found between these scores (all rs > .39, all ps < .001), justifying their aggregation.

The independent variables in the regression analyses included two dummy variables that identified Grade 2 and Grade 4 individuals, the scaled scores of the matrix reasoning test, and each of Arithmetic scale

Independent variables	B	SE	β	p
Grade 2	-14.480	1.231	-.777	<.001
Grade 4	-7.614	1.179	-.422	<.001
Matrix reasoning	.776	.233	.231	.001
Calculation	.285	.117	.184	.017
Notes: all *ps* two-sided, only significant results are presented				

Table 1: Summary of the multivariate regression analysis including overall FTA score as dependent variable and Grade, matrix reasoning and the indexes of the ENI Arithmetic scale as independent variables

scores of the ENI, mean-centred by Grade. The results are shown in Table 1.

Children in Grade 2 and Grade 4 scored lower in the FT test than children in Grade 6, which is consistent with the results of the ANOVA presented above. The coefficient of the matrix reasoning score indicated that those who had a more non-verbal reasoning also scored higher in the FT test. As for the arithmetic scores, counting, numerical understanding, and arithmetical problems, were not significantly related to the FT. In contrast, the positive and significant effect of calculation indicated that those who were more able to make numerical series and resolve arithmetical operations were also better at responding the FTA.

DISCUSSION

How do functional thinking aspects progress across elementary grades?

The comparisons by aspect, grade, and gender, are consistent with the results reported with other applications of the FTA (McEldoon & Rittle-Johnson, 2010), suggesting its adequateness for assessing functional thinking. The absence of gender effects suggests that functional reasoning is accessible for both boys and girls. Performance in all of the aspects increased across grades. However, there were differences in their rates of increase from one grade to another. The ability to apply a rule develops steadily, and approaches top performance by Grade 4. This seems only natural considering that applying rules is a form of following instructions, which is something that children get familiar with from early stages of education. Younger children might be unable to apply a given covariation rule because they do not understand it, as is indicated by their lower performance recognizing and representing such rules. Performance recognizing a rule seems to progress regularly across elementary grades, although is not fully commanded by older students. The difficulty to command verbal and symbolic representations is noticeable. The differences across grades are apparently not regular and rather modest, especially for symbolic representation. Recall that children in Grade 4 perform at the same level of children in Grade 2, and children in Grade 6 failed to reach above 30% of correct responses.

The low performance on symbolic representation might be the result of either low students' abilities or hard items. This is difficult to disentangle with the collected data, so the results of this aspect should be interpreted cautiously. Analyses of the items' discrimination and difficulty for the current sample showed that 5 out of the 9 items involved were very difficult, even for top performers. The rest were also difficult but at least 30% of top performers were able to solve them. The items also involved different mathematical relationships, including addition, subtraction, multiplication, and combinations of these. The effects of potential differences in the capacity to handle these operations might be confounded with the capacity to symbolize. Also, the assessment of symbolization as a unitary aspect might not be optimal. This might be addressed by decomposing it in sub-aspects of different difficulty. For instance, symbolizing a covariation rule that has been presented in natural language might be one easier sub-aspect than symbolizing directly from data.

Functional reasoning aspects change differently across grades, suggesting that the progression from one aspect to the other is not necessarily uniform. Further studies should be designed to replicate these results, especially those regarding symbolic representation aspect, considering the apparent difficulty for assessing this aspect.

Non-verbal intelligence and functional reasoning

The significant relationship between matrix reasoning and the FT scores reflects that perceptual reasoning, indexed by the understanding visual patterns, is closely linked with the development of mathematic abilities in general (Parkin & Beaujean, 2012). Nevertheless, future studies should investigate if undersanding numerical patterns could be specifically related to the understanding of functions.

What arithmetic skills are related to functional thinking?

The results of the multivariate regression analysis outline the arithmetic skills that might be associated with functional thinking. The effects of the Grade 2 and Grade 4 dummies are not discussed since they replicate the grade effects discussed above. The significant matrix reasoning effect was expected since performance in this test tends to be correlated with general mathematics ability (Jordan, Glutting, & Ramineni, 2010) and, therefore, it was important to account for the influence of this variable when assessing the relationships between arithmetic and functional thinking.

The lack of significant counting effects might reflect the abstract nature of functional thinking. Counting was assessed with tasks in which children numbered objects accessible to visual perception. In contrast, functional thinking tasks required working with relationships, either explicit or not, between abstract quantities, i.e., represented by numerals. The lack of numerical understanding effects might be seen as counterintuitive. One would expect that skills for mastering the symbolic number system might be also used for functional thinking. Both of these involve generalizations. However, this seems to be not the case, at least for this sample. Children might command the structure of ten base-10 system, generalizing the relationship between the location of a numeral in a number and its value. For instance, knowing what the numeral 3 represents depending of whether is located first (32) or second (132). However, this sort of generalization seems unrelated to generalizations about relationships between different sets of quantities.

The significant effects of calculation suggest that those more able for making sequences and resolving arithmetical operations also resolved more FT items. Probably they attempted the function tables with iterative calculations, or by trial and error, and then they figured out the covariation rules. Another possibility is that they figured out the covariation rule first and then proceeded to do the calculations. The later seems less likely considering that items involving representation were more difficult than items involving the imputation of missing data, such as following a rule or employing a non-explicit rule. Further studies might shed light on this issue. It is important to mention that this result seems consistent with suggestions made about the important role that calculation might have for grounding algebraic reasoning. Russell and colleagues (2011) identified activities that sustain both arithmetic and algebra, namely understanding operations, generalizing and justifying, extending the number system, and using notation with meaning. Whether children might engage with these activities whilst doing function tables deserves attention.

The lack of significant effects of arithmetic problems does not rule out that problem solving is associated with functional reasoning. There was a sizable coefficient and a large standard error (B= .64, SE= .47). This might be related to the instrument. This score was obtained from a single test with eight items, which is small compared to the calculation score, made with 42 items from 4 tests. Thus, a small increase in the arithmetic problems score could be associated with large increases in the FT score, producing the observed large B. However, with standardized scores, calculation's β remained sizeable, whereas the arithmetic problems one decreased notoriously (.18 and .09 respectively). This might suggest that calculation is more related to functional thinking than arithmetic problem solving. However, this is uncertain considering the differences in their measurement. Future studies should include convergent measures of arithmetic problem solving in order to make a fair measurement of this aspect and assess its relationship with functional thinking more accurately.

Limitations and further studies

The sample for this study was selected purposfully, and comes from a very particular population. It would be useful to conduct other studies with samples from different populations to observe similarities or differences in functional reasoning. Also, measurement limitations for symbolic representation and problem solving indicate cautios interpretations of the results related to these aspects. The cross-sectional design does not allow for developmental inferences. It is highly desirable to collect longitudinal data for studying the development of functional reasoning. This study is part of a larger project aimed to identify the cognitive underpinnings of functional reasoning. In future, studies will be carried out to confirm the presented findings, and to investigate a wide set of cognitive capacities in addition to arithmetic.

ACKNOWLEDGMENT

This research was generously funded by the Mexican Council of Science and Technology (CONACYT), Grant No. 168620.

Windows on students' algebra: Describing their habits of mind

Deniz Eroğlu and Dilek Tanişli

Anadolu University in Eskişehir, Faculty of Education, Eskişehir, Turkey, denizeroglu@anadolu.edu.tr

This paper illustrates students' algebraic habits of minds through interviews and demonstrates how students have difficulties in algebra. In this study we present data from clinical interviews with sixth grade students, which were analyse using Driscolls' (1999) framework of algebraic habits of mind. All students show different algebraic habits of mind and their difficulties in algebraic concepts constrain their ways of thinking.

Keywords: Algebra, habits of mind.

INTRODUCTION

One major learning goal of mathematics education is to improve students' different ways of thinking. When students spontaneously and are likely to use mathematical ways of thinking, it is reasonable to call them mathematical habits. Several researchers have studied mathematical habits of mind (Lim & Selden, 2009). Mathematical habits of mind are viewed as students' mathematical thinking in the same way mathematicians do (Cuoco, Goldenberg, & Mark; 1996). Mathematical habits of mind are general approaches and there are also content-specific habits such as algebraic habits of mind. Driscoll (1999) provides a theoretical framework for algebraic habits of mind. He considers algebraic habits of mind habituated ways of thinking that help students succeed in learning algebra. Further, Driscoll (1999) concentrates on three algebraic habits of mind: (1) doing-undoing, (2) building rules to represent functions, and (3) abstracting from computation. These critical habits of mind help students to use and apply what they know and have learned when they encounter any problem they haven not specifically learned. Students who have not developed different habituated ways of thinking struggle particularly with algebra and mathematics in general. This research, being in the initial stage of an ongoing longitudinal study is designed to bring students in algebraic habits of mind in over two years. The purpose of the study is to investigate sixth grade ele-

Table 1: Each student's algebraic habits of mind

mentary students' acquired algebraic habits of mind after completing their first year of algebra domain. Initial interview results will help us to plan the next steps of this research to support students' algebraic habits of mind.

METHODOLOGY

Participants of this study were four sixth grade middle school students. Data were collected through clinical interviews at the end of the sixth grade. Students were given problems to solve and, after solving each problem, they were asked for detailed descriptions, and to apply different ways to solve problem. The four interviews were fully transcribed and students' responses were put into one of the Driscoll's algebraic habits of mind indicators and categories.

RESULTS AND DISCUSSION

The results indicate that all students exhibited some algebraic habits of minds at the end of the sixth grade (Table 1). However, students' difficulties in conceptualizing algebraic concepts appeared to constrain their ways of thinking.

As shown in Table 1, the indicators of algebraic habits of mind vary across individual students. In the interviews, all students described change in a process and recognized equivalence between expressions. In addition, none of the students described the steps of a rule without using inputs, and justified why a rule works for any number. Thus, students did not seem to exhibit various and different thinking ways. This has implications for teachers and for us. Teachers should benefit from students' thinking in designing their mathematics courses, and use interviews as a tool to further investigate their students' thinking. As a next step, we will further design our mathematics course primarily to gain students how to describe the steps of the rules without using specific input and how to justify why a rule works for any number. Additionally, we will overcome students' difficulties about algebraic concepts and support all indicators of students' algebraic habits of mind.

Middle grade teachers' thinking of algebraic reasoning in relation to their classrooms

David Glassmeyer and Belinda Edwards

Kennesaw State University, Kennesaw, USA, dglassme@kennesaw.edu

The purpose of this study was to investigate United States mathematics teachers' thinking about algebraic reasoning within the context of their middle school classrooms. After collecting document and observation data from 19 teachers in a two-week summer professional development workshop, we analysed how teachers defined algebraic reasoning in their classroom and their description of algebraic reasoning tasks for their students. Our findings detail the ways teachers initially described algebraic reasoning in the context of their classroom and the changes in thinking teachers reported during and after the workshop.

Keywords: Algebraic reasoning, professional development, teacher thinking.

AIMS AND RESEARCH QUESTION

Algebraic reasoning is an essential habit of mind for building conceptual knowledge in K-12 mathematics (Kaput, 2008), yet little is known about how K-12 mathematics teachers think about algebraic reasoning in the context of their classroom (Blanton & Kaput, 2005; Ellis, 2011). In this project, we aimed to address this research need by examining how algebraic reasoning was considered by middle school in-service mathematics teachers who taught grades 6, 7, or 8 in the United States. Our research question was: how do teachers develop their understanding of algebraic reasoning in the context of their classroom through a two-week professional development session? This question focused our efforts on characterizing how teachers communicated their understanding of algebraic reasoning throughout the professional development and during the following months, after teachers returned to their classrooms. We use Blanton and Kaput's (2005) definition of algebraic reasoning as "a process in which students generalize mathematical ideas from a set of particular instances, establish those generalizations through the discourse of argumentation, and express them in increasingly formal and age-appropriate ways" (p. 413). We use these authors' depiction of algebraic reasoning as a framework for this study.

METHODS

The participants of this study were 19 middle school teachers from the Southern United States engaged in

Code	Reflection 1	Reflections 2–5	Reflection 6

Table 1: Counts of how many teachers (n=19) made statements coded using our coding dictionary before (reflection 1), during (reflections 2–5) and after (reflection 6) the professional development

a two-week professional development session and a follow-up meeting two months later. We conducted observations and collected documents from teachers during and after a two-week professional development session. Data consisted of teachers' daily reflections prompting teachers to reveal their thinking about algebraic reasoning and researcher notes about teacher work on various activities and conversations during the professional development sessions. We used content analysis to analyze teachers' reflections and our observation notes by creating and refining our codes based on existing literature.

FINDINGS

As summarized in Table 1, we found that teachers' initial thinking about algebraic reasoning included procedural tasks with a single solution, solution strategy, or representation. At the end of the two-week professional development, teachers described algebraic reasoning as requiring conceptual knowledge and multiple solutions, solution strategies, or representations. Some teachers also associated aspects of generalization and functional thinking as part of algebraic reasoning. Two months after the professional development, teachers still described algebraic reasoning as tasks requiring conceptual knowledge rather than procedural skills, and included multiple solutions or solutions strategies. Teachers did not continue to associate generalization or functional thinking as part of algebraic reasoning.

These findings may help other teacher educators anticipate teacher thinking when working to develop algebraic reasoning in professional development settings and identifies more work with teachers' algebraic reasoning is needed to support teachers' use of generalization and functional thinking in their classrooms.

Developing the notions of variation and covariation through patterns: An institutional analysis of primary school textbooks

Eudes Libert Mamas Mavoungou and Alejandro S. González-Martín

Université de Montréal, Département de Didactique, Montréal, Canada, eulimas19@yahoo.fr

We examine how pattern-based activities presented in textbooks for primary education allow developing the notions of variation and covariation, using the conceptual tool of institutional relationship of Chevallard (2003). Our sample is formed by the textbooks currently approved by the Quebec Ministry of Education. Ours results reveal a didactic void in the textbooks.

Keywords: Variation and covariation, textbook analysis, institutional relationship.

INTRODUCTION AND RESEARCH PROBLEM

Researchers have identified numerous difficulties faced by students in learning functions. Because elementary school students are able to grasp pre-algebraic concepts, researchers recommend introducing pre-algebra at the primary level to facilitate the subsequent learning of algebra and functions at higher levels. The notions of variation and covariation have been highlighted for their role in fostering a better understanding of functions at the secondary level (Hitt & González-Martín, 2015). In primary education, the notions of variation and covariation can be taught using pictorial growth patterns, which foster two modes of reasoning: figural and numerical. Becker and Rivera (2005) found that prospective elementary school teachers predominantly use numerical reasoning to analyse patterns with their pupils. Because both modes of reasoning should be present in the classroom, and considering the tendency of teachers and students to favour numerical reasoning, we are interested in examining how pattern-based activities are presented in elementary school textbooks and how this reveals the institutional relationship with these notions. Specifically, our research questions are: 1) how are notions related to pictorial growth patterns organised in elementary school textbooks and what type of reasoning do they tend to favour, and, 2) do the textbooks' activities effectively allow students to develop the notions of variation and covariation?

THEORETICAL FRAMEWORK

Our research leans heavily on Chevallard's anthropological theory of the didactic (ATD, 2003). In particular, we employ the notion of *institutional relationship* to study institutional choices concerning the use of the mathematical objects of variation and covariation in textbooks. We also use the notion of praxeology to characterise the institutional relationship with the notions of variation and covariation.

METHODOLOGY

The content analysis applied to textbooks in this study was performed with tools provided by ATD. We analysed the three current elementary school textbooks approved by the Quebec Ministry of Education for the final years of primary school (10- and 11-year-old students), focusing on the following elements: the nature of symbols used (numerical or pictorial), the types of tasks and the praxeologies they define, the goal of these tasks, the independent and dependent variables at play in the task, the regularity from one position to subsequent positions, the mode of reasoning favoured, and the relationships between variables. We paid particular attention to how the textbooks lead students to use the information presented to accomplish tasks and develop an awareness of relationships between two given quantities.

DATA ANALYSIS AND DISCUSSION

We found only 18 cases, in two of the three textbooks, in which a task makes use of patterns: 11 tasks using numerical patterns, six tasks using patterns presented both numerically and pictorially, and one task using pictorial patterns. We identified three different types of tasks: 1) introducing the definition of a pattern, 2) predicting subsequent terms, and, 3) generalising through an expression. Each of these types of task defines a different mathematical organisation: the first attempts to familiarise students with the idea of change or variation, the second aims to teach students the idea of covariation, and the third focuses on dependence relations through a rule. The relationship between variables is not specified in either of the two textbooks and both use the symbol n in formulae without explicitly giving any meaning to it. All 18 tasks can be solved using just two standard techniques, which favour the use of numerical reasoning. Moreover, the technology that could reinforce and give meaning to the notions of variation and covariation is absent, and therefore students are not provided with optimal conditions for developing these notions. The institutional relationship with these notions is characterised by a didactic void, especially with regard to the theoretical block. We are aware that this research has been conducted on a small scale and that further study is necessary to investigate whether children are given better opportunities to develop the notions of variation and covariation in primary school. For this reason, we are planning to examine potential difficulties students may encounter when presented with patterns and other generalisation activities. We also wish to study teachers' practices and professional teacher education in the effective use of patterns.

Creative reasoning more beneficial for cognitively weaker students

Mathias Norqvist[1], Johan Lithner[1], Bert Jonsson[1] and Yvonne Liljekvist[2]

1 Umeå University, Umeå, Sweden, mathias.norqvist@umu.se
2 Karlstad University, Karlstad, Sweden

In a study with 91 upper-secondary students the efficiency of two different types of mathematical practice tasks, procedural based algorithmic tasks and creative reasoning tasks, were studied. It was found that although the algorithmic group outperformed the creative group during practice the latter performed significantly better on a follow-up test. Closer inspection revealed that the difference in test performance was, contrary to common beliefs, driven by the cognitively weaker students.

Keywords: Mathematical reasoning, creative reasoning, cognitive proficiency.

LEARNING BY IMITATIVE AND CREATIVE REASONING

Starting off from research that points to the inefficiency of rote learning, the LICR design research project is studying the efficiency of different kinds of practice tasks. One sort of task where the student is presented with an already complete solution or formula and has to practice this, much like the layout in most textbooks (Algorithmic Reasoning, AR). This is contrasted by a task type that gives no indication on how to solve the specific task, constructed in such a way that it gives the student a chance to, with small creative steps, construct a general solution (Creative Mathematically founded Reasoning, CMR). The tasks are designed based on the mathematical reasoning framework (Lithner, 2008) utilizing a specific adidactical situation (Brousseau, 1997).

METHOD

Our sample consisted of 131 students at the Natural Science program from four Swedish upper secondary schools (16–17 year olds) that after attrition and screening for ceiling effects was reduced to 91 (48 AR and 43 CMR). We used two cognitive tests, Raven's

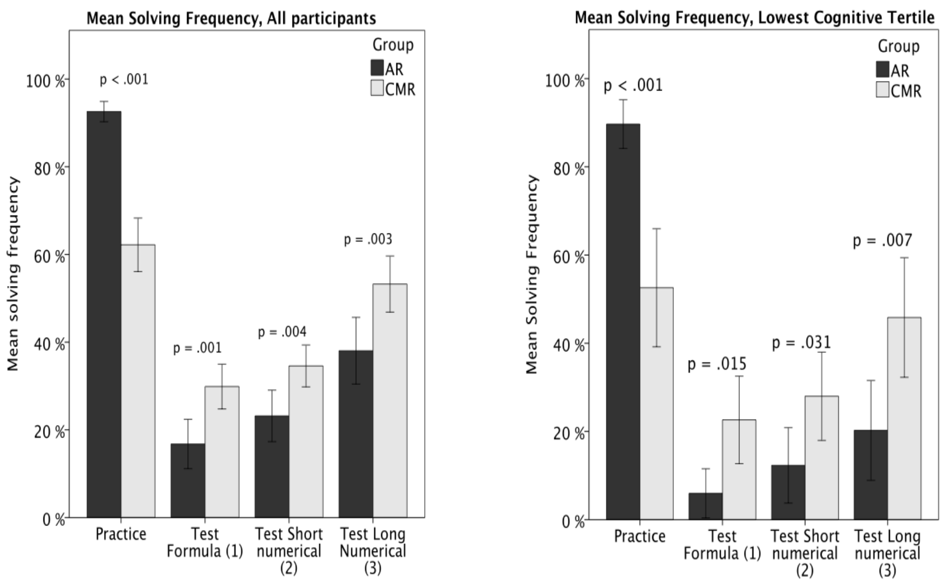

Figure 1: The left diagram shows the mean result for practice and test for all participants while the right shows the mean result for the lowest cognitive tertile (error bars represent two standard error of means)

Progressive Matrices (non-verbal problem solving ability) and Operation Span (working memory capacity), to construct a cognitive composite score. Both of these tests have been proven to be of importance for mathematics achievement (Primi, Ferrão, & Almedia, 2010; Alloway, Gathercole, Kirkwood, & Elliot, 2009). The cognitive composite score, mathematics grade and gender were used to match the participants into two comparable practice groups, AR and CMR.

The two groups got to practice on 14 task sets, each with a specific target knowledge. The CMR-group solved three tasks per task set while the AR-group solved five tasks to compensate for the quicker AR-tasks. The allotted practice time was the same for both groups but there was a slight difference in used practice time, 29 min (SD, 10) for CMR and 21 min (SD, 6) for AR. One week later the two groups took the same test. The test consisted of three tasks per task set. They evaluated: 1) memorized knowledge of a specific formula, 2) if a mathematical principle was memorized, and 3) if the formula or principle could be reconstructed if forgotten.

RESULT

Looking at the test result (Figure 1) the CMR-group significantly outperformed the AR-group, $t(89) = 3.54$, $p = .001$, $d = 0.73$, on all three tasks even though the AR-group performed much better during practice. The analysis also showed that the test performance of the AR-group was highly predicted by their cognitive score. The test performance of the CMR-group was predicted by their practice result and here a teacher can have huge impact. The most interesting result however is that the differences in test results were mainly driven by the cognitively weaker students rather than by the stronger students as might be expected according to common beliefs. Put together, these results would imply that CMR practice is more efficient with regard to remembered knowledge and also more neutral in terms of cognitive prerequisites (Jonsson, Norqvist, Liljekvist, & Lithner, 2014).

Prototypes in secondary and university mathematical education

Derek Pilous and David Janda

Charles University, Faculty of Education, Department of Mathematics and Mathematical Education, Prague, derek.pilous@seznam.cz

The aim of presentation was to demonstrate our extension of previous theoretical framework of prototypes – a term of cognitive psychology – in mathematics education, illustrated by examples of students' outcomes and sets out a research project based on this framework. The study was supported by Charles University in Prague, project GA UK No 227-364.

Keywords: Prototype, function, example, mathematical concept, classification.

THE THEORY OF PROTOTYPES

The theoretical framework of the concept of prototypes lying in cognitive psychology is presented in two ways. First, traditionally, by a description of historical evolution from first research studies carried out by Eleanor Rosch in the 70'th and introduction of prototypes to mathematics education by Rina Hershkowitz and others in the 80'th of the twentieth century. Second, we will demonstrate inherent usage of prototypes in mental representation of mathematical, well-defined concepts through introspection of poster readers.

Schwarz and Hershkowitz (1999) describe prototypes as construct of probabilistic approach to concept learning –"special examples, that are more central to learning than others". Hadjidemetriou and Williams (2010) offer strong example, linearity, ascribing it to schooling. Our goal is to define and identify prototypes of mathematical concepts and also observe long-term development of prototypes. In this poster, we concentrate on two questions:

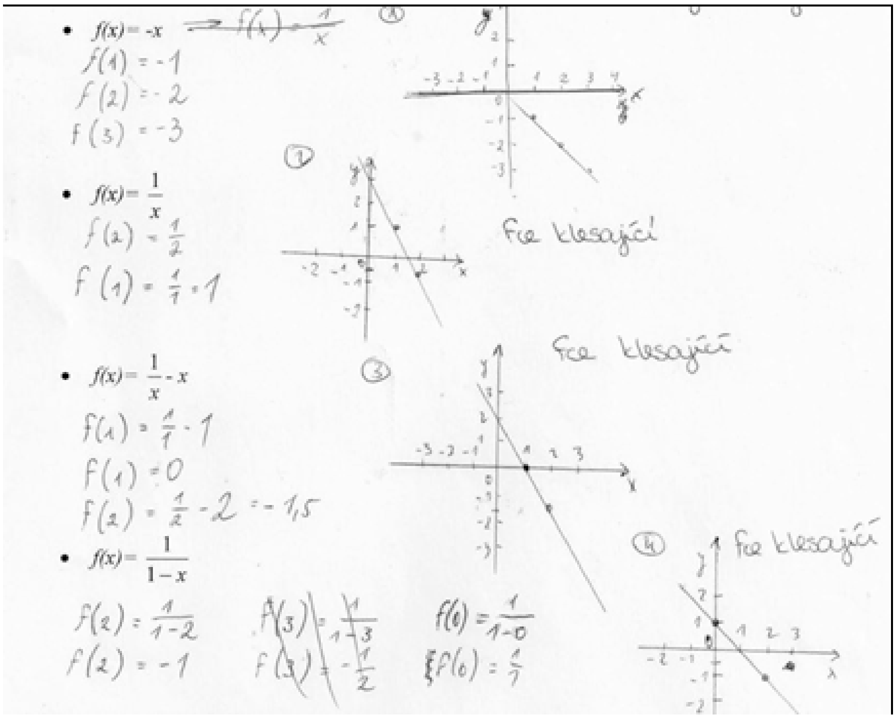

Figure 1: A student's solution

1) How to characterize prototypes of mathematical concepts in a way which will provide criteria for their detection?

2) Which prototypes of common important mathematical concepts like functions and real numbers do students use?

In the theoretical part of poster we pose two conditions for useful definition of prototypes in context of mathematical education and present our working definition: *A prototype is any instance of concept, a set of instances or any property functionally connected to concept, which is statistically preferred by an individual in usage of that concept, if this preference cannot be explained by a mathematical essence of that concept and informational complexity of the would-be prototype.*

Theoretical framework is followed by examples of prototypes from our observations of students' prototypes in ordinary lessons of mathematics and from our research not specifically focused on prototypes (Janda, 2013). One such example is given in Figure 1. A group of 40 secondary school students solved the problem "*How does f(x) change if we replace x by various integers? Describe or represent it.*" for four functions.

As we can see, substituting two or three numbers for x satisfied the student enough to draw supposed graphs of functions. Numbers 1 and 2 were the most often used (hence, we consider small positive integers to be prototypes of real numbers), number 0 was used only once, negative numbers were not used at all (only 14% of the students inserted at least one negative number into any of the rules).

Figure 1 is an example of the tendency to "linearize" graphs of functions which was generally very strong among students; in Figure 1, we can even see that the student omitted the result of the evaluation for $x = 3$ (by crossing out the evaluation itself and the corresponding point in the Cartesian plane) because it did not conform with the linear function passing through points which resulted from previous evaluations.

Generalising from visual spatial patterns

Aisling Twohill

Dublin City University, St. Patrick's College, Dublin, Ireland, aisling.twohill@spd.dcu.ie

In the research project presented, I categorise the strategies employed by four Fourth class girls and four Sixth class girls when asked to construct a general term for a visual spatial pattern. The approach adopted by each girl is categorised as either explicit or recursive, and the mode of generalisation is categorised as either linear or numeric.

Keywords: Visual spatial pattern, generalisation strategies, reasoning.

THEORETICAL BACKGROUND

Generalisation is considered by many to be a highly significant component of algebraic reasoning (Kaput, 2008). Patterning plays a key role in supporting children's developing skills in generalisation, and internationally visual spatial patterning tasks have been utilised in many research projects to investigate children's success in generalising (e.g., Rivera & Becker, 2011).

Lannin (2004) presents two approaches to the construction of generalisations from patterns. An 'explicit' approach involves identifying a rule for the relationship between a term and its position in the pattern, whereas a 'recursive' approach focuses on a relationship between successive terms. Rivera and Becker (2011) discuss the tendency of some children in their research to adopt a 'numerical' rather than 'figural' mode of generalising, which in some cases caused difficulty in the children's own reasoning about the generalisations they had constructed.

Within the algebra strand of the Irish Primary School Mathematics Curriculum (PSMC) it is proposed that children be facilitated in establishing rules for number sequences, but explicit approaches are not mentioned, and examples given all indicate constant differences between terms (Government of Ireland, 1999). Generalisation is not mentioned and visual spatial patterning is not suggested for consideration, beyond repeating patterns of shapes aimed at the youngest children in primary school. In light of this, the research discussed in this paper aims to explore the responses of primary school children in Ireland when asked to construct generalisations from a visual spatial pattern.

METHOD

Individual clinical interviews were used to gather data on children's constructions of generalisations.

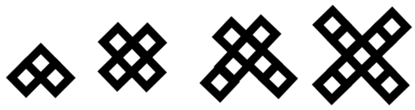

Figure 1: Diamonds pattern

Four girls were randomly selected from each of Fourth class and Sixth class in an Irish primary school. The cohorts from the two classes had mean ages of 10.08 years and 12.19 years respectively. Pseudonyms are used. The girls were asked to describe, extend and construct near and far generalisations from the pattern terms shown in Figure 1. Suggestive questions were asked to support children in making progress in the solution of tasks.

FINDINGS AND DISCUSSION

During the clinical interview, each girl was asked to identify the 100th term in the pattern, as a far generalisation. Each girl's generalisation, or work towards a generalisation, was deemed to be figural or numeric. A response was deemed to be figural if the child referred to the position of the diamonds, by referring to the 'top' or 'bottom' or through gesture and use of the deictic 'there'. Table 1 summarises the mode of generalisation adopted by each girl and whether the approach adopted in working with the pattern was recursive or explicit. An incomplete generalisation

Name	Class Level	Numeric/figural mode of generalisation	Recursive or explicit approach	Validity of generalisation
Natasha	4th	Figural	Explicit	Complete, but flawed numerically
Bella	4th	Figural	Explicit	Complete and valid
Tara	4th	Did not respond	Did not respond	No response
Nikki	4th	Numeric	Recursive and later explicit	Complete and valid
Lisa	6th	Numeric	Recursive and later explicit	Complete and valid
Sarah	6th	Figural	Did not explain her thinking	Complete and valid
Aoife	6th	Numeric	Recursive	Incomplete
Rachel	6th	Numeric	Recursive	Incomplete

Table 1: Classifications of girls' constructions of a far generalisation

refers to an instance when a participant did not construct the 100th term.

Within the PSMC the 6th Class girls may have encountered many number sequences which favour recursive thinking. Lannin (2004) suggests that such immersion may cause difficulty in considering an explicit approach. Additionally, the numeric approach of Aoife and Rachel seemed to inhibit their thinking about the general term, in a manner consistent with the findings of Rivera and Becker (2011).

Teachers' procedures when introducing algebraic expression in two Norwegian grade 8 classrooms

Unni Wathne

University of Agder, Kristiansand, Norway, unni.wathne@uia.no

We investigate similarities and differences in two teachers' way of introducing algebraic expressions by designed examples. One teacher moves from the specific to the general, and the other moves from the general to the specific. They both mediate the passage from the students' real world and the school mathematics they know, to algebra.

Keywords: The introduction of algebra, designed examples, mediating tools.

Two teachers, Kari and Ola, are introducing algebra in two Norwegian grade eight classrooms. Kari holds up a set of large playing cards and writes on the blackboard what is written in the corner of the cards. Ola starts walking in one direction in the classroom, asking the students to describe what he is doing. These are the starting points of two examples that each teacher has designed as a tool for communicating and explaining new algebraic ideas in her/his classroom. Kari makes the students familiar with using letters for numbers with the help of playing cards. Ola makes the students familiar with algebraic expressions and variables with the help of body movement.

The aim of this study is to investigate the introductory lesson when two teachers mediate algebraic concepts through their examples. The purpose of the analysis is to capture how the teachers approach the complexity students meet in such learning situations. More specifically: Which procedures do the teachers' use to introduce the concept of algebraic expressions?

THE THEORETICAL FRAMEWORK

The shift in school mathematics from arithmetic to algebra is known to be challenging for students. The learning of algebra includes new symbols, new concepts and also new ways of thinking. Examples play a central role in the teaching and learning of mathematics as described among others by Rowland (2008).

The concepts of mediation and mediating tool (Wertsch, 1991) have emerged from our empirical material. The theoretical term of mediating tools facilitates our analysis in making a distinction between the goals of the lessons (including the mathematical objects of variables and algebraic expressions) and the tools (designed examples, concretes and semiotic items) that the teachers employ in their interaction with the students.

THE METHOD

In order to accomplish the aims of the study we use a qualitative approach to collect and analyze the empirical data grounded in a sociocultural theoretical perspective of learning. The data has been collected after the VIDEOMAT design (Kilhamn & Röj-Lindberg, 2013); we observed the first five algebra lessons in each classroom (videotaping), interviewed the teachers after the fifth lesson (audiotaping) and collected written material used in the classrooms (teacher and student material). As a first approach to the collected data, lesson graphs for each lesson were elaborated, and the first lesson in all classrooms was transcribed.

The two examples were chosen through a process involving the lesson graphs and several viewings of the video material. They comprise the introductory part of the first lesson in each classroom. The designed examples stood out as unique in the international video material. The examples are also referred to in later lessons by the teachers and therefore play an important role in the introduction of algebra in these two classrooms.

RESEARCH RESULTS

There are similarities and differences in these teachers' way of introducing algebra. The two teachers both design introductory examples which are used as their central means for explaining the same concepts (variable and algebraic expression). The examples are easily distinguishable in their use of concrete materials, cards versus the body. However, there are more fundamental differences in the examples' structures.

Kari starts with numbers, number operations, and arithmetic expressions, and she makes generalizations introducing algebraic expressions. She continually connects the arithmetic and the algebraic elements, and sees variables as numbers. Kari moves from the specific to the general in her approach to introduce algebraic expressions.

Ola, on the other hand, establishes an algebraic expression directly from the imaginary number line with given direction and units (first step, then foot) without using numbers. He builds the algebraic expression through a transformation chain following this path: bodily movement – words – abbreviations – variables, and sees variables as quantities, numbers included. Ola moves from the general to the specific in his approach to introduce algebraic expressions.

The aim of this study has not been to propose how algebra should be introduced in the classroom. The analysis illuminates the complexity students meet when facing introductory algebra in school, and the challenge it is for teachers to make algebra accessible for all students. The main procedure of the teachers in this study has been to use examples designed by themselves, mediating the passage from the students' real world and the school mathematics they know to algebra.

INTRODUCTION

TWG04 on geometrical thinking had more than 22 participants from 10 countries. During the sessions, the participants discussed thirteen papers and three posters (one paper and two posters were submitted but not discussed in the working group).

TWG04 about geometrical thinking has been working on this topic for many CERME sessions, and mostly studied what geometrical thinking would mean. It is concerned with research and development of geometrical thinking from pre-school up to University teaching and learning, including any type of geometry. In line with the previous sessions, CERME8 tried to identify four competencies that helped describe geometrical thinking: reasoning, figural, operational and visual (Maschietto et al., 2013). The discussion paper focused on educational aspects related to the development of these geometrical competencies for students, the difficulties of learning and the design of curricula and their implementation. These four poles were very helpful to use a common language and shared reference concepts. They also allowed to show how the many faces of geometrical activity are intertwined, which made necessary a clarification of what was meant by these poles.

In this working group at CERME 9, there were more specific contributions about the way geometry is, or should be, taught: for instance, in-class observations, pre-service teachers education, going from everyday concepts to geometrical knowledge, specific issues in geometry. As a consequence, the four competencies were used as a general way of describing the geometrical activity and for creating links between different points of view. For instance, line symmetry was studied either in a didactical engineering perspective or to characterize ordinary classrooms practices. Then, the papers and posters contributed to study what is at stake in the teaching and learning processes.

During the discussions, the work was structured by four specific themes, specifically studied in the contributions:

- Initial geometrical knowledge
- Visualization
- Transformations and 3D
- Actions on objects (material and mental)

We will emphasize here how the papers about these four themes deal with the following questions, and more specifically:

- Who is the research about?
  - Pupils
  - Teachers
  - Teachers educators
- What are the aims of the research?

  - In the description of existing teaching and learning phenomena
  - In the design of new tasks
- How do we study this?
  - Theoretical tools
  - Methodology
- What are the interactions with the other themes? This question also concerned the role of language and social interactions that appeared as a common issue to several papers.

THE ROLE OF INITIAL GEOMETRICAL KNOWLEDGE

We chose to use this notion, instead of pre-concepts, to emphasize a general issue in geometry: going to everyday concepts to geometrical ones does not only concern early ages geometry. The participants showed that "intuitive notions" are very important for the construction of geometrical knowledge. This is true for many topics as rotation (Swoboda), line symmetry (Chesnais & Mathé), polygons (Ulusoy), polyhedra (Mithalal-Le Doze & Papadaki) and at every age from the beginning of the primary school (Rodrigues & Serrazina) to prospective teachers' education (Brunheria & da Ponte, Kuzniak & Nechache).

This idea of initial geometrical knowledge is linked to the idea of "geometrization", seen as a dynamical and continuous process that turns it into an institutionalized geometrical knowledge, with the development of geometrical competencies. This process is a fundamental part of geometrical thinking, like the more scientific knowledge it helps building. We could see that this process involves at the same time pupils, teachers, teacher educators, and researchers.

It is necessary for teachers to be aware of how pupils' personal previous experience may influence their learning geometry, in order to design efficient teaching sequences (Loureiro & Serrazina, Herendiné-Kónya). Therefore, they need theoretical tools, especially pedagogical and didactical knowledge, to adapt the in-class experience to the pupils and the topics.

Many frameworks were evoked - and had been mentioned in the previous CERME works. Some of those frameworks are very specific to geometry, as Van Hiele levels (Papadaki), Geometrical Working Spaces (Kuzniak & Nechache), concept image and concept definition (Rodrigues & Serrazina, Ulusoy), figural concept (Ulusoy), visualization (Papadaki, Mithalal-Le Doze). Other frameworks are more general in mathematics education, as Theory of Didactical Situation (Douaire & Emprin) or from psychologists (mainly Battista or Gagatsis' works exploited by Loureiro and Serrazina). The papers have shown that in this case, it is possible to design tasks involving outdoor activities, real-life experiences, with high didactical potential (Douaire & Emprin).

ACTION ON OBJECTS

The first point concerns the role of action on objects, both mental ones and material ones. A paradoxical situation was raised, as it is at the same time very natural to pupils, and quite difficult for the teachers to develop their geometrical competencies from it and not to use it only with young pupils to increase their engagement.

"Action on objects" is quite confusing, and we decided to reduce its meaning to action performed by hand on material or tangible objects -- which includes the use of instruments (like transparent paper by Chesnais and Mathé, or Uygan et al.) or Dynamic Geometry Software (Mithalal-Le Doze). We studied the many functions of action (Pytlak): it helps the pupils to develop intuition, concept image and definition, geometrical imagination, and at the same time it makes children's knowledge more visible to the teachers.

This function strongly depends on specific conditions, and for many of us it was essential that manipulation came first, to create a need for anticipation, validation or control that may justify geometrical knowledge. This articulation is organized by the tasks themselves, the backing of the teacher and the social interactions.

TRANSFORMATION AND 3D GEOMETRY

These two topics were developed in many papers, which gave good examples of how complex the relations between action, visualization and geometrical knowledge, are.

The learning of geometrical transformations (rotation by Swoboda, line symmetry by Chesnais & Mathé, or isometrics by Thaqi et al. and Uygan et al.) depends on linking multiple contexts and representations. It also requires articulating a global and a punctual point of view and going from perception to geometrical properties.

The same questions were discussed for 3D geometry, and we showed that the greatest issues were not only "sight" issues. Indeed, a psychological point of view shows the role of getting better "images" to act on (physically or mentally), but many of the previously mentioned mathematical aspects are part of the visualization process. For instance, Dynamic Geometry Software, and more generally geometrical tools, were seen as ways of making geometrical knowledge useful for a better control of the actions and visualization. This knowledge was at the heart of the visualization process when using only the sense of touch: linking the subparts that were perceived by touch is a mathematical process linked to what Duval calls deconstructions (see Mithalal-Le Doze, Papadaki). At the end, we showed that visualization depends on perceptual, psychological, but also – and this is fundamental – on mathematical aspects.

VISUALIZATION

Eventually, we had to clarify what we called visualization. It was involved in studies of mental abilities (especially for initial geometrical knowledge and action on objects), classification (how do we discriminate the information while seeing), and analysis of drawings in a deductive geometry context (Brunheria & da Ponte, Herendiné-Kónya). We underlined that, in this case, visualizing aims at being able to solve geometry problems, so that it both depends on very particular cognitive processes and mathematical knowledge. Therefore, a great difficulty is the gap between visualization by teachers, based on categories and geometrical properties, and by pupils, often based on prototypes. The main theoretical tools used were Laborde's work about drawings and figures (Mithalal-Le Doze), and Duval's distinction between iconic and non-iconic visualization (see Mithalal-Le Doze).

CONCLUSION

The discussions in TWG04 confronted very different points of view on geometry teaching and learning, with complementary issues (e.g., teaching practices studies vs. task design), very different cultural and educational contexts that change the role of geometry in the curricula and the way it is presented. It also appeared that these contexts had an influence on our researcher positioning, which not only concerns geometry: Does it mean our research practice or the teachers' education practice that most of us share? What can we learn from research on everyday practices? How is it possible to better combine our teacher, teacher educators, and researcher positions?

Eventually, let us mention the new issue of the role of language and social interactions in the teaching and learning geometry processes. This has been little discussed during the previous sessions, but it appeared that this could play a great role in each of the topics mentioned above and that some of the phenomena are very specific to geometry.

Prospective teachers' development of geometric reasoning through an exploratory approach

Lina Brunheira[1] and João Pedro da Ponte[2]

1 Escola Superior de Educação do Instituto Politécnico de Lisboa, Lisboa, Portugal, lbrunheira@eselx.ipl.pt

2 Universidade de Lisboa, Instituto de Educação, Lisboa, Portugal

We aim to characterize how prospective teachers perform in defining and classifying quadrilaterals through working on exploratory tasks. Data was gathered from the participants' reports and portfolios. Results show most understood the meaning of defining and presented correct definitions, using properties they previously ignored, and showing comprehension of the underlying concepts. They produced economical definitions in few cases, and performed better in inductive than deductive reasoning. The classifications showed conflicts between prior classifications and structural criteria that rules a geometrical classification. The exploratory work allowed participants to construct their knowledge in a meaningful way and reflection played an important role in becoming aware of personal preconceptions and knowledge.

Keywords: Teacher education, geometry, geometric reasoning, exploratory approach.

INTRODUCTION

This paper addresses prospective elementary teachers' preparation in geometry. Recent studies in Portugal show less than satisfactory results concerning the geometric knowledge they present before and after attending their teacher education programs (Menezes, Serrazina, & Fonseca, 2014; Tempera, 2010). A similar conclusion is also found in studies from other countries, concerning teachers and prospective teachers, indicating that geometry is an area in which they perform poorly, have little self-confidence, and show weak geometric vocabulary (Clements & Sarama, 2011; Fujita & Jones, 2006; Jones, Mooney, & Harries, 2002). In addition, there are very different views about what geometry can or should be taught in teacher preparation courses, which is problematic as the success of the teachers' work depends, to a great extent, on their deep understanding of geometry. And, we must also remember that knowing geometry does not ensure effectiveness, how teachers come to know it matters as well (Jones, Mooney, & Harries, 2002).

This scenario challenges us to improve teacher's curriculum and preparation in this area and investigate its outcomes. The work we report in this paper fits into a wider study with that goal. We developed a design research experiment in the context of a curricular unit of geometry based on exploratory work, linking geometry and didactics and valuing prospective teachers' reflection on their learning. We seek to characterize how prospective teachers perform in processes which are components of geometric reasoning, focusing on defining, but also looking at classifying.

CONCEPTUAL FRAMEWORK

Prospective elementary teacher education in geometry

For the National Council of Teachers of Mathematics [NCTM] the knowledge necessary for teaching includes

> the content and discourse of mathematics, including mathematical concepts and procedures and the connections among them; multiple representations of mathematical concepts and procedures; ways to reason mathematically, solve problems, and communicate mathematics effectively at different levels of formality. (1991, p. 132)

This perspective is coherent with the idea advocated by Ma (1999) that teachers need a profound understanding of fundamental mathematics. But what does this mean in geometry? The NCTM (1991) states that all teachers should understand how geometry is used to describe the world we leave in and how it is used to solve concrete problems; analyze a diverse set of two and three dimensional figures; use synthetic geometry, coordinates and transformations; improve their skills in producing arguments, justifications and privilege spatial visualization. In 2000, the Conference Board for the Mathematical Sciences (CBMS) proposed that prospective K-5 teachers must develop competence in the following areas: Visualization skills (projections, cross-sections, decompositions; representing 3D objects in 2D and constructing 3D objects from 2D representations); basic shapes, their properties, and relationships among them (angles, transformations, congruence and similarity); and communicating geometric ideas (learning technical vocabulary and understanding the role of mathematical definition). The recent report of CBMS (2012) updates the main ideas for teaching preparation in geometry, presenting less topics and less complex competencies:

— Understanding geometric concepts of angle, parallel, and perpendicular, and using them in describing and defining shapes; describing and reasoning about spatial locations (including the coordinate plane).

— Classifying shapes into categories and reasoning to explain relationships among the categories.

— Reason about proportional relationships in scaling shapes up and down. (p. 30)

This shift confirms the lack of agreement about the geometric knowledge teachers should hold. In addition, the education of teachers concern also the ways they are taught. Regarding the results of several studies about prospective teachers' knowledge of mathematics, Watson and Mason (2007) propose that courses should prompt participants to engage in mathematical thinking through working on suitable mathematics tasks, develop their understanding about the features and power of those tasks, reflect on the experience of doing mathematics tasks individually or with others, challenge approaches dominated by procedures which depend on rote memorization and observe and listen to learners. These orientations are also consistent with ideas underlined by other investigators: in teacher education, the prospective teachers should learn using the same methods that are recommended they should use in the future (Ponte & Chapman, 2008); connecting subject matter knowledge and pedagogy is a promising strategy to develop both kinds of knowledge and their integration, which is critical to teach well (Ball, 2000). The work we conducted follows these proposals, as we focus on prospective teachers' learning as they work on exploratory tasks and reflect on their own learning. Exploratory tasks demand students to engage actively in the construction of their knowledge by solving situations where there is no clear solution or method. Sometimes, they are also challenged to ask questions or extend the purpose of the task. Students need to interpret the given information, develop strategies, represent and communicate their solutions. This promotes the understanding of representations, concepts, and procedures, and also develops the ability to argue about ideas, as they communicate such ideas to others. Work on exploratory tasks develops usually in three phases (Ponte, 2005): (i) presenting and interpreting the task; (ii) carrying out the task individually, in pairs, or in small groups; and (iii) presenting and discussing results and final synthesis.

Geometric reasoning

The study of geometry is the natural context to develop and use visualization, special reasoning and geometric modeling to solve problems (NCTM, 2000). Despite the growing focus on geometric reasoning and visualization in research, clarification of their meanings is still missing (Gutiérrez, 1996). This is even more complicated by the many expressions used with similar meanings (geometric reasoning, visual reasoning, visualization, spatial thinking...). For example, for Battista (2007) "geometric reasoning consists, first and foremost, of the invention and use of formal conceptual systems to investigate shape and space" (p. 843), a definition we may find too broad. Also, the van Hiele's model describes how students' geometric reasoning develops and includes five levels: 1) visual-holistic reasoning; 2) descriptive-analytic reasoning; 3) relational-inferential reasoning; 4) formal deductive proof; and 5) rigor (Battista, 2009). These levels cover different forms of reasoning. So the need to investigate the development of geometric reasoning drove us to ask what is specific of this kind of reasoning and what main features does it have. A possible approach to study geometric reasoning consists in analyzing it from its processes, which are present in other areas but have some specificity in geometry. In this paper we will focus on the processes of defining and classifying.

Defining is a crucial activity in mathematics. For de Villiers, Govender and Patterson (2009), it is so import as solving problems, conjecturing or proving and, despite that, is much neglected in mathematics teaching. Their work with students in grades 9 to 12 suggests that producing definitions improves students' understanding of geometric definitions and concepts. Zazkis and Leikin (2008) emphasize that, for teachers to be able to support students in this process, they need to be competent in performing it. In a study involving prospective teachers, the construction and analysis of definitions for square showed their ability to distinguish necessary and sufficient conditions, use adequate language and show conceptions about defining.

The process of defining implies also classifying because of their mutual relationship:

> The classifications of any set of concepts implicitly or explicitly involves defining the concepts involved, whereas defining concepts in a certain way automatically evolves their classification. (de Villiers et al., 2009, p. 191)

In the perspective of Mariotti and Fischbein (1997), the process of defining must also be considered as a component of geometric reasoning. For those investigators,

> a classification task consists of stating an equivalence among similar but figurally different objects, towards a generalization. That means overcoming the particular case and consider this particular case as an instance of a general class. In other terms, the process of classification consists of identifying pertinent common properties, which determine a category. (pp. 243–244)

In a study with grade 6 students, those investigators found that classifications often resort to structural criteria which are not immediately clear and very often conflict with perceptual criteria we are used to refer in spontaneous classifications. Hence, achieving correct definitions makes students to question their prototypes which frequently introduces properties perceptually relevant that do not conform to the general requirements of the definition.

METHODOLOGY

This paper addresses an investigation with an intervention, in order to change practices and enhance teachers' preparation in geometry. The research focus is on learning in context, starting from the conception of strategies and teaching tools, following a design-based research as methodology, in the form of a prospective teacher experiment (Cobb, Confrey, diSessa, Lehrer, & Schauble, 2003) in which the teacher also plays the role of researcher. We expect to run trough cycles of creation and revision, trying to deal with the problems that we will find along the way. At the present time, a first cycle was conducted involving 60 prospective teachers. The participants are in the second year of their teacher education program and attend a curricular unit of geometry taught by the first author of this paper. The study of quadrilaterals was developed in five lessons, following three sequential steps suggested by de Villiers and colleagues (2009): (i) to investigate the properties of quadrilaterals using the dynamic geometry environment (DGE) Geogebra; (ii) to classify them; and (iii) to define quadrilaterals. In the first step, they solved the clown task (Battista, 2007) adapted for Geogebra, where one has to manipulate quadrilaterals to overlap others, forcing them to use the relations among them (e.g., a rectangle may overlap a square but not the opposite). Afterwards, the participants registered all the properties that they found in each quadrilateral. In the second step, they classified the figures using a flowchart and a Venn diagram with the purpose of realizing that different criteria lead to different organizations. In addition, the participants also worked on a definition task.

Data gathered includes the participants' records of tasks solved in the classroom, an assessment task and reflections concerning quadrilaterals collected from portfolios. We also present the results of two multiple choice questions about quadrilaterals addressed in an initial individual diagnostic test. In the first question the participants identified relations among quadrilaterals, and in the second one they had to decide on possible definitions for square. The data was analyzed through several processes. Regarding the process of defining we adopted the categorization of de Villiers' and colleagues (2009): economical definitions, correct definitions and incorrect definitions. In this last case we considered definitions containing necessary properties but insufficient to define the intended set; in this category are also the definitions presenting properties that do not apply to some or all objects. Correct definitions present properties necessary and sufficient; if those properties are minimal, the definition is economical. In respect to the processes of classifying, the categorization emerged from the data, and we refer the comprehension of inclusive classification of quadrilaterals and the use of logical reasoning and communication skills.

RESULTS

In the first lesson, 57 prospective teachers solved the diagnostic test. The results show that only 25% considered that all squares are rectangles (but not the opposite) and 39% considered incorrectly that all quadrilaterals with two pairs of congruent sides are rectangles. Confronted with four possible definitions for square, 86% chose correctly "Polygon with four congruent sides and four congruent angles", but 75% also pointed "Polygon with four congruent sides". Only 23% considered valid "Quadrilateral with congruent and perpendicular diagonals". These results are not significantly different for participants that studied and did not studied mathematics in high school. They show that most of the participants ignored the relations between quadrilaterals and did not notice properties related to diagonals or lines of symmetry. In addition they were very connected to rigid prototypes and reasoned about figures by comparison to those prototypes, which is associated to van Hiele's level 1. Also they seemed to accept that a correct description of the quadrilateral may function as a definition.

The first two tasks of the sequence confronted the participants with their previous conceptions and made them realize there are relations among figures they did not know or expect and helped them to understand these relations:

> When I began to solve this task, I thought I would only recall some ideas about quadrilaterals. However, trough out the activity not only I recall them but also I was able to fit in to my head the hierarchy between some quadrilaterals. (Reflection written in the participant's portfolio about the classification task)

In the definition task, the participants worked in small groups, registered their answers which were discussed collectively at the end of the lesson. They were asked to: 1) Identify all the rectangles' properties; 2) Propose two different definitions for rectangle; 3) Propose two different definitions for parallelogram.

In respect to 1), most of the groups identified correctly all the main properties of rectangles (using sides, angles, diagonals and symmetry). Questions 2) and 3) show that they understood that there is no need to present all properties of an object to define it and most produced correct definitions, which is associated to van Hiele's level 2 (Battista, 2009). The next response is an example of a correct definition for rectangle, in which one of the properties is valid but unnecessary:

> Group A: Rectangles' properties: 4 right angles; 2 by 2 parallel sides; 2 lines of symmetry; bisected diagonals; congruent diagonals.
>
> Definition: quadrilateral with 4 right angles and 2 lines of symmetry.

Although less frequent, some definitions were incorrect:

> Group A: Parallelogram: quadrilateral without lines of symmetry.
>
> Group B: A parallelogram is a figure composed by 2 paires of congruent and parallel sides, forming 2 acute angles (opposite) and another 2 obtuse (opposite).
>
> Group E: Rectangle: The diagonals intercept in the center but are not perpendicular;
>
> 2 symmetry lines (1 horizontal, 1 vertical) passing in the center of the figure.
>
> Group F: Rectangle: Geometric figure with 4 sides where the length should be bigger than the height.
>
> Parallelogram: Geometric figure similar to rectangle, where the shorter lines are oblique.

The definitions for parallelogram proposed by groups A and B exclude all rhombuses in the first case and all the rectangles in the second, so their definitions are not inclusive. Similarly, the first definition presented by group E excludes squares. These examples show some difficulty to abandon previous conceptions and recognize the hierarchical organization of quadrilaterals. Still in group E, the second definition is incorrect because it does not exclude some rhombuses. Yet, the more striking feature of this definition is that it is dependent of the position that rectangles are usually presented. Group F's response is the only one that considers as properties the relations between the dimension of the sides and its position. Although incorrect, these definitions were presented collectively, which led into an important discussion. Some students argued about their validity giving counter-examples or correcting the statements and others noticed and reflected on their own misunderstandings.

Finally, some examples of economical definitions demonstrate an interesting analysis, where students used less usual properties they discovered with Geogebra:

Group C: Rectangle: Quadrilateral with two congruent and bisecting diagonals.

Figure 1

Parallelogram: Each diagonal divides it into congruent triangles.

Group D: Rectangle: Quadrilateral with 2 lines of symmetry passing through the middle points of opposite sides.

In the first definition of group C, the prospective teachers draw a quadrilateral where the diagonals do not bisect so they justify the need to include this property. The second, although roughly written, is very interesting because the word "each" makes a difference (one diagonal would not be enough because of kites). Group D presents a definition focused on the lines of symmetry, but stating their position which is necessary (all rhombuses have also two lines of symmetry in a different location).

Overall, we found four types of problems. Producing economical definitions was the most common difficulty and the hardest to overcome, especially because the participants did not know how to be sure that the properties were sufficient to identify each quadrilateral. A second problem that came up some times was the production of non-inclusive definitions. Even for participants that seemed to understand previously the hierarchical relation between quadrilaterals, sometimes they stopped to consider it, showing difficulties to let go previous conceptions. All these cases correspond to van Hiele's level 2, according do Battista (2009). The third problem, happened in very few cases and corresponds to definitions linked to certain positions or relations between parts of the quadrilaterals, clearly associated to frequent prototypes (corresponding to van Hiele's level 1). Despite their low frequency, these cases must keep us aware of how striking the systematic exposure to rigid prototypes may be (Yu, Barret, & Presmeg, 2009). Finally, there was only one definition containing an insufficient property to define the quadrilateral.

The previous examples demonstrate some difficulties, but also some interesting successes if we remember that it was the first time that these participants defined something. To formulate definitions implies to investigate invariants. We must identify the common properties to all the elements we include in that class, mobilizing inductive reasoning and visual abilities, in particular visual discrimination and perceptual constancy (Gutierrez, 1996). So, given the fact that most of the definitions were correct, we consider that as a positive indicator regarding those abilities and inductive reasoning. The few participants that produced economical definitions moved to van Hiele's level 3 (Battista, 2009) and showed a significant improvement. Given the fact that formulating economical definitions involves also deductive reasoning, it appears the participants showed more difficulty in it.

The production of definitions was a good opportunity for the participants to learn about the quadrilaterals and to revise their conceptions about the process of defining, as this reflection shows:

> This task raised some doubts because, before we done it, I thought I knew the definitions of each figure, I thought there existed only one for each figure . . . I came across basic definitions about square or rectangle completely different from what I learned until then. To define figures I never had use angles, diagonals or even lines of symmetry; indeed, I was unaware of their major role. (Reflection written in the participant's portfolio)

Regarding the process of classifying, the work we have developed prompted most of the participants to consider quadrilaterals as classes of figures. However, this evolution does not happen all at once. It is possible that an individual recognize some relations and others do not. The following response regards a question in the final test, where the participants were asked to comment on two sentences: *All kites are squares*; *there are trapeziums with perpendicular diagonals*.

> The first sentence is wrong. Kites are not squares. The squares can be kites because they have two equal consecutive sides.
>
> The second sentence is wrong. A quadrilateral with perpendicular diagonals is a rhombus, which doesn't belong to trapezium's family.

These answers show several difficulties we also identified in other cases. In the first place, this participant recognized that a square is a kite, but did not recognize that a rhombus is a trapezium, supporting the conclusion that learning to classify is progressive and is not independent of the objects it regards. Second, it shows a logical problem: for the second sentence to be true, it is not necessary that all the trapeziums have perpendicular diagonals, so one counterexample does not deny that statement. Third, a problem of rigor in communicating: instead of "Kites are not squares", one should say "Some kites are not squares" and also the word "pairs" is missing from the kite's description. Communicating using the precise words has a fundamental role in the processes we are dealing with. A prospective teacher asked once during a lesson: "If a parallelogram is a trapezium, why do they have different names?", a question that shows difficulties in interpretation.

CONCLUSION

In the beginning of the experience, the prospective teachers showed weak knowledge about quadrilaterals and their relations. However, the work on the sequence of tasks (investigating quadrilaterals' properties, classifying and defining) seems to have promoted their reasoning and the reconstruction of their knowledge. In the definition task, most of the participants understood the meaning of the process itself and presented mostly correct definitions using properties that they previously ignored, showing the comprehension of the underlying concepts, which supports de Villiers and colleagues's conjecture (2009). However, the participants produced economical definitions in few cases, suggesting that they perform better in inductive rather than deductive reasoning. Classifications (associated or not with definitions) showed, in some cases, a conflict between prior classifications, based on perception, and structural criteria that rules geometrical classifications, which is fundamental to the learning process (also a result indicated by Mariotti and Fischbein, 1997). The process of classifying also mobilized logical reasoning and communication, which presented difficulties for some participants. However, the nature of the work developed in classes favored discussion and negotiation of meanings, which is essential to overcome those difficulties (de Villiers, 1994). This idea lead us to conclude that the exploratory work in which the participants engaged, using a DGE, allowed them to investigate and discuss their findings and construct their knowledge in a meaningful way. As the testimony of a prospective teacher shows, reflection may play an important role in becoming aware of personal preconceptions and knowledge, which is an essential part of teacher education (Ponte & Chapman, 2008).

Articulation between students' and teacher's activity during sessions about line symmetry

The research presented here builds on an experimental work ran at the end of primary school (9–10 y. o. children) about line symmetry. We intend on questioning the factors that drive the evolution of geometrical activity of students and analyze in that purpose the articulation between student's and teacher's activity. We try to highlight the fact that learning in geometry relies on both an adaptation process when confronted to a task (individual and adaptationist dimension) and a collective and social construction mediated by interactions between teacher and students and between students.

Keywords: Line symmetry, adaptation, social construction, language.

This paper focuses on the teaching and learning of line symmetry at the end of primary school (9–10 year old children). The corpus that we study was collected during 5th grade classroom sessions where situations were used that had been created by a group mixing teachers from primary and secondary school and a researcher (one of the authors of this paper). The group had elaborated situations trying to take into account difficulties related to the transition from primary to secondary school and then implemented them in the classes of the teachers belonging to the group (Chesnais & Munier, 2013). Some videos of these classroom sessions are used here as a corpus for a research which intends on questioning the articulation between students' and teacher's geometrical activities. This research coordinates two different ways to understand the learning and teaching of geometry. The first one tries to describe the geometrical activity of students interacting with a given task, in all its complexity. It studies the factors that drive the evolutions of this activity in a movement for learning (Mathé, 2012; Bulf, Mathé, & Mithalal, 2011; Barrier, Hache, & Mathé, 2013). The other one, following up with previous work about everyday teaching practices and line symmetry, (Chesnais, 2009; Chesnais & Mathé, 2013; Chesnais & Munier, 2013), tries to investigate more precisely how teaching practices influence students' activity and hence students' learning, and also to get a better understanding of what drives teaching practices.

We take as a premise that learning in geometry relies on both an adaptation process when confronted to a task (individual and adaptationist dimension) and a collective and social construction mediated by interactions between teacher and students and between students. Our goal is here to highlight the complementarity of two approaches to get a better understanding of how the two processes articulate. After clarifying the elements of knowledge at stake in the learning of the concept of line symmetry, we will present the task and the methodology we used to analyze the productions of a pair of students and the teacher's activity during two sessions. We finally present on the results of this analysis and conclude.

ABOUT LINE SYMMETRY

What is mainly aimed at in 5th grade in France about line symmetry is that pupils understand an "instrumental definition" of symmetrical figures: two figures are symmetrical to each other with respect to a line if they are superimposable by folding along this line. They are also supposed to be able to find lines of symmetry on simple figures and to know some properties such as the fact that the mirror image is flipped over compared to the initial figure, the two figures are equidistant (in a global way) from the line and have same shape and dimensions.

At this stage, symmetry is mainly handled as a transformation acting on surfaces (2D-elements), and considered as restriction to the plane of a rotation of 180° around an axis included in the plane. Properties are then considered in a global manner and closely related to perception. However, working on symmetry might imply back-and-forth movements from relations between surfaces (and a line) and relations between 2D, 1D or 0D elements of the figures. For example, the dimension conservation property can either be perceived globally or focusing on the length of segment lines. In a similar way, equidistance to the line may be understood in terms of surfaces or elements of surfaces or event points. In fact, the idea of distance from a figure to a line is difficult at this level. It may refer either to the distance between the figure and the line perceived globally (Grenier, 1988), the distance between elements of the figure and the line perceived globally, the fact that the midpoint of a segment joining a point to its image belongs to the line, the distance from points to the line, seen as the length of the segment joining the point and its orthogonal projection on the line or its projection in a given direction.

About instruments, students at this level essentially use folding or tracing paper to control the symmetry of figures or to construct mirror images, mainly working on surfaces. Students might sometimes also use a ruler – as in the corpus presented below – which implies another way of considering figures (which is also the one that is at stake when working on grid paper): working with 1D-objects (segment lines, sides of surfaces). Switching from one way to the other makes it necessary to coordinate a view of figures as surfaces on one hand and as a network of segment lines on the other hand (what Duval (2005) calls "dimensional deconstruction"). The relation between symmetry and a movement in 3D-space is also less obvious.

Moreover, one of the goals of the work about symmetry in primary school is to make pupils overcome some wrong conceptions they might have about line symmetry, which particularly appear when working on surfaces (Grenier, 1988). Particularly those related to vertical lines, making them act as if the mirror image of a horizontal (resp. vertical) segment line is also horizontal (resp. vertical); the conception of alignment (resulting from the conjunction of vertical or horizontal lines and vertical and horizontal figures: the image of a segment line perpendicular to the axis is then aligned with its image); confusion with translation (which is related to the flipping over property); conception of symmetry as a transformation moving figures from one half-plane onto the other one (essentially related to folding) (Chesnais, 2009).

THE IMPLEMENTED TASK

The task is the second one in a sequence about line symmetry in a 5th grade class. In the first task, taking place during a previous session, students were supposed to predict what would paint stains become when folding a paper along various axes and then to identify some properties of line symmetry (equidistance of the two figures from the axis, shape and size conservation, flipping over property). In the present task, pupils were asked to draw the mirror image of a geometric figure (in the shape of an "L") with respect to a given line in various configurations (cf. Figure 1). Didactic variables (orientation of the figure and orientation of the axis) were used to make students

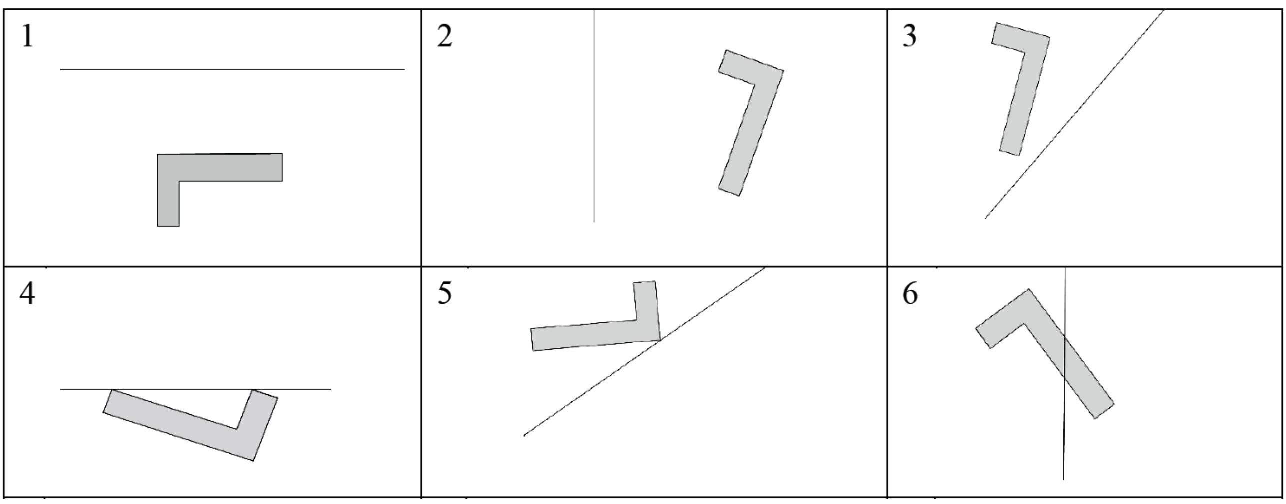

Figure 1: Configurations for the task

encounter one or the other of the properties and/or wrong conceptions.

Work was organized as follows: pairs of students were successively given six sheets – corresponding to each configuration. They were asked to draw the images approximately without folding they were allowed to use a pen and a ruler. A tracing paper on which the initial figure and the line were drawn for the first two cases and which was blank for the other four was provided to control their answer. The teacher went from one pair to another one to help them, and provided tracing paper when they were done drawing. A collective discussion with the whole class, based on some productions selected by the teacher, took place between the work in pairs on each case. The first three configurations were handled in a first session, which ended up by writing a couple of rules (mentioning the flipping over property, the equidistance to the line, conservation of shape and dimensions and the relation with folding), on a paper then posted on the wall. The work on the three other cases took place in a second session.

In this paper, we will particularly focus on one of the major properties of reflection: the "flipping over property" even if some other ones were also mobilized in the task. Mathematically speaking, it corresponds to the fact that line symmetry is an inversion. It is also related to the idea of "mirror image" or "reflection in a mirror". Materially speaking, it implies that a figure and its image are superimposable when the figure is flipped over, which means that a rotation of 180° degrees in 3D-space around a line included in the plane is applied to it. In practical terms, it can be obtained by folding the paper along the line or by flipping over tracing paper (and positioning it such that the line stays invariant). This property is difficult to express with common words because "flipping over" could also refer to a half-turn and then symmetry around a point whereas turning a page would end up flipping it over for example. Eventually, verbal language is not sufficient to handle this property and coordinating it with movements and material actions is necessary to make students identify and understand it (Chesnais & Mathé, 2013).

This property is part of what is at stake in the task. In the first case, flipping doesn't change the orientation of the sides of the figure (vertical stays vertical and horizontal stays horizontal). It does change it in all the other cases. Hence, it will be contradictory with what would other conceptions imply (especially the conceptions related to vertical and horizontal axis, and the one about alignment). In case 6, flipping can be hard to anticipate if the students have a conception of symmetry as transformation acting from one half-plane onto the other one (related to folding).

METHODOLOGY

We try to characterize students' activity, teacher's activity and the way they both articulate. Our indicators are mostly the material actions (folding, use of tracing paper and hands movements) and the interactions between students and students and teacher. We describe difficulties experienced by one pair of students throughout the work on the task, especially when the flipping over property is at stake. Based on the observation of this evolution, we then investigate how the task and social interactions participate in it towards an understanding of the flipping over property and symmetry. We also aim at understanding how the teacher identifies and uses students' activities and how she helps them completing the task.

GEOMETRICAL ACTIVITY OF A PAIR OF STUDENTS AND ITS EVOLUTION, BETWEEN ADAPTATIONISM AND SOCIAL PROCESS

In this part, we present an overview of what happened for each configuration during the sessions, focusing our attention on what the pair of students produced, the way they validated their answer and the content of the interactions with the teacher (when there are some) and of collective discussions. We aim at describing the evolution of geometrical activity of this pair of students throughout their work on the six configurations and try to identify what drives this evolution.

Configuration 1. They used a ruler to draw the image, taking into account the conservation of shape and dimensions, but without flipping the figure over (Figure 2). They probably didn't imagine the movement in 3D-space and then didn't anticipate the image. They used tracing paper for validation, but they couldn't figure out how to proceed differently when they found out that they did not get the right answer.

During the discussion with the class, the teacher chose to comment on their production. The class pointed out the absence of inversion. The teacher accompanied

Figure 3: Construction of configuration 2

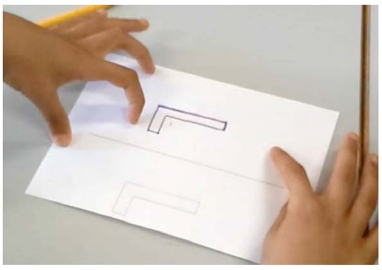

Figure 2: Production of configuration 1

the students trying to put this in words. Students used various wordings ("the other side", "in the other way around", "transferred", "turned over"). Their difficulties ended up in making the use of gestures necessary. The words "turned over" and gestures were also used by the teacher.

Configuration 2. One of the two students of the pair started by drawing globally the image with her finger: the position and orientation seemed correct and she flipped the figure over. Afterwards, she folded (not completely) the sheet of paper in order to find the precise position of one of the vertices of the image and then used a ruler to measure a first side of the figure to construct its image, transferring its length.

They finally gave then a third try, switching the orientation of the biggest part of the "L" but not the one of the smallest one (Figure 4).

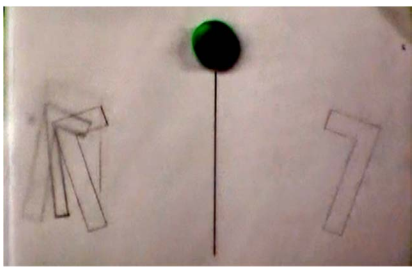

Figure 4: Final

The teacher chose again their production to comment during the final discussion. She makes the class explicit a mistake related to the conservation of shape (one of the students says "we had a 7, we get a 1"), but the link between the change of shape and flipping over the figure or elements of the figure is not pointed out. Flipping is not mentioned.

Configuration 3. They drew an image on the other side of the line, with the same size and same shape but without flipping it over (Figure 5). The students didn't seem to take into account the line and translated the figure, without imagining the rotation in 3D-space. Afterwards, they validated their answer using tracing paper (on which they draw both the figure and the line) but they slided the tracing paper, instead of flipping it over (Figure 6).

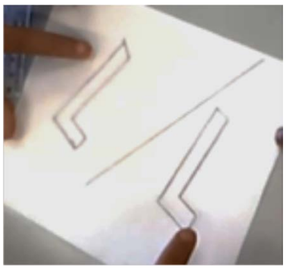

Figure 5: Production

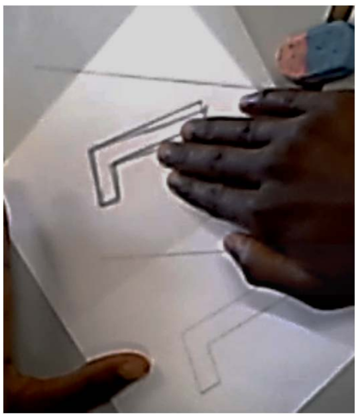

Figure 6: Validation

The teacher asked them how they controlled their answer and she pointed out the fact that the way they tried to control their answer was not correct, without mentioning a correct way to do it.

Part of the collective discussion was devoted to discussing this production. The class immediately pointed out the flipping over "problem". A work on putting it into words was conducted once again by the teacher and expressions like "in the same direction", "a little bit turned around", "completely turned around" were said.

"Turned over" was finally mentioned, repeated by the teacher and accompanied with gestures. At the end of this first session, the teacher elaborated a paper trail. She mentioned the "mistake often made" by this pair of students, pointing out that they often drew the figure "in the wrong direction". The teacher then wrote down that "the image has to be flipped over compared to the initial figure".

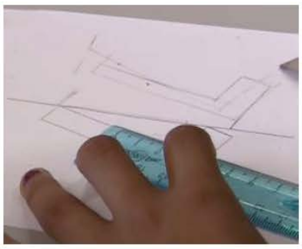
Configuration 4 (session 2). At first, the two students translated the figure along a direction given by the small part of the L (Figure 7); one of the two students, taking a wider look at it, realized the mistake. But constructing the image line by line made her do the same mistake again for her second try. Realizing it, they did a third try. The image was flipped over, but they did not switch the orientation, extending the sides of the small part of the L (Figure 7) and acting as if the line of symmetry was perpendicular to these sides. The other student tried to modify it so that the image touches the line at the same place as the initial figure (Figure 7). Taking into account the conservation of the shape led them to end up at the final production (Figure 7).

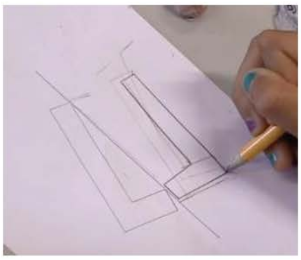
Trying to validate their answer, one of them drew the initial L and the line on tracing paper and then tried to turn the paper around (keeping it in the horizontal plane). The other one took it, flipped it over and replaced it so that the two lines matched.

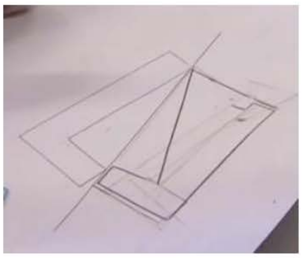
The teacher then started a discussion with the pair. She placed the tracing paper sheet in its original position, then flipped it over and placed it such that the two lines matched. She tried here to link explicitly the flipping over movement of the tracing paper sheet and the flipping over property characterizing the relation between the initial L and its image (considered as relation between two figures in the plane). She then accompanied the two students to interpret feedback from superimposition of their production with the flipped over tracing paper. In particular, she showed them that the orientation of the bigger part of the L was correctly switched whereas the orientation of the smaller part didn't match. "Your line is straight, prolonging the other one, while it should have been tilted like that (she showed the side of the flipped over L)". She helped them taking into account the relation between global flipping of the figure and change in the orientation of 2D elements of the figure (the smaller part of the L and the bigger part), relation that was difficult for them to identify in the previous tasks.

The flipping over property was not mentioned during the collective discussion.

Observing the resolution of this four cases, we see the difficulties students encountered to perceive and take into account the fact that the initial figure and its image are flipped over, one compared to the other. They often anticipate approximately the correct position and orientation of the image in a global way, as well as they realize their mistakes when they look globally at their production after drawing. But drawing the image with a ruler makes them consider the figure in a very different way. It is not seen as a surface (2D) anymore, but as a grid of segment lines (1D) which images have to be constructed separately. Students seem then to forget about the symmetry as rotation of 180° degrees around the line in 3D-space and they keep working in the plane. Yet they don't have any other definition of symmetry than this instrumental definition (see above), which refers to folding (real or simulated). The different attempts for case 2 show that it is difficult for them to articulate the switch of orientation for each of the segments (or 2D elements of the figure – smaller or bigger part of the L) and conservation of shape. Students also have difficulties using tracing paper to control their productions,







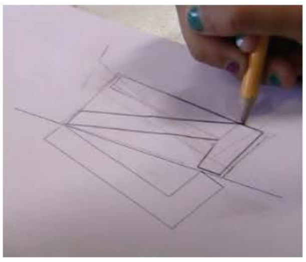


Figure 7: Try 1 Try 3 Try 4 Final production

which makes it hard to use pragmatic feedback as we could observe about cases 2 and 3.

Configuration 5. At first, one of the two students drew an image, flipped over compared to the initial figure, but with an approximate orientation. The other one changed the drawing to get a better orientation and a better corresponding size. (Figure 8)

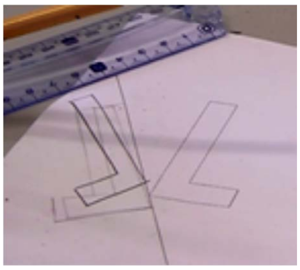

Figure 8

The collective discussion dealt with the question of the difference between "turned around" and "flipped over", about the productions of students who applied a symmetry around a point. Flipping over (rotation in 3D-space of 180° around the line) was again pointed out by the teacher, as opposed to rotation in the plane. Words were accompanied by a lot of gestures.

The teacher then pointed out the link between the need for flipping over and folding, which had been used to construct mirror images during the previous session. She folded a sheet of tracing paper so that folding makes the initial L flip over.

Configuration 6 The pair of students produced a flipped over figure, with same size and same shape as the initial L (Figure 9). The orientation of each part of the figure was correctly reversed. The invariance of points of the line was only partially completed.

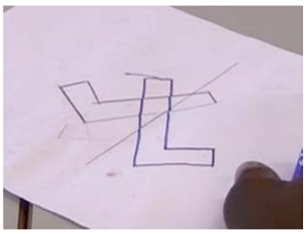

Figure 9

The teacher pointed it out during the collective discussion that followed.
